
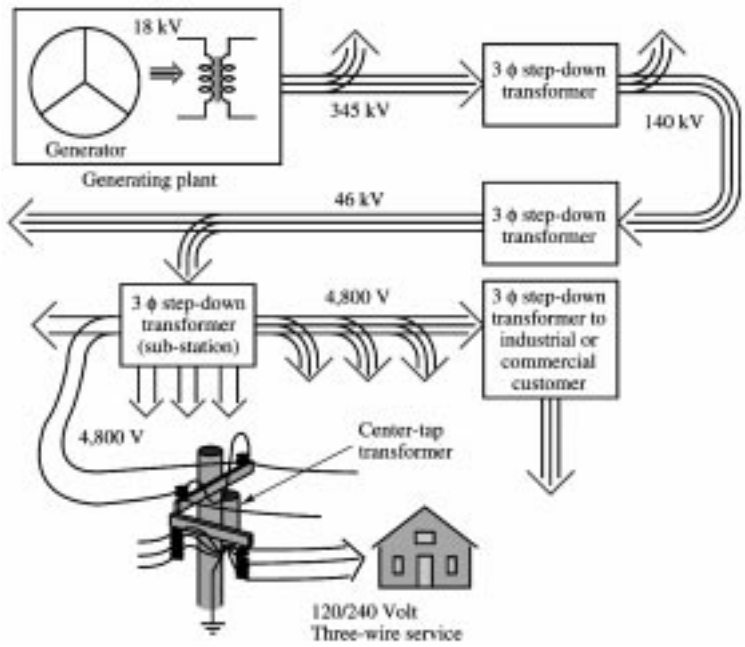

FIGURE 5.5.18 Structure of an AC power distribution network.

The local electric company operates a power-generating plant that is capable of supplying several hundred megavolt-amperes (MVA) on a three-phase basis. For this reason, the power company uses a three-phase step-up transformer at the generation plant to increase the line voltage to around 345 kV. One can immediately see that at the rated power of the generator (in MVA) there will be a significant reduction of current beyond the step-up transformer.

Beyond the generation plant, an electric power network distributes energy to several **substations**. This network is usually referred to as the **power grid**. At the substations, the voltage is stepped down to a lower level (10 to 150 kV, typically). Some very large loads (for example, an industrial plant) may be served directly from the power grid, although most loads are supplied by individual substations in the power grid. At the local substations (one of which you may have seen in your own neighborhood), the voltage is stepped down further by a three-phase step-down transformer to 4800 V. These substations distribute the energy to residential and industrial customers. To further reduce the line voltage to levels that are safe for residential use, step-down transformers are mounted on utility poles. These drop the voltage to the 120/240-V three-wire single-phase residential service discussed in the previous section. Industrial and commercial customers receive 460- and/or 208-V three-phase service.

5.6 Frequency Response, Filters, and Transient Analysis

The aim of the present section is twofold: first, to exploit AC circuit analysis methods to study the frequency response of electric circuits; and second, to continue the discussion of dynamic circuit equations for the purpose of analyzing the transient response of electrical circuits.

The **sinusoidal frequency response** (or, simply, **frequency response**) of a circuit provides a measure of how the circuit responds to sinusoidal inputs of arbitrary frequency. In other words, given the input signal amplitude, phase, and frequency, knowledge of the frequency response of a circuit permits the computation of the output signal.

The frequency response of a circuit is a measure of the variation of a load-related voltage or current as a function of the amplitude, phase, and frequency of the excitation signal.

To express the frequency response of a circuit in terms of variation in output voltage as a function of source voltage, we use the general formula

$$H_V(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} \tag{5.6.1}$$

One method that allows for representation of the load voltage as a function of the source voltage (this is, in effect, what the frequency response of a circuit implies) is to describe the source and attached circuit by means of the Thévenin equivalent circuit. The frequency response of the circuit shown in Figure 5.6.1 is given by the expression

$$\frac{\mathbf{V}_L}{\mathbf{V}_S}(j\omega) = H_V(j\omega) = \frac{Z_L Z_2}{Z_L(Z_S + Z_1 + Z_2) + (Z_S + Z_1)Z_2} \tag{5.6.2}$$

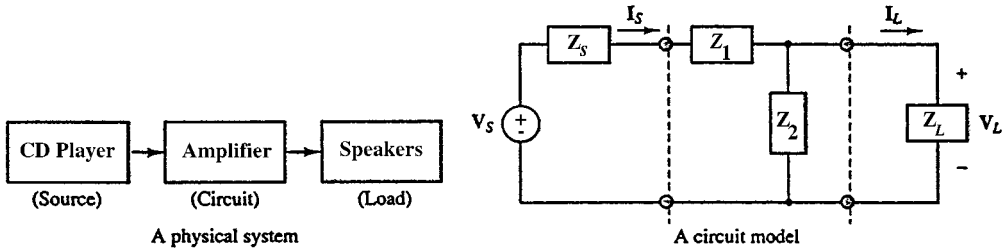

FIGURE 5.6.1 A circuit model.

The expression for $H_V(j\omega)$ could be evaluated for any given $\mathbf{V}_S(j\omega)$ (i.e., for any given source signal amplitude, phase, and frequency) to determine what the resultant load voltage would be. Note that $H_V(j\omega)$ is a complex quantity (dimensionless, because it is the ratio of two voltages), and that it therefore follows that $\mathbf{V}_L(j\omega)$ is a phase-shifted and amplitude-scaled version of $\mathbf{V}_S(j\omega)$:

$$\mathbf{V}_L(j\omega) = H_V(j\omega) \cdot \mathbf{V}_S(j\omega) \tag{5.6.3}$$

$$V_L e^{j\phi_L} = |H_V| e^{j\phi_H} \cdot V_S e^{j\phi_S} \tag{5.6.4}$$

or

$$V_L e^{j\phi_L} = |H_V| \mathbf{V}_S e^{j(\phi_H + \phi_S)} \tag{5.6.5}$$

where

$$V_L = |H_V| \cdot V_S$$

and

$$\phi_L = \phi_H + \phi_S \tag{5.6.6}$$

The effect of inserting a linear circuit between a source and a load is best understood by considering that, at any given frequency, ω, the load voltage is a sinusoid at the same frequency as the source voltage, with amplitude given by $V_L = |H_V| \cdot V_S$ and phase equal to $\phi_L = \phi_H + \phi_S$, where $|H_V|$ is the magnitude of the frequency response and ϕ_H its phase angle. Both $|H_V|$ and ϕ_H are functions of frequency.

The importance and usefulness of the frequency response concept lies in its ability to summarize the response of a circuit in a single function of frequency, $H(j\omega)$, which can predict the load voltage or current at any frequency, given the input. Note that the frequency response of a circuit can be defined in four different ways:

$$H_V(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} \qquad H_I(j\omega) = \frac{\mathbf{I}_L(j\omega)}{\mathbf{I}_S(j\omega)}$$
$$H_Z(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{I}_S(j\omega)} \qquad H_Y(j\omega) = \frac{\mathbf{I}_L(j\omega)}{\mathbf{V}_S(j\omega)} \tag{5.6.7}$$

If $H_V(j\omega)$ and $H_I(j\omega)$ are known, one can directly derive the other two expressions:

$$H_Z(j\omega) = \frac{\mathbf{V}_L(j\omega)}{\mathbf{I}_S(j\omega)} = Z_L(j\omega)\frac{\mathbf{I}_L(j\omega)}{\mathbf{I}_S(j\omega)} = Z_L(j\omega)H_I(j\omega) \tag{5.6.8}$$

$$H_Y(j\omega) = \frac{\mathbf{I}_L(j\omega)}{\mathbf{V}_S(j\omega)} = \frac{1}{Z_L(j\omega)}\frac{\mathbf{V}_L(j\omega)}{\mathbf{V}_S(j\omega)} = \frac{1}{Z_L(j\omega)}H_V(j\omega) \tag{5.6.9}$$

With these definitions in hand, it is now possible to introduce one of the central concepts of electrical circuit analysis: **filters.** The concept of filtering an electrical signal will be discussed in the next section.

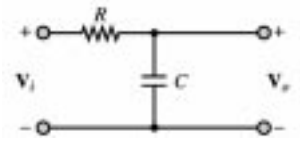
Filters

There are a host of practical, everyday applications that involve filters of one kind or another. Just to mention two, filtration systems are used to eliminate impurities from drinking water, and sunglasses are used to filter out eye-damaging ultraviolet radiation and to reduce the intensity of sunlight reaching the eyes. An analogous concept applies to electrical circuits: it is possible to *attenuate* (i.e., reduce in amplitude) or altogether eliminate signals of unwanted frequencies, such as those that may be caused by electrical noise or other forms of interference. This section will be devoted to the analysis of electrical filters.

Low-Pass Filters

Figure 5.6.2 depicts a simple **RC filter** and denotes its input and output voltages by $\mathbf{V}_i$ and $\mathbf{V}_o$. The frequency response for the filter may be obtained by considering the function.

$$H(j\omega) = \frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) \tag{5.6.10}$$



RC low-pass filter. The circuit preserves lower frequencies while attenuating the frequencies above the cutoff frequency, $\omega_0 = 1/RC$. The voltages V_i and V_0 are the filter input and output voltages, respectively.

FIGURE 5.6.2 A simple RC filter.

and noting that the output voltage may be expressed as a function of the input voltage by means of a voltage divider, as follows:

$$\mathbf{V}_o(j\omega) = \mathbf{V}_i(j\omega)\frac{1/j\omega C}{R + 1/j\omega C} = \mathbf{V}_i(j\omega)\frac{1}{1 + j\omega RC} \tag{5.6.11}$$

$$H(j\omega) = \frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{1}{1 + j\omega CR}$$

or

$$H(j\omega) = |H(j\omega)|e^{j\phi_H(j\omega)} \tag{5.6.12}$$

with

$$|H(j\omega)| = \frac{1}{\sqrt{1 + (\omega CR)^2}} = \frac{1}{\sqrt{1 + (\omega/\omega_0)^2}} \tag{5.6.13}$$

and

$$\phi_H(j\omega) = -\arctan(\omega CR) = -\arctan\left(\frac{\omega}{\omega_0}\right) \tag{5.6.14}$$

with

$$\omega_0 = \frac{1}{RC} \tag{5.6.15}$$

The simplest way to envision the effect of the filter is to think of the phasor voltage $\mathbf{V}_i = V_i e^{j\phi_i}$ scaled by a factor of $|\mathbf{H}|$ and shifted by a phase angle ϕ_H by the filter *at each frequency*, so that the resultant output is given by the phasor $V_o e^{j\phi_o}$, with

$$V_o = |H| \cdot V_i$$
$$\phi_o = \phi_H + \phi_i \tag{5.6.16}$$

and where $|H|$ and ϕ_H are functions of frequency. The frequency ω_0 is called the **cutoff frequency** of the filter and, as will presently be shown, gives an indication of the filtering characteristics of the circuit.

It is customary to represent $H(j\omega)$ in two separate plots, representing $|H|$ and ϕ_H as functions of ω. These are shown in Figure 5.6.3 in normalized form — that is, with $|H|$ and ϕ_H plotted vs. ω/ω_0, corresponding to a cutoff frequency $\omega_0 = 1$ rad/sec. Note that, in the plot, the frequency axis has been scaled logarithmically. This is a common practice in electrical engineering, because it allows viewing a very broad range of frequencies on the same plot without excessively compressing the low-frequency end of the plot. The frequency response plots of Figure 5.6.3 are commonly employed to describe the frequency response of a circuit, since they can provide a clear idea at a glance of the effect of a filter on an excitation signal. For example, the *RC* filter of Figure 5.6.2 has the property of "passing" signals at low frequencies ($\omega \ll 1/RC$) and of filtering out signals at high frequencies ($\omega \gg 1/RC$). This type of filter is called a **low-pass filter**. The cutoff frequency $\omega = 1/RC$ has a special significance in that it represents — approximately — the point where the filter begins to filter out the higher-frequency signals. The value of $H(j\omega)$ at the cutoff frequency is $1/\sqrt{2} = 0.707$. Note how the cutoff frequency depends exclusively on the values of R and C. Therefore, one can adjust the filter response as desired simply by selecting appropriate values for C and R, and therefore choose the desired filtering characteristics.

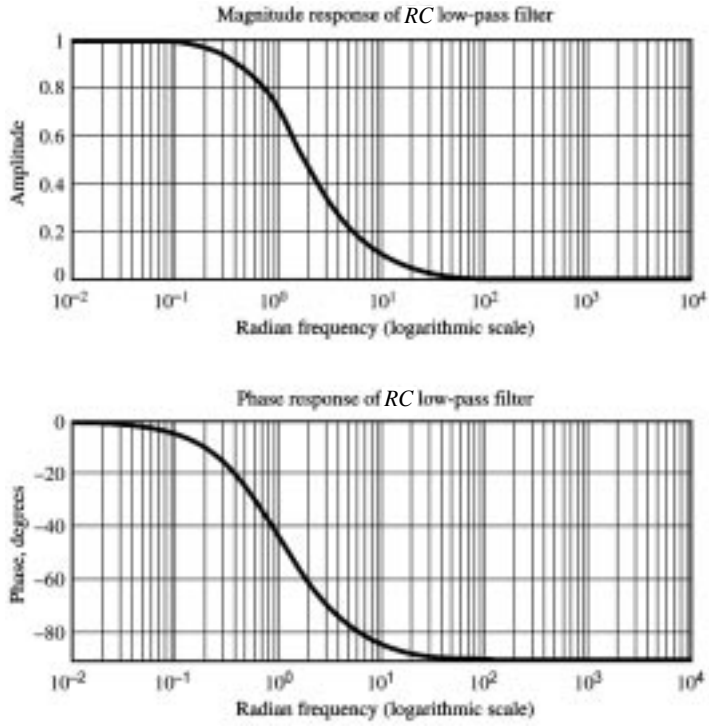


FIGURE 5.6.3 Magnitude and phase response plots for *RC* filter.

Example 5.6.1 Wheatstone Bridge Filter

The Wheatstone bridge circuit is used in a number of instrumentation applications, including the measurement of force (see Example 5.6.2, describing the strain gauge bridge). Figure 5.6.4 depicts the appearance of the bridge circuit. When undesired noise and interference are present in a measurement,

it is often appropriate to use a low-pass filter to reduce the effect of the noise. The capacitor that is connected to the output terminals of the bridge in Figure 5.6.4 constitutes an effective and simple low-pass filter, in conjunction with the bridge resistance. Assume that the average resistance of each leg of the bridge is 350 Ω (a standard value for strain gauges) and that we desire to measure a sinusoidal force at a frequency of 30 Hz. From prior measurements, it has been determined that a filter with a cutoff frequency of 300 Hz is sufficient to reduce the effects of noise. Choose a capacitor that matches this filtering requirement.

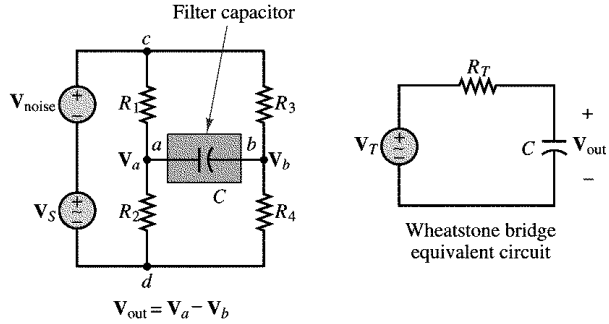

FIGURE 5.6.4 Wheatstone bridge with equivalent circuit and simple capacitive filter.

Solution. By evaluating the Thévenin equivalent circuit for the Wheatstone bridge, calculating the desired value for the filter capacitor becomes relatively simple, as illustrated at the bottom of Figure 5.6.4. The Thévenin resistance for the bridge circuit may be computed by short-circuiting the two voltage sources and removing the capacitor placed across the load terminals:

$$R_T = R_1 \| R_2 + R_3 \| R_4 = 350 \| 350 + 350 \| 350 = 350\ \Omega$$

Since the required cutoff frequency is 300 Hz, the capacitor value can be computed from the expression

$$\omega_0 = \frac{1}{R_T C} = 2\pi \times 300$$

or

$$C = \frac{1}{R_T \omega_0} = \frac{1}{350 \times 2\pi \times 300} = 1.51\ \mu\text{F}$$

The frequency response of the bridge circuit is of the form

$$\frac{\mathbf{V}_{out}}{\mathbf{V}_T}(j\omega) = \frac{1}{1 + j\omega C R_T}$$

This response can be evaluated at the frequency of 30 Hz to verify that the attenuation and phase shift at the desired signal frequency are minimal:

$$\frac{\mathbf{V}_{out}}{\mathbf{V}_T}(j\omega = j2\pi \times 30) = \frac{1}{1 + j2\pi \times 30 \times 1.51 \times 10^{-6} \times 350}$$

$$= 0.9951\angle -5.7°$$

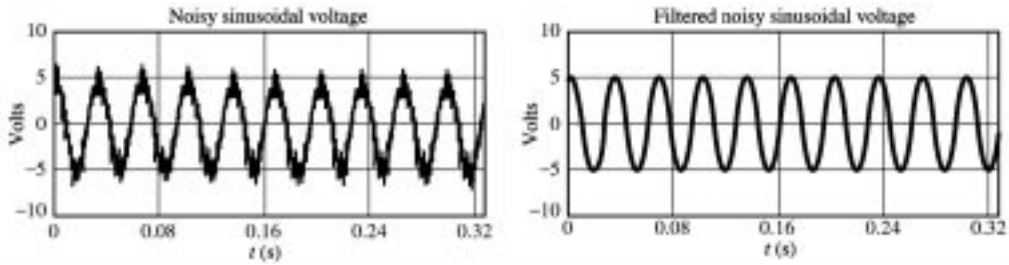

FIGURE 5.6.5 Unfiltered and filtered bridge output.

Figure 5.6.5 depicts the appearance of a 30-Hz sinusoidal signal before and after the addition of the capacitor to the circuit.

High-Pass Filters

Just as you can construct a simple filter that preserves low frequencies and attenuates higher frequencies, you can easily construct a **high-pass filter** that passes mainly those frequencies *above a certain cutoff frequency*. The analysis of a simple high-pass filter can be conducted by analogy with the preceding discussion of the low-pass filter. Consider the circuit shown in Figure 5.6.6.

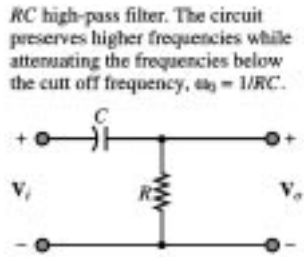

FIGURE 5.6.6 High-pass filter.

The frequency response of the filter is

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{j\omega CR}{1 + j\omega CR}$$

or

$$H(j\omega) = |H|e^{j\phi_H}$$

with

$$H(j\omega) = \frac{\omega CR}{\sqrt{1 + (\omega CR)^2}}$$

$$\phi_H(j\omega) = 90° - \arctan(\omega CR)$$

Amplitude-and-phase response curves for the high-pass filter are shown in Figure 5.6.7. These plots have been normalized to have the filter cutoff frequency $\omega_0 = 1$ rad/sec. Note that, once again, it is possible to define a cutoff frequency at $\omega_0 = 1/RC$ in the same way as was done for the low-pass filter.

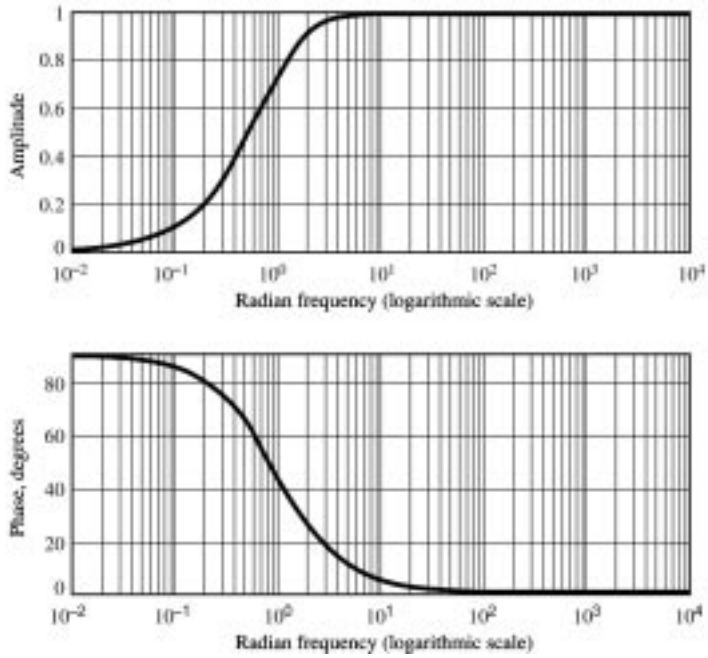

FIGURE 5.6.7 Frequency response of a high-pass filter.

Band-Pass Filters

Building on the principles developed in the preceding sections, we can also construct a circuit that acts as a **band-pass filter**, passing mainly those frequencies *within a certain frequency range*. The analysis of a simple *second-order* band-pass filter (i.e., a filter with two energy-storage elements) can be conducted by analogy with the preceding discussions of the low-pass and high-pass filters. Consider the circuit shown in Figure 5.6.8, and the related frequency response function for the filter $H(j\omega) = (\mathbf{V}_o/\mathbf{V}_i)(j\omega)$.

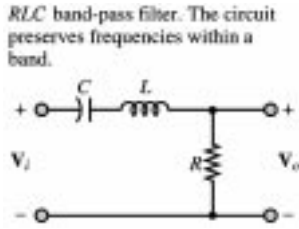

FIGURE 5.6.8 *RLC* band-pass filter.

We may write the frequency response of the filter as

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{j\omega CR}{1 + j\omega CR + (j\omega)^2 LC} \tag{5.6.17}$$

Equation (5.6.17) can often be factored into the following form:

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{jA\omega}{(j\omega/\omega_1 + 1)(j\omega/\omega_2 + 1)} \tag{5.6.18}$$

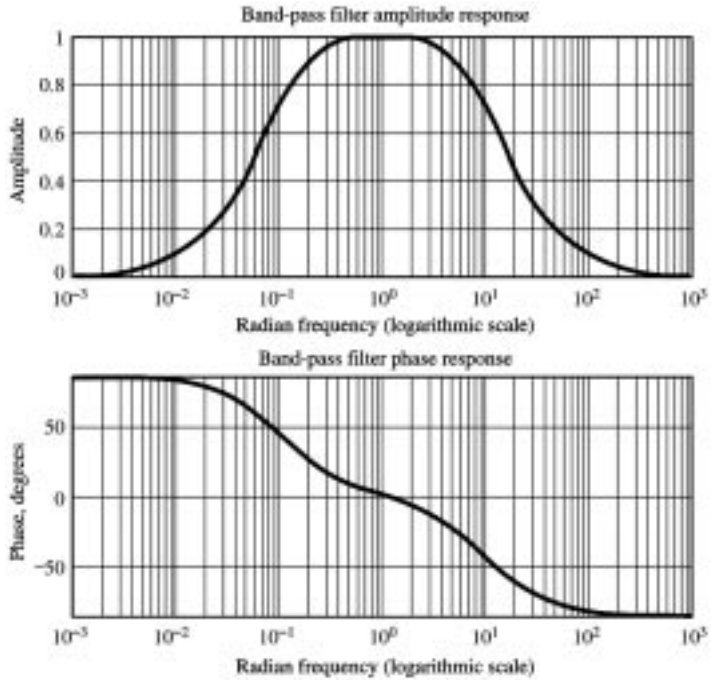

FIGURE 5.6.9 Frequency response of *RLC* band-pass filter.

where ω_1 and ω_2 are the two frequencies that determine the **pass-band** (or **band-width**) of the filter — that is, the frequency over which the filter "passes" the input signal. The magnitude and phase plots for the frequency response of the band-pass filter of Figure 5.6.8 are shown in Figure 5.6.9. These plots have been normalized to have the filter pass-band centered at the frequency $\omega = 1$ rad/sec.

The expression for the frequency response of a second-order band-pass filter (Equation (5.6.17)) can also be rearranged to illustrate two important features of this circuit: the **quality factor**, Q, and the **resonant frequency**, ω_0. Let

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad \text{and} \quad Q = \omega_0 CR = \frac{R}{\omega_0 L} \tag{5.6.19}$$

Then we can write $\omega CR = \omega_0 CR(\omega/\omega_0) = Q(\omega/\omega_0)$ and rearrange Equation 5.6.18 as follows:

$$\frac{\mathbf{V}_o}{\mathbf{V}_i}(j\omega) = \frac{jQ\dfrac{\omega}{\omega_0}}{\left(\dfrac{j\omega}{\omega_0}\right)^2 + jQ\dfrac{\omega}{\omega_0} + 1} \tag{5.6.20}$$

In Equation (5.6.20), the resonant frequency, ω_0, corresponds to the center frequency of the filter, while Q, the quality factor, indicates the *sharpness* of the resonance, that is, how narrow or wide the shape of the pass-band of the filter is. The width of the pass-band is also referred to as the *bandwidth*, and it can easily be shown that the bandwidth of the filter is given by the expression

$$B = \frac{\omega_0}{Q} \tag{5.6.21}$$

Thus, a high-Q filter has a narrow bandwidth, while a low-Q filter has a large bandwidth and is therefore less selective. The quality factor of a filter provides an immediate indication of the nature of the filter.

Transient Analysis

In analyzing the frequency response of AC circuits earlier in this chapter, we made the assumption that the particular form of the voltages and currents in the circuit was sinusoidal.

There are many signals, however, for which the steady-state sinusoidal representation is not adequate. In particular, the sinusoidal, or AC method of analysis does not apply to **transient signals**, that is, voltages and currents that vary as a function of time as a consequence of a sudden change in the input. Figure 5.6.10 illustrates the appearance of the voltage across some hypothetical load when a DC and an AC source, respectively, are abruptly switched on at time $t = 2$ sec. The waveforms in Figure 5.6.10 can be subdivided into three regions: a *steady-state region* for $0 \le t \le 0.2$ sec; a *transient region*, for 0.2 sec $\le t \le 2$ sec (approximately); and a new steady-state region for $t > 2$ sec, where the waveform reaches a new steady-state DC or sinusoidal condition. The objective of **transient analysis** is to describe the behavior of a voltage or current during the transition that takes place between two different steady-state conditions.

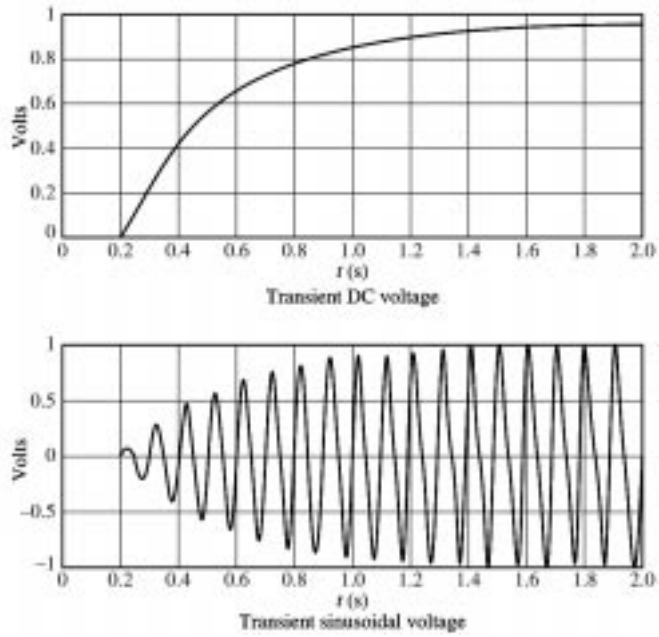

FIGURE 5.6.10 Examples of transient response.

You already know how to analyze circuits in a sinusoidal steady state by means of phasors. The material presented in the remainder of this chapter will provide the tools necessary to describe the *transient response* of circuits containing resistors, inductors, and capacitors. A general example of the type of circuit that will be discussed in this section is shown in Figure 5.6.11. The switch indicates that we turn the battery power on at time $t = 0$. Transient behavior may be expected whenever a source of electrical energy is switched on or off, whether it be AC or DC. A typical example of the transient response to a switched DC voltage would be what occurs when the ignition circuits in an automobile are turned on, so that a 12-V battery is suddenly connected to a large number of electrical circuits. The degree of complexity in transient analysis depends on the number of energy-stored elements in the circuit; the analysis can become quite involved for high-order circuits. In this chapter, we shall analyze

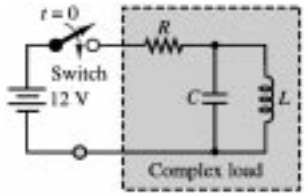

FIGURE 5.6.11 Circuit with switched DC excitation.

only first- and second-order circuits — that is, circuits containing one or two energy-storage elements, respectively. In electrical engineering practice, we would typically resort to computer-aided analysis for higher-order circuits.

A convenient starting point in approaching the transient response of electrical circuits is to consider the general model shown in Figure 5.6.12, where the circuits in the box consist of a combination of resistors connected to a *single energy-storage element*, either an inductor or a capacitor. Regardless of how many resistors the circuit contains, it is a **first-order circuit**. In general, the response of a first-order circuit to a switched DC source will appear in one of the two forms shown in Figure 5.6.13 which represent, in order, **a decaying exponential** and a **rising exponential** waveform. In the next sections, we will systematically analyze these responses by recognizing that they are exponential in nature and can be computed very easily once we have the proper form of the differential equation describing the circuit.

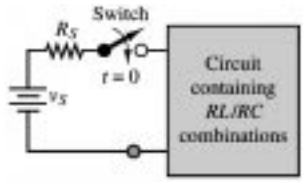

FIGURE 5.6.12 A general model of the transient analysis problem.

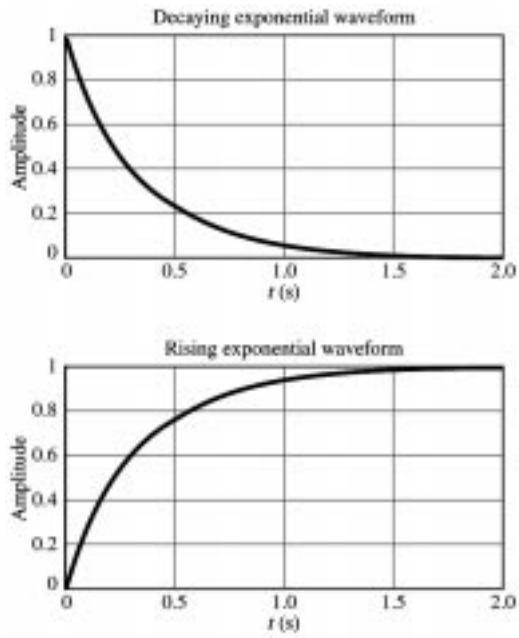

FIGURE 5.6.13 Decaying and rising exponential responses.

Example 5.6.2 Pulse Response

A problem of great practical importance is the transmission of voltage *pulses* along cables. Short voltage pulses are used to represent the two-level binary signals that are characteristic of digital computers; it is often necessary to transmit such voltage pulses over a long distance through **coaxial cables**, which are characterized by a finite resistance per unit length and by a certain capacitance per unit length, usually expressed in units of pF/m. A simplified model of a long coaxial cable is shown in Figure 5.6.14. It has the appearance of a low-pass filter. If a 100-m cable has a capacitance of 40 pF/m and a series resistance of 0.2 Ω/m, what will the output pulse look like after traveling the length of the cable? Assume the input pulse has a duration of 0.1 μsec and has an amplitude of 5 V. The load resistance is 150 Ω.

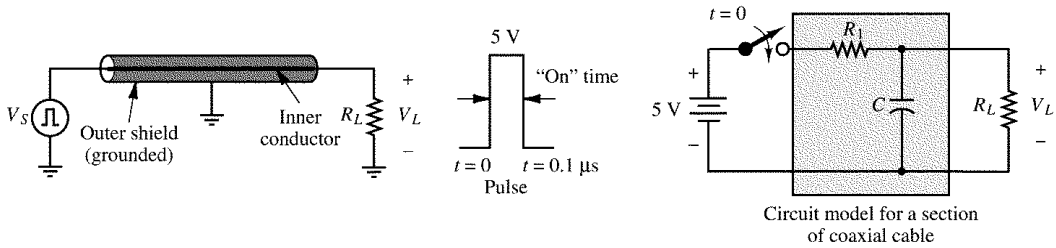

FIGURE 5.6.14 Pulse transmission in a coaxial cable.

Solution. The Thévenin equivalent circuit seen by the capacitor will vary, depending on whether the pulse is "on" or "off". In the former case, the equivalent resistance consists of the parallel combination of R_1 and R_L; in the latter case, since the switch is open, the capacitor is connected only to R_L. Thus, the effect of the pulse is to charge C through the parallel combination of R_1 and R_L during the "on" time ($0 \le t < 0.1$ μsec); the capacitor will then discharge through R_L during the "off" time. This behavior is depicted by the circuit model of Figure 5.6.14 in which the pulse signal is represented by a 5-V battery in series with a switch.

The charging time constant of the coaxial cable equivalent circuit when the switch is closed is therefore given by

$$\tau_{\text{on}} = \left(R_1 \| R_L\right) C = 17.65 \times 4000 \times 10^{-12} = 0.07 \ \mu\text{sec}$$

and the transient response of the cable during the "on" time is

$$v_L(t) = 4.41\left(1 - e^{-t/\tau}\right) = 4.41\left(1 - e^{-1.42 \times 10^7 t}\right) \qquad 0 \le t \le 0.1 \ \mu\text{sec}$$

where $V_T = R_L/(R_1 + R_L) \times 5 = 4.41$ V. At $t = 0.1$ μsec we calculate the load voltage to be

$$v_L(0.1 \ \mu\text{sec}) = 4.41\left(1 - e^{-1.42}\right) = 3.35 \text{ V}$$

For $t \ge 0.1$ μsec, the output will naturally decay to zero, starting from the initial condition, v_L (0.1 μsec), with a time constant τ_{off} equal to

$$\tau_{\text{off}} = R_L C = 150 \times 4000 \times 10^{-12} = 0.6 \ \mu\text{sec}$$

The load voltage will therefore decay according to the following expression:

$$v_L(t) = 3.35\left(e^{-1.67 \times 10^6 \left(t - 0.1 \times 10^{-6}\right)}\right) \qquad t > 0.1 \ \mu\text{sec}$$

The appearance of the response is shown in Figure 5.6.15. It should be apparent that as the cable becomes longer, both R_1 and C increase, and therefore the output voltage will respond more slowly to the input pulse; according to the simple model of a long coaxial cable given in this example, there is a limit to the maximum distance over which a voltage pulse can be transmitted by cable.

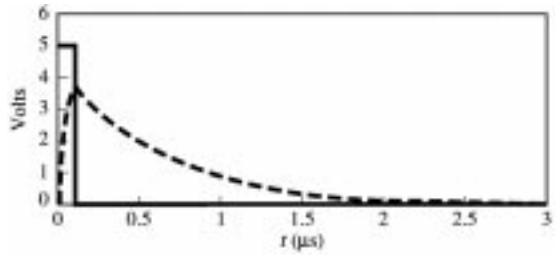

FIGURE 5.6.15 Pulse response of 100-m-long coaxial cable.

5.7 Electronics

This chapter introduces semiconductor-based electronic devices, and in so doing, it provides a transition between the fundamentals of electrical circuit analysis and the study of electronic circuits.

Semiconductors and *pn* Junctions

This section briefly introduces the mechanism of conduction in a class of materials called **semiconductors**. Semiconductors are typically materials consisting of elements from group IV of the periodic table and having electrical properties falling somewhere between those of conducting and of insulating materials. As an example, consider the conductivity of three common materials. Copper, a good conductor, has a conductivity of 0.59×16^6 S/cm; glass, a common insulator, may range between 10^{-16} and 10^{-13} S/cm; while silicon, a semiconductor, has a conductivity that varies from 10^{-8} to 10^{-1} S/cm. You see, then, that the name *semiconductor* is an appropriate one.

A conducting material is characterized by a large number of conduction-band electrons, which have a very weak bond with the basic structure of the material. Thus, an electric field easily imparts energy to the outer electrons in a conductor and enables the flow of electric current.

The free valence electrons are not the only mechanism of conduction in a semiconductor, however, Whenever a free electron leaves the lattice structure, it creates a corresponding positive charge within the lattice. The vacancy caused by the departure of a free electron is called a **hole**. Note that whenever a hole is present, we have, in effect, a positive charge. The positive charges also contribute to the conduction process, in the sense that if a valence-band electron "jumps" to fill a neighboring hole, thereby neutralizing a positive charge, it correspondingly creates a new hole at a different location. Thus, the effect is equivalent to that of a positive charge moving.

Semiconductor technology rarely employs pure, or intrinsic, semiconductors. To control the number of charge carriers in a semiconductor, the process of **doping** is usually employed. Doping consists of adding impurities to the crystalline structure of the semiconductor. The amount of these impurities is controlled, and the impurities can be of one of two types.

Semiconductors doped with donor elements conduct current predominantly by means of free electrons and are therefore called ***n*-type semiconductors**. When an acceptor element is used as the dopant, holes constitute the most common carrier, and the resulting semiconductor is said to be a ***p*-type semiconductor**. Doping usually takes place at such levels that the concentration of carriers due to the dopant is significantly greater than the intrinsic concentration of the original semiconductor. If n is the total number of free electrons and p that of holes, then in an n-type doped semiconductor, we have

$$n \gg n_i$$

and

$$p \ll p_i$$

Thus, free electrons are the **majority carriers** in an n-type material, while holes are the **minority carriers**. In a p-type material, the majority and minority carriers are reversed.

A simple section of semiconductor material does not in and of itself possess properties that make it useful for the construction of electronic circuits. However, when a section of p-type material and a section of n-type material are brought in contact to form a ***pn* junction**, a number of interesting properties arise. The pn junction forms the basis of the **semiconductor diode**, a widely used circuit element.

Figure 5.7.1 depicts an idealized pn junction, where on the p side, we see a dominance of positive charge carriers, or holes, and on the n side, the free electrons dominate. The charge separation causes a **contact potential** to exist at the junction. This potential is typically on the order of a few tenths of a

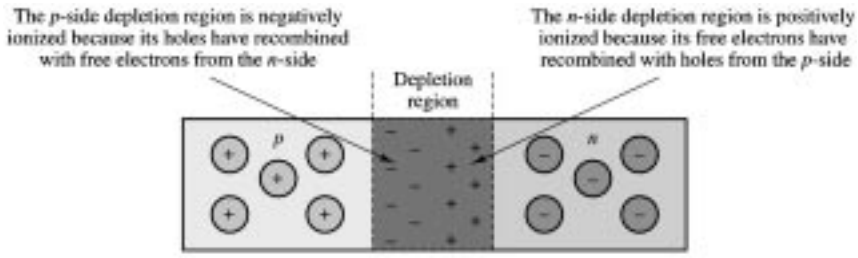

FIGURE 5.7.1 A *pn* junction.

volt and depends on the material (about 0.6 to 0.7 V for silicon). The contact potential is also called the *offset voltage*, V_γ.

Consider the diagrams of Figure 5.7.2, where a battery has been connected to a *pn* junction in the **reverse-biased** direction (Figure 5.7.2(a)), and in the **forward-biased** direction (Figure 5.7.2(b)). We assume that some suitable form of contact between the battery wires and the semiconductor material can be established (this is called an **ohmic contact**). The effect of a reverse bias is to increase the contact potential at the junction. Now, the majority carriers trying to diffuse across the junction need to overcome a greater barrier (a larger potential) and a wider depletion region. Thus, the diffusion current becomes negligible. The only current that flows under reverse bias is the very small reverse saturation current, so that the diode current, i_D (defined in the figure), is

$$i_D = -I_0$$

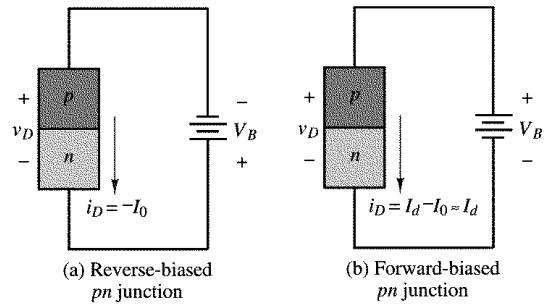

FIGURE 5.7.2 Forward- and reverse-biased *pn* junctions.

When the *pn* junction is forward-biased, the contact potential across the junction is lowered (note that V_B acts in opposition to the contact potential). Now, the diffusion of majority carriers is aided by the external voltage source; in fact, the diffusion current increases as a function of the applied voltage, according to the expression

$$I_d = I_0 e^{qv_D/kT} \tag{5.7.1}$$

where v_D is the voltage across the *pn* junction, $k = 1.381 \times 10^{-23}$ j/K is Boltzmann's constant, q the charge of one electron, and T the temperature of the material in kelvins (K). The quantity kT/q is constant at a given temperature and is approximately equal to 25 mV at room temperature. The net diode current under forward bias is given by the expression

$$i_D = I_d - I_0 = I_0\left(e^{qv_D/kT} - 1\right) \tag{5.7.2}$$

which is known as the **diode equation**. Figure 5.7.3 depicts the diode *i-v* characteristic described by the diode equation for a fairly typical silicon diode for positive diode voltages. Since the reverse saturation current, I_0, is typically very small (10^{-9} to 10^{-15} A), the expression

$$i_D = I_0 e^{qv_D/kT} \tag{5.7.3}$$

is a good approximation if the diode voltage, v_D, is greater than a few tenths of a volt.

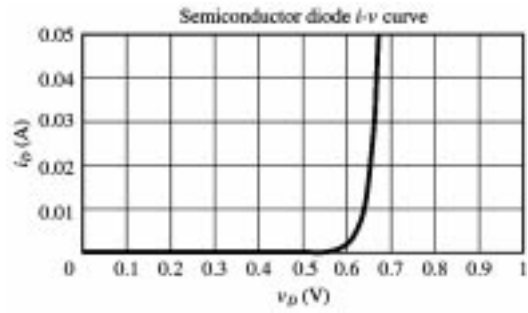

FIGURE 5.7.3 Semiconductor diode *i-v* characteristic.

The ability of the *pn* junction to essentially conduct current in only one direction — that is, to conduct only when the junction is forward-biased — makes it valuable in circuit applications. A device having a single *pn* junction and ohmic contacts at its terminals, as described in the preceding paragraphs, is called a *semiconductor diode,* or simply *diode*. As will be shown later in this chapter, it finds use in many practical circuits. The circuit symbol for the diode is shown in Figure 5.7.4, alongside with a sketch of the *pn* junction.

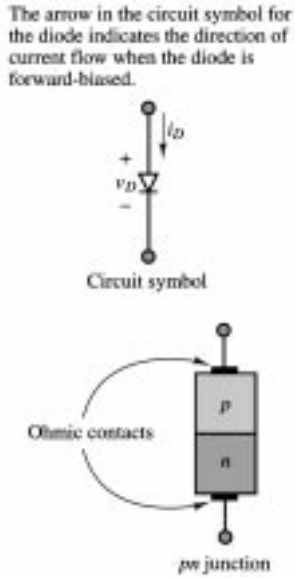

FIGURE 5.7.4 Semiconductor diode circuit symbol.

Circuit Models for the Semiconductor Diode

From the viewpoint of a *user* of electronic circuits (as opposed to a *designer*), it is often sufficient to characterize a device in terms of its *i-v* characteristic, using appropriate circuit models to determine the operating currents and voltages.

Ideal Diode Model

The large-signal model treats the diode as a simple on–off device (much like a check valve in hydraulic circuits). Figure 5.7.5 illustrates how, on a large scale, the *i-v* characteristic of a typical diode may be approximated by an open circuit when $v_D < 0$ and by a short circuit when $v_D \geq 0$ (recall the *i-v* curves of the ideal short and open circuits presented in Section 5.2). The analysis of a circuit containing a diode may be greatly simplified by using the short-circuit–open-circuit model. From here on, this diode model will be known as the **ideal diode model**. In spite of its simplicity, the ideal diode model (indicated by the symbol shown in Figure 5.7.5 can be very useful in analyzing diode circuits.

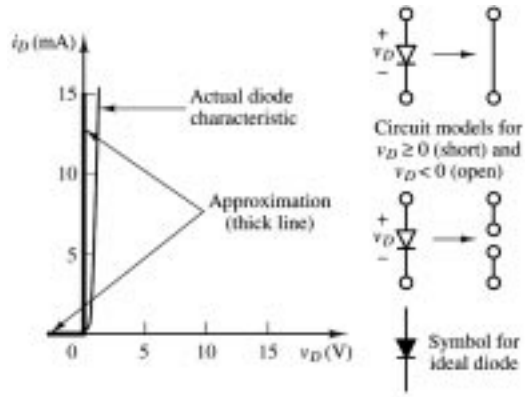

FIGURE 5.7.5 Large-signal on–off diode model.

One of the important applications of the semiconductor diode is **rectification** of AC signals, that is, the ability to convert an AC signal with zero average (DC) value to a signal with a nonzero DC value. The application of the semiconductor diode as a rectifier is very useful in obtaining DC voltage supplies from the readily available AC line voltage. Here we illustrate the basic principle of rectification using an ideal diode, for simplicity, and also because the large-signal model is appropriate when the diode is used in applications involving large AC voltage and current levels.

Consider the circuit of Figure 5.7.6, where an AC source, $v_i = 155.56 \cdot \sin \omega t$, is connected to a load by means of a series ideal diode. The diode will conduct only during the positive half-cycle of the sinusoidal voltage — that is, that the condition $v_D \geq 0$ will be satisfied only when the AC source voltage is positive — and that it will act as an open circuit during the negative half-cycle of the sinusoid ($v_D < 0$). Thus, the appearance of the load voltage will be as shown in Figure 5.7.7 with the negative portion of the sinusoidal waveform cut off. The rectified waveform clearly has a nonzero DC (average) voltage, whereas the average input waveform voltage was zero. When the diode is conducting, or $v_D \geq 0$, the unknowns v_L and i_D can be found by using the following equations:

$$i_D = \frac{v_i}{R_L} \quad \text{when} \quad v_i > 0 \tag{5.7.4}$$

and

$$v_L = i_D R_L \tag{5.7.5}$$

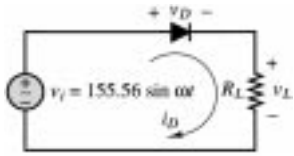

FIGURE 5.7.6

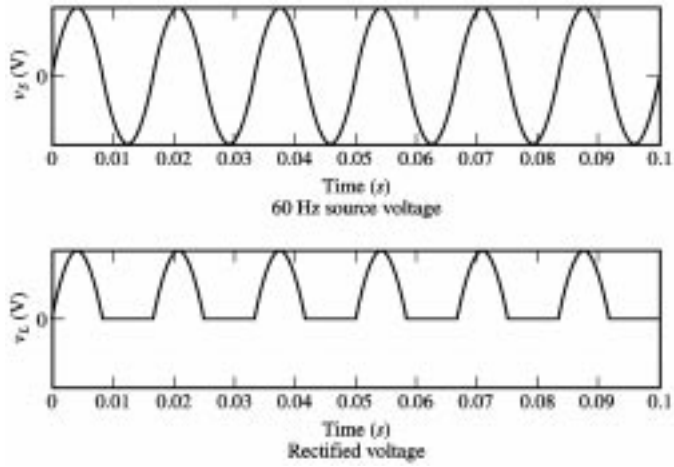

FIGURE 5.7.7 Ideal diode rectifier input and output voltages.

The load voltage, v_L and the input voltage, v_i, are sketched in Figure 5.7.7. From Equation (5.7.5) it is obvious that the current waveform has the same shape as the load voltage. The average value of the load voltage is obtained by integrating the load voltage over one period and dividing by the period:

$$v_{\text{load,DC}} = \frac{\omega}{2\pi}\int_0^{\pi/\omega} 155.56 \sin \omega t \, dt = \frac{155.56}{\pi} = 49.52 \text{ V} \tag{5.7.6}$$

The circuit of Figure 5.7.6 is called a **half-wave rectifier**, since it preserves only half of the waveform. This is not usually a very efficient way of rectifying an AC signal, since half the energy in the AC signal is not recovered. It will be shown in a later section that it is possible to recover also the negative half of the AC waveform by mans of a *full-wave rectifier.*

Offset Diode Model

While the ideal diode model is useful in approximating the large-scale characteristics of a physical diode, it does not account for the presence of an offset voltage, which is an unavoidable component in semiconductor diodes. The **offset diode model** consists of an ideal diode in series with a battery of strength equal to the offset voltage (we shall use the value $V_\gamma = 0.6$ V for silicon diodes, unless otherwise indicated). The effect of the battery is to shift the characteristic of the ideal diode to the right on the voltage axis, as shown in Figure 5.9.3. This model is a better approximation of the large-signal behavior of a semiconductor diode than the ideal diode model.

According to the offset diode model, the diode of Figure 5.7.8 acts as an open circuit for $v_D < 0.6$ V, and it behaves like a 0.6-V battery for $v_D \geq 0.6$ V. The equations describing the offset diode model are as follows:

$$\begin{aligned} v_D &\geq 0.6 \text{ V} \quad \text{Diode} \rightarrow \text{0.6-V battery} \\ v_D &< 0.6 \text{ V} \quad \text{Diode} \rightarrow \text{Open circuit} \end{aligned} \tag{5.7.7}$$

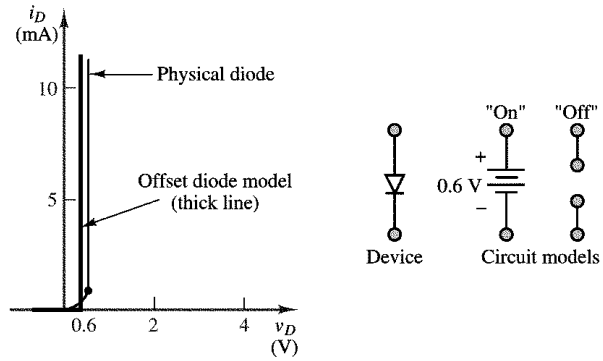

FIGURE 5.7.8

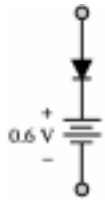

FIGURE 5.7.9 Offset diode as an extension of ideal diode model.

The diode offset model may be represented by an ideal diode in series with a 0.6-V ideal battery, as shown in Figure 5.7.9.

Practical Diode Circuits

The Full-Wave Rectifier

The half-wave rectifier discussed earlier is one simple method of converting AC energy to DC energy. The need for converting one form of electrical energy into the other arises frequently in practice. The most readily available form of electric power is AC (the standard 110- or 220-V rms AC line power), but one frequently needs a DC power supply, for applications ranging from the control of certain types of electric motors to the operation of electronic circuits.

The half-wave rectifier, however, is not a very efficient AC–DC conversion circuit, because it fails to utilize half the energy available in the AC waveform by not conducting current during the negative half-cycle of the AC waveform. The full-wave rectifier shown in Figure 5.7.10 offers a substantial improvement in efficiency over the half-wave rectifier. The first section of the full-wave rectifier circuit includes an AC source and a center-tapped transformer (see Section 5.5) with 1:2 N turns ratio. The purpose of the transformer is to obtain the desired voltage amplitude prior to rectification. Thus, if the peak amplitude of the AC source voltage is v_s, the amplitude of the voltage across each half of the output side of the transformer will be Nv_s; this scheme permits scaling the source voltage up or down (depending on whether N is greater or less than 1), according to the specific requirements of the application. In addition to scaling the source voltage, the transformer also isolates the rectifier circuit from the AC source voltage, since there is no direct electrical connection between the input and output of a transformer.

The Bridge Rectifier

Another rectifier circuit commonly available "off the shelf" as a single *integrated circuit package* is the *bridge rectifier*, which employs four diodes in a bridge configuration, similar to the Wheatstone bridge already explored in Section 5.2. Figure 5.7.11 depicts the bridge rectifier, along with the associated integrated circuit (IC) package.

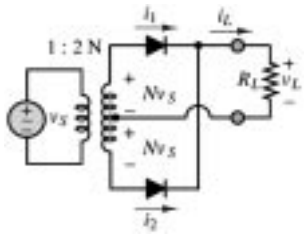

FIGURE 5.7.10 Full-wave rectifier.

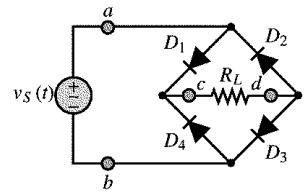
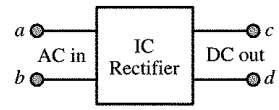


Bridge rectifier



Corresponding IC package

FIGURE 5.7.11 Full-wave bridge rectifier.

The analysis of the bridge rectifier is simple to understand by visualizing the operation of the rectifier for the two half-cycles of the AC waveform separately. The key is that, as illustrated in Figure 5.7.12, diodes D_1 and D_3 conduct during the positive half-cycle, while diodes D_2 and D_4 conduct during the negative half-cycle. Because of the structure of the bridge, the flow of current through the load resistor is in the same direction (from *c* to *d*) during both halves of the cycle; hence, the full-wave rectification of the waveform.

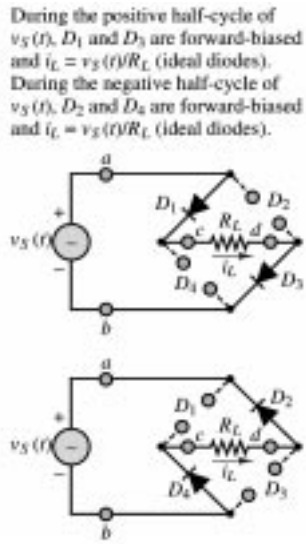


FIGURE 5.7.12 Diodes conduct.

DC Power Supplies and Voltage Regulation

The principal application of rectifier circuits is in the conversion of AC to DC power. A circuit that accomplishes this conversion is usually called a **DC power supply**. In power supply applications, transformers are employed to obtain an AC voltage that is reasonably close to the desired DC supply voltage. DC power supplies are very useful in practice: many familiar electrical and electronic appliances (e.g., radios, personal computers, TVs) require DC power to operate. For most applications, it is desirable

that the DC supply be as steady and ripple-free as possible. To ensure that the DC voltage generated by a DC supply is constant, the DC supply is made up of voltage regulators, that is, devices that can hold a DC load voltage relatively constant in spite of possible fluctuations in the DC supply. This section will describe the fundamentals of voltage regulators.

A typical DC power supply is made up of the components shown in Figure 5.7.13. In the figure, a transformer is shown connecting the AC source to the rectifier circuit to permit scaling of the AC voltage to the desired level. For example, one might wish to step the 110-V rms line voltage down to 24 V rms by means of a transformer prior to rectification and filtering, to eventually obtain a 12-VDC regulated supply (*regulated* here means that the output voltage is a DC voltage that is constant and independent of load and supply variations). Following the step-down transformer are a bridge rectifier, a filter capacitor, a voltage regulator, and, finally, the load.

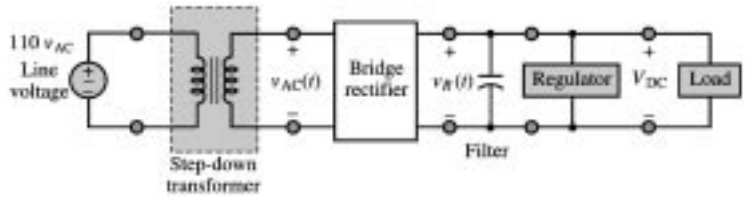

FIGURE 5.7.13 DC power supply.

The most common device employed in voltage regulation schemes is the Zener diode. Zener diodes function on the basis of the reverse portion of the *i-v* characteristic of the diode with forward offset voltage V_γ and **reverse Zener voltage** V_Z.

The operation of the Zener diode may be analyzed by considering three modes of operation:

1. For $v_D \geq V_\gamma$, the device acts as a conventional forward-biased diode (Figure 5.7.14).
2. For $V_Z < v_D < V_\gamma$, the diode is reverse-biased but Zener breakdown has not taken place yet. Thus, it acts as an open circuit.
3. For $v_D \leq V_Z$, Zener breakdown occurs and the device holds a nearly constant voltage, $-V_Z$ (Figure 5.7.15).

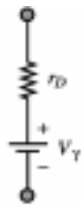

FIGURE 5.7.14 Zener diode model for forward bias.

FIGURE 5.7.15 Zener diode model for reverse bias.

To illustrate the operation of a Zener diode as a voltage regulator, consider the circuit of Figure 5.7.16, where the unregulated DC source, v_S, is regulated to the value of the Zener voltage, V_Z. Note how the diode must be connected "upside down" to obtain a positive regulated voltage. Note also that if v_S is greater than V_Z, it follows that the Zener diode is in its reverse-breakdown mode. Thus, one need not

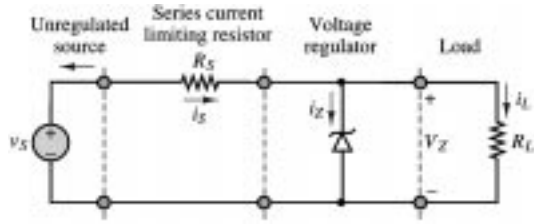

FIGURE 5.7.16 A Zener diode voltage regulator.

worry whether the diode is conducting or not in simple voltage regulator problems, provided that the unregulated supply voltage is guaranteed to stay above V_Z (a problem arises, however, if the unregulated supply can drop below the Zener voltage). Assuming that the resistance r_Z is negligible with respect to R_S and R_L, we replace the Zener diode with the simplified circuit mode of Figure 5.7.17 consisting of a battery of strength V_Z.

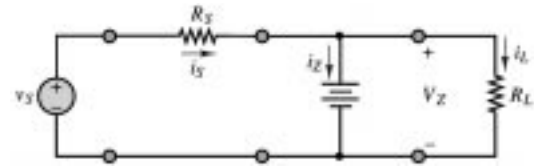

FIGURE 5.7.17 Simplified circuit for Zener regulator.

Three simple observations are sufficient to explain the operation of this voltage regulator:

1. The load voltage must equal V_Z, as long as the Zener diode is in the reverse-breakdown mode. Then,

$$i_L = \frac{V_Z}{R_L} \tag{5.7.10}$$

2. The load current (which should be constant if the load voltage is to be regulated to sustain V_Z) is the difference between the unregulated supply current, i_s, and the diode current i_z:

$$i_L = i_S - i_Z \tag{5.7.11}$$

   This second point explains intuitively how a Zener diode operates: any current in excess of that required to keep the load at the constant voltage V_Z is "dumped" to ground through the diode. Thus, the Zener diode acts as a sink to the undesired source current.
3. The source current is given by

$$i_S \frac{v_S - V_Z}{R_S} \tag{5.7.12}$$

The Zener diode is usually rated in terms of its maximum allowable power dissipation. The power dissipated by the diode, P_Z, may be computed from

$$P_Z = i_Z V_Z \tag{5.7.13}$$

Thus, one needs to worry about the possibility that i_Z will become too large. This may occur either if the supply current is very large (perhaps because of an unexpected upward fluctuation of the unregulated

supply), or if the load is suddenly removed and all of the supply current sinks through the diode. The latter case, of an open-circuit load, is an important design consideration.

Another significant limitation occurs when the load resistance is small, thus requiring large amounts of current from the unregulated supply. In this case, the Zener diode is hardly taxed at all in terms of power dissipation, but the unregulated supply may not be able to provide the current required to sustain the load voltage. In this case, regulation fails to take place. Thus, in practice, the range of load resistances for which load voltage regulation may be attained is constrained to a finite interval:

$$R_{L\,\min} \le R_L \le R_{L\,\max} \tag{5.7.14}$$

where $R_{L\max}$ is typically limited by the Zener diode power dissipation and $R_{L\min}$ by the maximum supply current.

Example 5.7.1

This example illustrates the calculation of the range of allowable load resistances for a Zener regulator design. For the Zener regulator shown in Figure 5.7.18, we want to maintain the load voltage at 14 V. Find the range of load resistances for which regulation can be obtained if the Zener diode is rated at 14 V, 5 W.

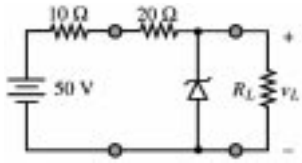

FIGURE 5.7.18 Circuit for example.

Solution. The minimum load resistance for which a regulated load voltage of 14 V may be attained is found by requiring that the load voltage be 14 V and applying KVL subject to this constraint:

$$50\left(\frac{R_{L\,\min}}{R_{L\,\min} + 30}\right) = 14$$

$$R_{L\,\min} = \frac{14}{50}\left(R_{L\,\min} + 30\right)$$

$$= 11.7\ \Omega$$

The maximum current through the Zener diode that does not exceed the diode power rating may be computed by considering the 5-W power rating:

$$i_{Z\,\max} = \frac{5}{14} = 0.357\ \text{A}$$

The current through the 20-Ω resistor will be

$$\frac{50 - 14}{30} = 1.2\ \text{A}$$

so that the maximum load resistance for which regulation occurs is

$$R_{L\max} = \frac{14}{1.2 - 0.357}$$

$$= 16.6\ \Omega$$

Finally, the range of allowable load resistances is:

$$16.6\ \Omega \geq R_L \geq 11.7\ \Omega$$

Photodiodes

Another property of semiconductor materials that finds common application in measurement systems is their response to light energy. In appropriately fabricated diodes, called **photodiodes**, when light reaches the depletion region of a *pn* junction, photons cause hole-electron pairs to be generated by a process called *photo-ionization*. This effect can be achieved by using a surface material that is transparent to light. As a consequence, the reverse saturation current depends on the light intensity (i.e., on the number of incident photons), in addition to the other factors mentioned earlier. In a photodiode, the reverse current is given by $-(I_0 + I_p)$, where I_p is the additional current generated by photo-ionization. The result is depicted in the family of curves of Figure 5.7.19, where the diode characteristic is shifted downward by an amount related to the additional current generated by photo-ionization. Figure 5.7.19 depicts the appearance of the *i-v* characteristic of a photodiode for various values of I_p, where the *i-v* curve is shifted to lower values for progressively larger values of I_p. The circuit symbol is depicted in Figure 5.7.20.

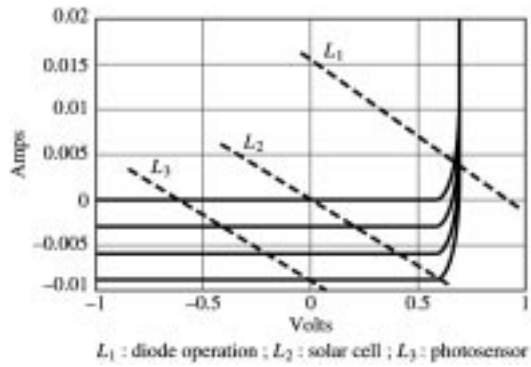

FIGURE 5.7.19 Photodiode *i-v* curves.

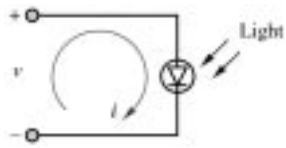

FIGURE 5.7.20 Photodiode circuit symbol.

As displayed in Figure 5.7.19 are three load lines, which depict the three modes of operation of a photodiode. Curve L_1 represents normal diode operation, under forward bias. Note that the operating point of the device is in the positive *i*, positive *v* (first) quadrant of the *i-v* plane; thus, the diode dissipates positive power in this mode, and is therefore a passive device, as we already know. On the other hand, load line L_2 represents operation of the photodiode as a **solar cell**; in this mode, the operating point is in the negative *i*, positive *v*, or fourth, quadrant, and therefore the power dissipated by the diode is *negative*. In other words, the photodiode is generating power by converting light energy to electrical energy. Note further that the load line intersects the voltage axis at zero, meaning that no supply voltage is required to bias the photodiode in the solar-cell mode. Finally, load line L_3 represents the operation

of the diode as a light sensor: when the diode is reverse-biased, the current flowing through the diode is determined by the light intensity; thus, the diode current changes in response to changes in the incident light intensity.

The operation of the photodiode can also be reversed by forward-biasing the diode and causing a significant level of recombination to take place in the depletion region. Some of the energy released is converted to light energy by emission of photons. Thus, a diode operating in this mode emits light when forward-biased. Photodiodes used in this way are called **light-emitting diodes** (LEDs); they exhibit a forward (offset) voltage of 1 to 2 volts. The circuit symbol for the LED is shown in Figure 5.7.21.

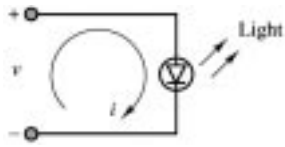

FIGURE 5.7.21 Light-emitting diode (LED) circuit symbol.

Gallium arsenide (GaAs) is one of the more popular substrates for creating LEDs; gallium phosphide (GaP) and the alloy $GaAs_{1-x}P_x$ are also quite common. Table 5.7.1 lists combinations of materials and dopants used for common LEDs and the colors they emit. The dopants are used to create the necessary *pn* junction.

TABLE 5.7.1 LED Materials and Wavelengths

Material	Dopant	Wavelength (nm)	Color
GaAs	Zn	900	Infrared
GaAs	Si	910–1020	Infrared
GaP	N	570	Green
GaP	N	590	Yellow
GaP	Zn,O	700	Red
$GaAs_{0.6}P_{0.4}$		650	Red
$GaAs_{0.35}P_{0.65}$	N	632	Orange
$GaAs_{0.15}P_{0.85}$	N	589	Yellow

Example 5.7.2 Opto-Isolators

One of the common applications of photodiodes and LEDs is the **opto-coupler**, or **opto-isolator**. This device, which is usually enclosed in a sealed package, uses the light-to-current and current-to-light conversion property of photodiodes and LEDs to provide signal connection between two circuits without any need for electrical connections. Figure 5.7.22 depicts the circuit symbol for the opto-isolator.

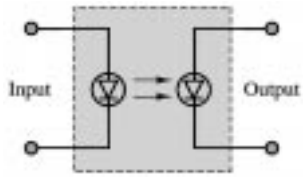

FIGURE 5.7.22 Opto isolator.

Because diodes are nonlinear services, the opto-isolator is not used in transmitting analog signals: the signals would be distorted because of the nonlinear diode *i-v* characteristic. However, opto-isolators find a very important application when on–off signals need to be transmitted from high-power machinery to delicate computer control circuitry. The optical interface ensures that potentially damaging large currents cannot reach delicate instrumentation and computer circuits.

Transistors

A transistor is a three-terminal semiconductor device that can perform two functions that are fundamental to the design of electronic circuits: **amplification** and **switching**. Put simply, amplification consists of magnifying a signal by transferring energy to it from an external source; whereas a transistor switch is a device for controlling a relatively large current between or voltage across two terminals by means of a small control current or voltage applied at a third terminal. In this chapter, we provide an introduction to the two major families of transistors: *bipolar junction transistors*, or *BJTs*; and *field-effect transistors*, or *FETs*.

The operation of the transistor as a linear amplifier can be explained qualitatively by the sketch of Figure 5.7.23 in which the four possible modes of operation of a transistor are illustrated by means of circuit models employing controlled sources. In Figure 5.7.23 controlled voltage and current sources are shown to generate an output proportional to an input current or voltage; the proportionality constant, μ, is called the internal *gain* of the transistor. As will be shown, the BJT acts essentially as a current-controlled device, while the FET behaves as a voltage-controlled device.

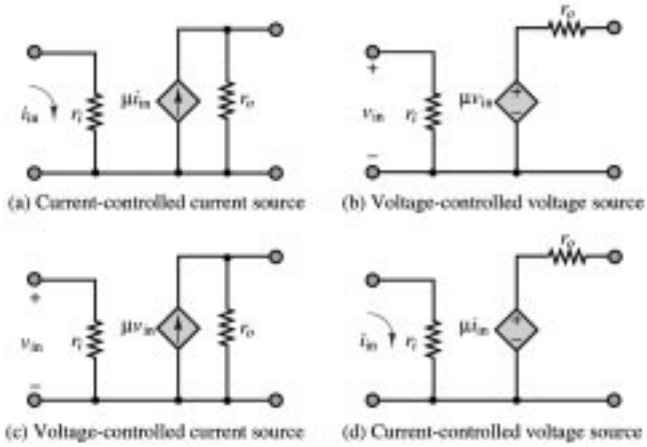

FIGURE 5.7.23 Controlled-source models of linear amplifier transistor operation.

Transistors can also act in a nonlinear mode, as voltage- or current-controlled switches. When a transistor operates as a switch, a small voltage or current is used to control the flow of current between two of the transistor terminals in an on–off fashion. Figure 5.7.24 depicts the idealized operation of the transistor as a switch, suggesting that the switch is closed (on) whenever a control voltage or current is greater than zero and is open (off) otherwise. It will later become apparent that the conditions for the switch to be on or off need not necessarily be those depicted in Figure 5.7.24.

The Bipolar Junction Transistor (BJT)

The *pn* junction forms the basis of a large number of semiconductor devices. The semiconductor diode, a two-terminal device, is the most direct application of the *pn* junction. In this section, we introduce the **bipolar junction transistor** (BJT). As we did in analyzing the diode, we will introduce the physics of transistor devices as intuitively as possible, resorting to an analysis of their *i-v* characteristics to discover important properties and applications.

A BJT is formed by joining three sections of semiconductor material, each with a different doping concentration. The three sections can be either a thin *n* region sandwiched between p^+ and *p* layers, or a *p* region between *n* and n^+ layers, where the superscript "plus" indicates more heavily doped material.

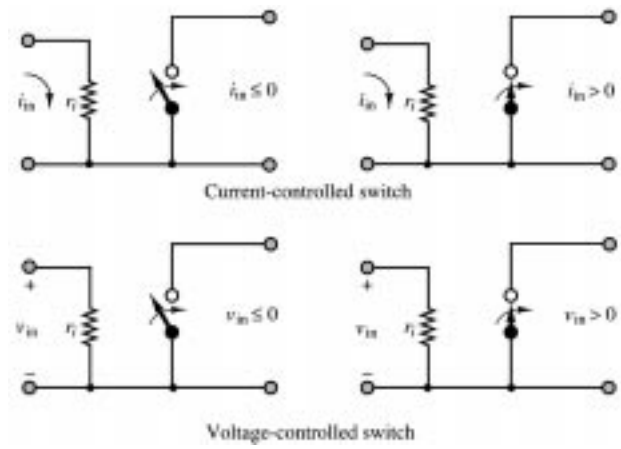

FIGURE 5.7.24 Models of ideal transistor switches.

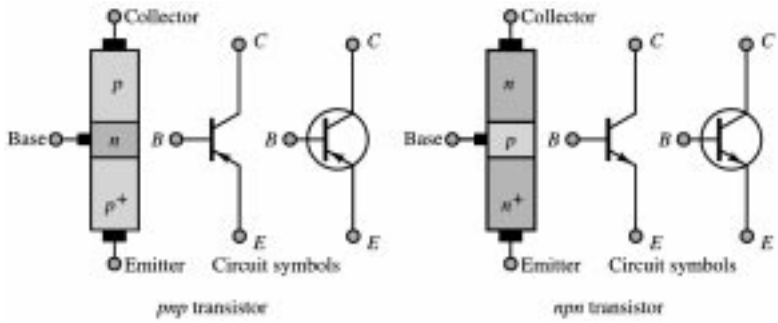

FIGURE 5.7.25 Bipolar junction transistors.

The resulting BJTs are called *pnp* and *npn* transistors, respectively; we shall discuss only the latter in this section. Figure 5.7.25 illustrates the approximate construction, symbols, and nomenclature for the two types of BJTs.

The most important property of the bipolar transistor is that the small base current controls the amount of the much larger collector current

$$I_C = \beta I_B \tag{5.7.15}$$

where β is a current amplification factor dependent on the physical properties of the transistor. Typical values of β range from 20 to 200.

The detailed operation of bipolar transistors can be explained by resorting to a detailed physical analysis of the *npn* or *pnp* structure of these devices. The reader interested in such a discussion of transistors is referred to any one of a number of excellent books on semiconductor electronics.

The focus of this section will be on the analysis of the *i-v* characteristic of the *npn* BJT, based on the circuit notation defined in Figure 5.7.26. The device *i-v* characteristics will be presented qualitatively, without deriving the underlying equations, and will be utilized in constructing circuit models for the device.

The number of independent variables required to uniquely define the operation of the transistor may be determined by applying KVL and KCL to the circuit of Figure 5.7.26. It should be apparent that two voltages and two currents are sufficient to specify the operation of the device. Note that, since the BJT is a three-terminal device, it will not be sufficient to deal with a single *i-v* characteristic; it will soon

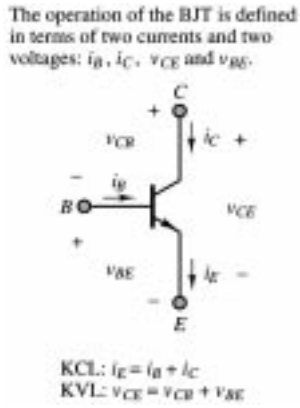

FIGURE 5.7.26 Definition of BJT voltages and currents.

become apparent that two such characteristics are required to explain the operation of this device. One of these characteristics relates the base current, i_B, to the base-emitter voltage, v_{BE}; the other relates the collector current, i_C, to the collector-emitter voltage, v_{CE}. As will be shown, the latter characteristic actually consists of a *family* of curves. To determine these *i-v* characteristics, consider the *i-v* curves of Figures 5.7.27 and 5.7.28 using the circuit notation of Figure 5.7.26. In Figure 5.7.27, the collector is open and the *BE* junction is shown to be very similar to a diode. The ideal current source, I_{BB}, injects a base current, which causes the junction to be forward-biased. By varying I_{BB}, one can obtain the open-collector *BE* junction *i-v* curve shown in the figure.

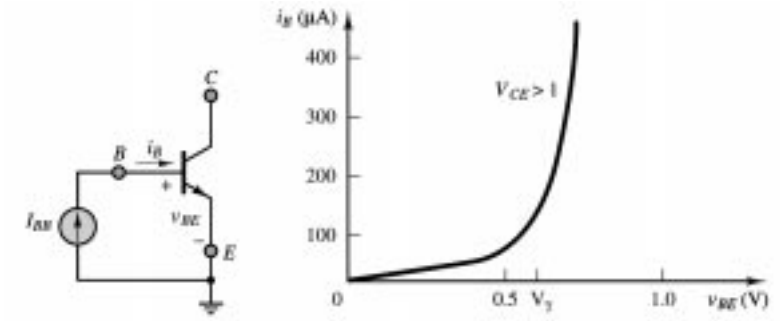

FIGURE 5.7.27 Determining the *BE* junction open-collector *i-v* characteristic.

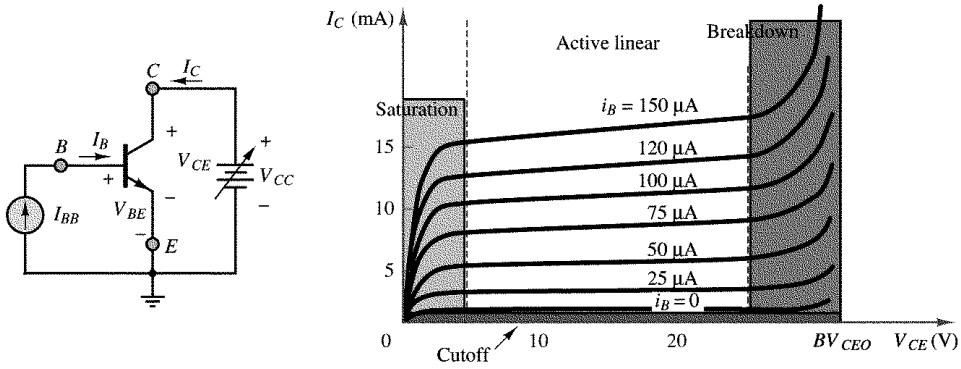

FIGURE 5.7.28 (a) Ideal test circuit to determine the *i-v* characteristic of a BJT; (b) the collector-emitter output characteristics of a BJT.

If a voltage source were now to be connected to the collector circuit, the voltage v_{CE} and, therefore, the collector current, i_C, could be varied, in addition to the base current, i_B. The resulting circuit is depicted in Figure 5.7.28(a). By varying both the base current and the collector-emitter voltage, one could then generate a plot of the device **collector characteristic**. This is also shown in Figure 5.7.28(b). Note that this figure depicts not just a single i_C-v_{CE} curve, but an entire family, since for each value of the base current, i_B, an i_C-v_{CE} curve can be generated. Four regions are identified in the collector characteristic:

1. The **cutoff region**, where both junctions are reverse-biased, the base current is very small, and essentially no collector current flows
2. The **active linear region**, in which the transistor can act as a linear amplifier, where the *BE* junction is forward-biased and the *CB* junction is reverse-biased
3. The **saturation region**, in which both junctions are forward-biased
4. The **breakdown region**, which determines the physical limit of operation of the device.

Large-Signal Model of the *npn* BJT

The large-signal model for the BJT recognizes three basic operating modes of the transistor (Figure 5.7.29). When the *BE* junction is reverse-biased, no base current (and therefore no forward collector current) flows, and the transistor acts (virtually as an open circuit; the transistor is said to be in the *cutoff region*. In practice, there is always a leakage current flowing through the collector, even when $V_{BE} = 0$ and $I_B = 0$. This leakage current is denoted by I_{CEO}. When the *BE* junction becomes forward-biased, the transistor is said to be in the *active region,* and the base current is amplified by a factor of β at the collector:

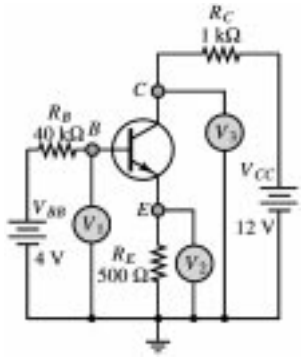

FIGURE 5.7.29 Determination of the operating state of a BJT.

$$I_C = \beta I_B \tag{5.7.16}$$

Since the collector current is controlled by the base current, the controlled-source symbol is used to represent the collector current. Finally, when the base current becomes sufficiently large, the collector-emitter voltage, V_{CE}, reaches its saturation limit, and the collector current is no longer proportional to the base current; this is called the *saturation region*. The three conditions are described in Figure 5.7.30 in terms of simple circuit models.

Example 5.7.3 illustrates the application of this large-signal model in a practical circuit and illustrates how to determine which of the three states is applicable, using relatively simple analysis.

Example 5.7.3 LED Driver

The circuit shown in Figure 5.7.31 is being used to "drive" (i.e., provide power for) a light-emitting diode (LED) from a desktop computer. The signal available from the computer consists of a 5-V low-current output. The reason for using a BJT (rather than driving the LED directly with the signal available

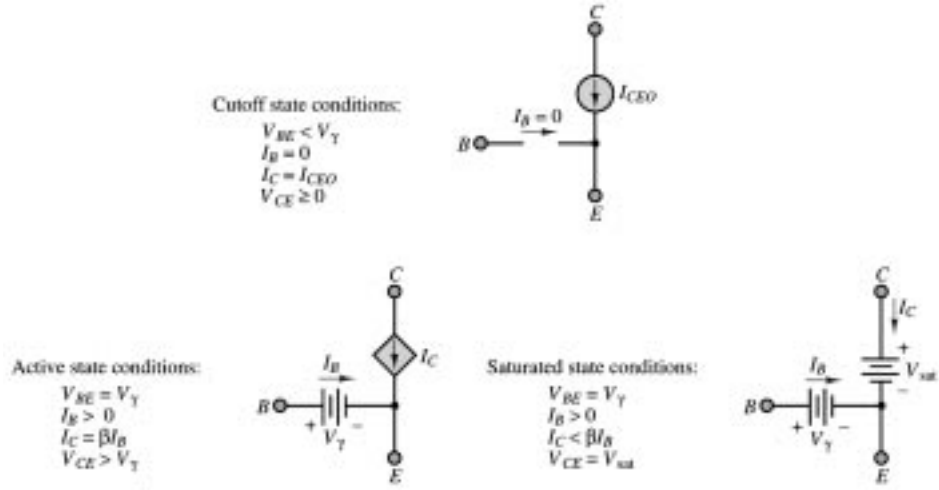

FIGURE 5.7.30 *npn* BJT large-signal model.

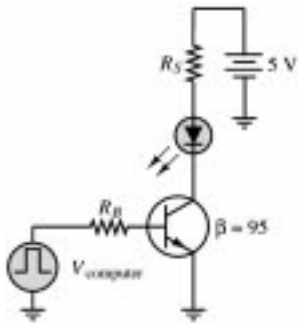

FIGURE 5.7.31 LED driver circuit.

from the computer) is that the LED requires a substantial amount of current (at least 15 mA for the device used in this example) and the computer output is limited to 5mA. Thus, some current amplification is required. The LED has an offset voltage of 1.4 V and a maximum power dissipation rating of 280 mW. The circuit has been designed so that the transistor will be either in cutoff, when the LED is to be turned off, or in saturation, when the LED is to be turned on.

Assume that the base-emitter junction of the transistor has an offset voltage of 0.7 V and that R_B = 1 kΩ and R_S = 42.5 Ω.

1. When the computer is supplying 5 V to the circuit, is the transistor in cutoff, in saturation, or in the linear region of operation?
2. Determine the current in the LED when "turned on" and, thus, state whether the LED will exceed its power rating.

Solution. The base-emitter circuit is considered first, to determine whether the *BE* junction is forward-biased. The equivalent circuit is shown in Figure 5.7.32

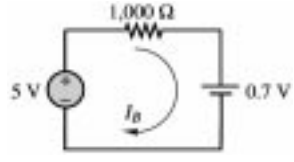

FIGURE 5.7.32 *BE* circuit for LED driver.

Writing KVL around the base circuit, we obtain

$$(5 - 0.7) = I_B(1000)$$

or

$$I_B = 4.3 \text{ mA}$$

Since this current is greater than zero (i.e., since positive current flows into the base), the transistor is not in cutoff.

Next, we need to determine whether the transistor is in the linear active or in the saturation region. One method that can be employed to determine whether the device is in the active region is to assume that it is and to solve for the circuit that results from the assumed condition. If the resulting equations are consistent, then the assumption is justified. Assuming that the transistor is in its active region, the following equations apply:

$$I_C = \beta I_B$$

or

$$I_C = 95(4.3 \text{ mA}) = 408.5 \text{ mA}$$

With reference to the circuit of Figure 5.7.33, KVL may be applied around the collector circuit, to obtain

$$5 = 1.4 + V_{CE} + I_C R_S$$

or

$$(5 - 1.4) - 408.5(42.5) = V_{CE}$$

or

$$V_{CE} = -13.76 \text{ V}$$

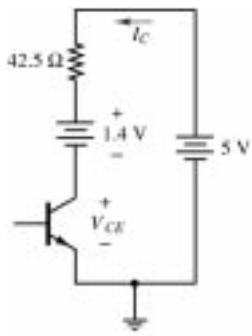

FIGURE 5.7.33 Equivalent collector circuit of LED driver, assuming that the BJT is in the linear active region.

This result is clearly not possible, since the supply voltage is only 5V! It must therefore be concluded that the transistor is not in the linear region and must be in saturation. To test this hypothesis, we can substitute the nominal saturation voltage for the BJT in place of V_{CE} (a typical saturation voltage would be V_{CE} sat = 0.2 V) and verify that in this case we obtain a consistent solution:

$$I_C = \frac{(5 - 1.4 - 0.2)}{42.5} = 80 \text{ mA}$$

This is a reasonable result, stating that the collector current in the saturation region for the given circuit is of the order of 80 mA.

In the above part, it was determined that the transistor was in saturation. Using the circuit model for saturation, we may draw the equivalent circuit of Figure 5.7.34. Since $I_C = 80$ mA, the power dissipated by the LED may be calculated as follows:

$$P_{\text{LED}} = I_C V_{\text{LED}} = 80 \text{ mA} \times 1.4 \text{ V} = 112 \text{ mW}$$

Thus, the power limitation of the LED will not be exceeded.

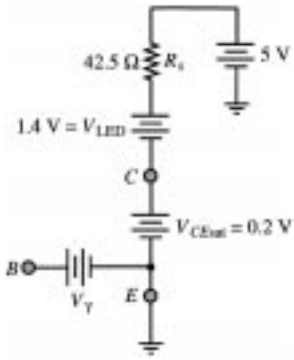

FIGURE 5.7.34 LED driver equivalent collector circuit, assuming that the BJT is in the saturation region.

Field-Effect Transistors

The second transistor family discussed in this section operates on the basis of a principle that is quite different from that of the *pn* junction devices. The concept that forms the basis of the operation of the **field-effect transistor**, or FET, is that the width of a conducting channel in a semiconductor may be varied by the external application of an electric field. Thus, FETs behave as *voltage-controlled resistors*. This family of electronic devices can be subdivided into three groups, all of which will be introduced in the remainder of this chapter. Figure 5.7.35 depicts the classification of field-effect transistors, as well as the more commonly used symbols for these devices. These devices can be grouped into three major categories. The first two categories are both types of **metal-oxide-semiconductor field-effect transistors**, or MOSFETs: **enhancement-mode MOSFETs** and **depletion-mode MOSFETs**. The third category consists of **junction field-effect transistors**, or JFETs. In addition, each of these devices can be fabricated either as an ***n*-channel** device or as a ***p*-channel** device, where the *n* or *p* designation indicates the nature of the doping in the semiconductor channel.

The construction of the MOSFET is shown in Figure 5.7.36, along with its circuit symbol. The device consists of a metal **gate**, insulated from the bulk of the *p*-type semiconductor material by an oxide layer (thus the terminology *metal-oxide-semiconductor*). Two n^+ regions on either side of the gate are called **source** and **drain**, respectively. An electric field can be applied between the gate and the *bulk* of the semiconductor by connecting the gate to a voltage source. The effect of the electric field, the intensity of which depends on the strength of the gate voltage, is to push positive charge carriers away from the surface of the bulk material. As a consequence of this effect, the *p*-type material has a lower concentration of positive charge carriers near its surface, and it behaves progressively more like intrinsic semiconductor material and then, finally, like *n*-type material as the electric field strength increases. Thus, in a narrow layer between n^+ regions, the *p*-type material is *inverted* and *n*-type charge carriers become available for conduction. This layer is called the *channel*. The device of Figure 5.7.36 takes the name *n-channel*

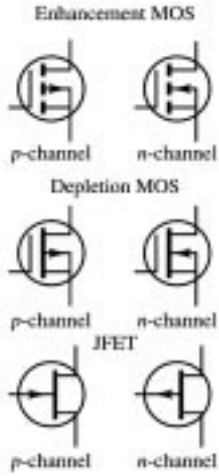

FIGURE 5.7.35 Classification of field-effect transistors.

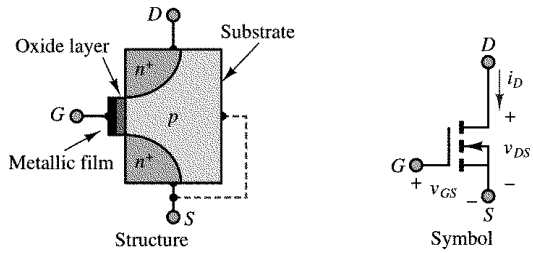

FIGURE 5.7.36 *n*-Channel enhancement MOSFET.

MOSFET. It is also called an *enhancement-mode* device, because the applied electric field "enhances" the conduction in the channel by attracting *n*-type charge carriers. There are also *depletion-mode* devices, in which the application of an electric field "depletes" the channel of charge carriers, reducing the effective channel width. It is useful to think of enhancement-mode devices as being normally off: current cannot flow from drain to source unless a gate voltage is applied. On the other hand, depletion-mode devices are normally on; that is, the gate voltage is used to reduce the conduction of current from drain to source.

An analogous discussion could be carried out for *p-channel MOSFETs*. In a *p*-channel device, conduction in the channel occurs through positive charge carriers. The correspondence between *n*-channel and *p*-channel devices is akin to that between *npn* and *pnp* bipolar devices.

We are now ready to describe qualitatively the *i-v* characteristic of this enhancement-mode MOSFET, for small values of drain-to-source voltage, v_{DS}, and for constant v_{GS}, the channel has essentially constant width and therefore acts as a constant resistance. As the gate voltage is changed, this resistance can be varied over a certain range. This mode of operation, for small drain voltages, is called the **ohmic state**, and, as depicted in Figure 5.7.37, it corresponds to a linear *i-v* curve for fixed v_{GS}, as would be expected of a resistor. Thus, in the ohmic state the MOSFET acts as a **voltage-controlled resistor**.

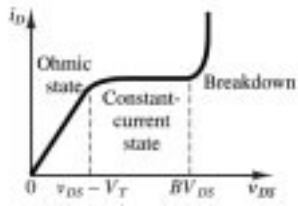

FIGURE 5.7.37 MOSFET *i-v* curve.

As the drain voltage is increased, the gate-to-drain voltage, v_{GD}, decreases, reducing the electric field strength at the drain end of the device.

When $v_{GD} = v_{GS} - v_{DS} < v_T$ and $v_{DS} > v_{GS} - v_T$, the channel is *pinched down*, and the electron flow into the drain is physically limited, so that the drain current becomes essentially constant. This phenomenon is clearly reflected in the curve of Figure 5.7.37, where it is shown that for drain-to-source voltages above $v_{DS} > v_{GS} - v_T$, the drain current becomes constant, independent of v_{DS}. This mode of operation is the **constant-current state**. If v_{DS} exceeds a given **drain breakdown voltage**, BV_{DS} (usually between 20 and 50 V), avalanche breakdown occurs and the drain current increases substantially. Operation in this **breakdown state** can lead to permanent damage because of the excessive heat caused by the large drain current. Finally, if v_{GS} exceeds the **gate breakdown voltage** (around 50 V), permanent damage to the oxide layer can occur. It is important to know that it is possible to generate *static* voltages of magnitude sufficient to exceed this breakdown voltage just by handling the device; thus, some attention must usually be paid to static voltage buildup in handling MOS circuits.

Transistor Gates and Switches

Transistor switching circuits form the basis of digital logic circuits. The objective of this section is to discuss the internal operation of these circuits and to provide the reader interested in the internal workings of digital circuits with an adequate understanding of the basic principles.

An **electronic gate** is a device that, on the basis of one or more input signals, produces one of two or more prescribed outputs; as will be seen shortly, one can construct both digital and analog gates. A word of explanation is required, first, regarding the meaning of the words *analog* and *digital*. An analog voltage or current — or, more generally, an analog signal — is one that varies in a continuous fashion over time, in *analogy* (hence the expression *analog*) with a physical quantity. An example of an analog signal is a sensor voltage corresponding to ambient temperature on any given day, which may fluctuate between, say, 30° and 50°F. A digital signal, on the other hand, is a signal that can take only a finite number of values; in particular, a commonly encountered class of digital signals consists of **binary signals**, which can take only one of two values (for example, 1 and 0). A typical example of a binary signal would be the control signal for the furnace in a home heating system controlled by a conventional thermostat, where one can think of this signal as being "on" (or 1) if the temperature of the house has dropped below the thermostat setting (desired value), or "off" (or 0) if the house temperature is greater than or equal to the set temperature (say, 68°F). Figure 5.7.38 illustrates the appearance of the analog and digital signals in this furnace example.

Analog Gates

A common form of analog gate — probably the most important, in practice — employs an FET and takes advantage of the fact that current can flow in either direction in an FET biased in the ohmic region. Recall that the drain characteristic of the MOSFET consists of three regions: ohmic, active, and breakdown. A MOSFET amplifier is operated in the active region, where the drain current is nearly constant for any given value of v_{GS}. On the other hand, a MOSFET biased in the ohmic state acts very much as a linear resistor. For example, for an *n*-channel enhancement MOSFET, the conditions for the transistor to be in the ohmic region are

$$v_{GS} > V_T \quad \text{and} \quad |v_{DS}| \le \frac{1}{4}(v_{GS} - V_T) \tag{5.7.17}$$

As long as the FET is biased within these conditions, it acts simply as a linear resistor, and it can conduct current in either direction (provided that v_{DS} does not exceed the limits stated in Equation (5.7.17). In particular, the resistance of the channel in the ohmic region is found to be

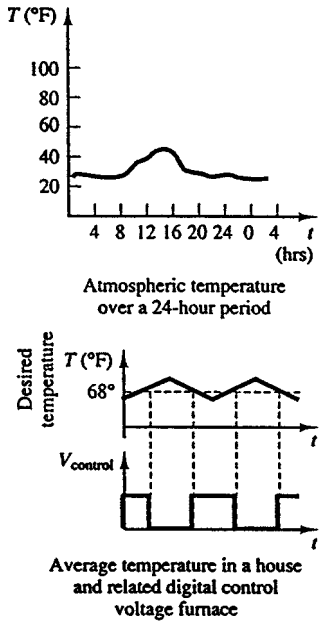

FIGURE 5.7.38 Illustration of analog and digital signals.

$$R_{DS} = \frac{V_T^2}{2I_{DSS}\left(v_{GS} - V_T\right)} \tag{5.7.18}$$

so that the drain current is equal to

$$i_D \approx \frac{v_{DS}}{r_{DS}} \quad \text{for} \quad \left|v_{DS}\right| \le \frac{1}{4}\left(v_{GS} - V_T\right) \quad \text{and} \quad v_{GS} > V_T \tag{5.7.19}$$

The most important feature of the MOSFET operating in the ohmic region, then, is that it acts as a voltage-controlled resistor, with the gate-source voltage, v_{GS}, controlling the channel resistance, R_{DS}. The use of the MOSFET as a switch in the ohmic region, then, consists of providing a gate-source voltage that can either hold the MOSFET in the cutoff region ($v_{GS} < V_T$) or bring it into the ohmic region. In this fashion, v_{GS} acts as a control voltage for the transistor.

Consider the circuit shown in Figure 5.7.39, where we presume that v_C can be varied externally and that v_{in} is some analog signal source that we may wish to connect to the load R_L at some appropriate time. The operation of the switch is as follows. When $v_C \le V_T$, the FET is in the cutoff region and acts as an open circuit. When $v_C > V_T$ (with a value of v_{GS} such that the MOSFET is in the ohmic region), the transistor acts as a linear resistance, R_{DS}. If $R_{DS} \ll R_L$, then $v_{\text{out}} \approx v_{\text{in}}$. By using a pair of MOSFETs, it is possible to improve the dynamic range of signals one can transmit through this analog gate.

MOSFET analog switches are usually produced in integrated circuit (IC) form and denoted by the symbol shown in Figure 5.7.40.

Digital Gates

BJT Gates. In discussing large-signal models for the BJT, we observed that the *i-v* characteristic of this family of devices includes a *cutoff* region, where virtually no current flows through the transistor. On the other hand, when a sufficient amount of current is injected into the base of the transistor, a bipolar transistor will reach *saturation*, and a substantial amount of collector current will flow. This behavior

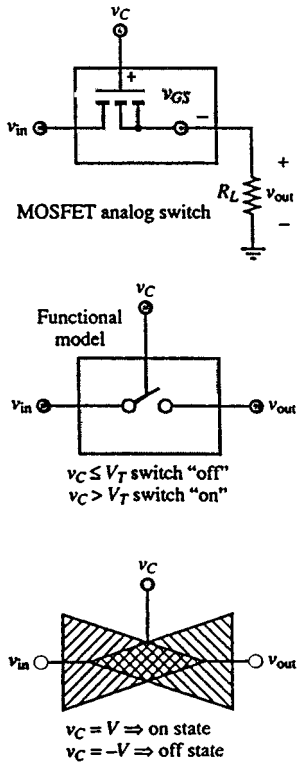

FIGURE 5.7.39 MOSFET analog switch.

FIGURE 5.7.40 Symbol for bilateral FET analog gate.

is quite well suited to the design of electronic gates and switches and can be visualized by superimposing a load line on the collector characteristic, as shown in Figure 5.7.41.

The operation of the simple **BJT switch** is illustrated in Figure 5.7.41 by means of load-line analysis. Writing the load-line equation at the collector circuit, we have

$$v_{CE} = V_{CC} - i_C R_C \tag{5.7.20}$$

and

$$v_{\text{out}} = v_{CE} \tag{5.7.21}$$

Thus, when the input voltage, v_{in}, is low (say, 0 V, for example) the transistor is in the cutoff region and little or no current flows, and

$$v_{\text{out}} = v_{CE} = V_{CC} \tag{5.7.22}$$

so that the output is "logic high."

When v_{in} is large enough to drive the transistor into the saturation region, a substantial amount of collector current will flow and the collector-emitter voltage will be reduced to the small saturation value, $V_{CE\,\text{sat}}$, which is typically a fraction of a volt. This corresponds to the point labeled B on the load line. For the input voltage v_{in} to drive the BJT of Figure 5.7.41 into saturation, a base current of approximately 50 mA will be required. Suppose, then, that the voltage v_{in} could take the values 0 or 5 V. Then, if $v_{\text{in}} = 0$ V, v_{out} will be nearly equal to V_{CC} or, again, 5 V. If, on the other hand, $v_{\text{in}} = 5$ V and R_B is, say, equal to 85 kΩ [so that the base current required for saturation flows into the base: $i_B \approx (5\text{ V} - 0.7\text{ V})/R_B = 50.6\ \mu\text{A}$], we have the BJT in saturation, and $v_{\text{out}} = V_{CE\,\text{sat}} \approx 0.2$ V.

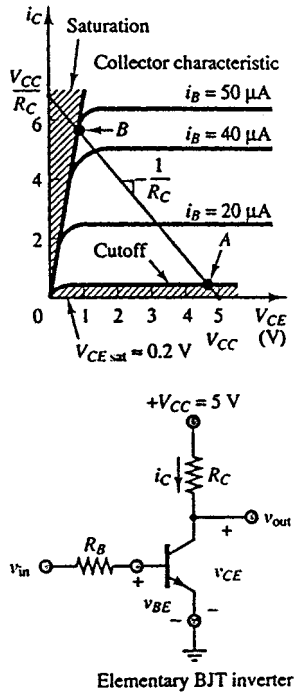

FIGURE 5.7.41 BJT switching characteristic.

Thus, you see that whenever v_{in} corresponds to a logic high (or logic 1), v_{out} takes a value close to 0 V, or logic low (or 0); conversely, v_{in} ="0" (logic "low") leads to v_{out} = "1". The values of 5 and 0 V for the two logic levels 1 and 0 are quite common in practice and are the standard values used in a family of logic circuits denoted by the acronym TTL, which stands for **transistor-transistor logic**. One of the more common TTL blocks is the **inverter** shown in Figure 5.7.41, so called because it "inverts" the input by providing a low output for a high input, and vice versa. This type of inverting, or "negative", logic behavior is quite typical of BJT gates (and of transistor gates in general).

MOSFET Logic Gates. Having discussed the BJT as a switching element, we might quite naturally suspect that FETs may similarly serve as logic gates. In fact, in some respects, FETs are better suited to be employed as logic stages than BJTs. The *n*-channel enhancement MOSFET serves as an excellent illustration: because of its physical construction, it is normally off (that is, it is off until a sufficient gate voltage is provided), and therefore it does not require much current from the input signal source. Further, MOS devices offer the additional advantage of easy fabrication into integrated circuit form, making production economical in large volume. On the other hand, MOS devices cannot provide as much current as BJTs, and their switching speeds are not quite as fast — although these last statements may not hold true for long, because great improvements are taking place in MOS technology. Overall, it is certainly true that in recent years it has become increasingly common to design logic circuits based on MOS technology. In particular, a successful family of logic gates called *CMOS* (for *complementary metal-oxide-semiconductor*) takes advantage of both *p*- and *n*-channel enchancement-mode MOSFETs to exploit the best features of both types of transistors. CMOS logic gates (and many other types of digital circuits constructed using the same technology) consume very little supply power and have become the mainstay in pocket calculators, wristwatches, portable computers, and many other consumer electronics products. Without delving into the details of CMOS technology, we shall briefly illustrate the properties of MOSFET logic gates and of CMOS gates in the remainder of this section.

Figure 5.7.42 depicts a MOSFET switch with its drain *i-v* characteristic. Note the general similarity with the switching characteristic of the BJT shown in the previous section. When the input voltage, v_{in},

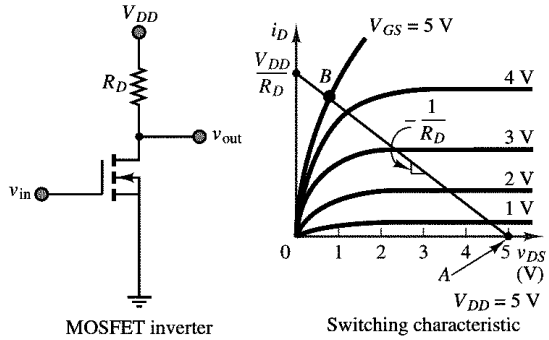

FIGURE 5.7.42 MOSFET switching characteristic.

is zero, the MOSFET conducts virtually no current and the output voltage, v_{out}, is equal to V_{DD}. When v_{in} is equal to 5 V, the MOSFET Q point moves from point A to point B along with the load line, with v_{DS} = 0.5 V. Thus, the circuit acts as an inverter. Much as in the case of the BJT, the inverter forms the basis of all MOS logic gates.

An elementary CMOS inverter is shown in Figure 5.7.43. Note first the simplicity of this configuration, which simply employs two enhancement-mode MOSFETs: *p*-channel at the top, denoted by the symbol Q_p, and *n*-channel at the bottom, denoted by Q_n. Recall from Chapter 8 that when v_{in} is low, transistor Q_n is off. However, transistor Q_p sees a gate-to-source voltage $v_{GS} = v_{in} - V_{DD} = -V_{DD}$; in a *p*-channel device, this condition is the counterpart of having $v_{GS} = V_{DD}$ for an *n*-channel MOSFET. Thus, when Q_n is off, Q_p is on and acts very much as a small resistance. In summary, when v_{in} is low, the output is $v_{out} \approx V_{DD}$. When v_{in} is high, the situation is reversed: Qn is now on and acts nearly as a short circuit while Q_p is open (since $v_{GS} = 0$ for Q_p). Thus, $v_{in} \approx 0$. The complementary MOS operation is depicted in Figure 5.7.43 in simplified form by showing each transistor as either a short or an open circuit, depending on it state. This simplified analysis is sufficient for the purpose of a qualitative analysis.

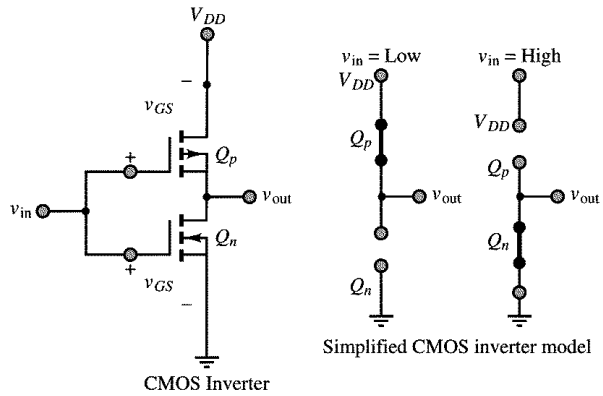

FIGURE 5.7.43 CMOS inverter.

5.8 Power Electronics

The objective of this section is to present a survey of power electronic devices and systems. Power electronic devices form the "muscle" of many electromechanical systems. For example, one finds such devices in many appliances, in industrial machinery, and virtually wherever an electric motor is found, since one of the foremost applications of power electronic devices is to supply and control the currents and voltages required to power electric machines, such as those introduced in Section 5.12.

Classification of Power Electronic Devices

Power semiconductors can be broadly subdivided into five groups: (1) power diodes, (2) thyristors, (3) power bipolar junction transistors (BJTs), (4) insulated-gate bipolar transistors (IGBTs), and (5) static induction transistors (SITs). Figure 5.8.1 depicts the symbols for the most common power electronic devices.

Device	Device symbol
Diode	Thyristor	Gate Turn-off Thyristor (GTO)	Triac	npn BJT	IGBT	n-channel MOSFET	
FIGURE 5.8.1 Classification of power electronic devices.

Power diodes are functionally identical to the diodes introduced in Section 5.7, except for their ability to carry much larger currents. A diode conducts in the forward-biased mode when the anode voltage ($V_{A)}$ is higher than the cathode voltage (V_K). Three types of power diodes exist: general-purpose, high-speed (fast-recovery), and Schottky. Typical ranges of voltage and current are 3000 V and 3500 A for general-purpose diodes and 3000 V and 1000 A for high-speed devices. The latter have switching times as low as a fraction of a microsecond. Schottky diodes can switch much faster (in the nanosecond range) but are limited to around 100 V and 300 A. The forward voltage drop of power diodes is not much higher than that of low-power diodes, being between 0.5 and 1.2 V. Since power diodes are used with rather large voltages, the forward bias voltage is usually considered negligible relative to other voltages in the circuit, and the switching characteristics of power diodes may be considered near ideal. The principal consideration in choosing power diodes is their power rating.

Thyristors function like power diodes with an additional gate terminal that controls the time when the device begins conducting; a thyristor starts to conduct when a small gate current is injected into the gate terminal, provided that the anode voltage is greater than the cathode voltage (or $V_{AK} > 0$ V). The forward voltage drop of a thyristor is of the order of 0.5 to 2 V. Once conduction is initiated, the gate current has no further control. To stop conduction, the device must be reverse-biased; that is, one must ensure that $V_{AK} \leq 0$ V. Thyristors can be rated at up to 6000 V and 3500 A. The **turn-off time** is an important characteristic of thyristors; it represents the time required for the device current to return to zero after external switching of V_{AK}. The fastest turn-off times available are in the range of 10 μsec; however, such turn-off times are achieved only in devices with slightly lower power ratings (1200 V, 1000 A). Thyristors can be subclassified into the following groups: force-commutated and line-commutated thyristors, gate turn-off thyristors (GTOs), reverse-conducting thyristors (RCTs), static induction thyristors (SITHs), gate-assisted turn-off thyristors (GATTs), light-activated silicon-controlled rectifiers (LASCSRs), and MOS-controlled thyristors (MCTs). It is beyond the scope of this chapter to go into a detailed description of each of these types of devices; their operation is typically a slight modification of the basic operation of the thyristor. The reader who wishes to gain greater insight into this topic may refer to one of a number of excellent books specifically devoted to the subject of power electronics.

Two types of thyristor-based device deserve some more attention. The **triac**, as can be seen in Figure 5.8.1, consists of a pair of thyristors connected back to back, with a single gate; this allows for current control in either direction. Thus, a triac may be thought of as bidirectional thyristor. The **gate turn-off** thyristor (GTO), on the other hand, can be turned on by applying a short positive pulse to the gate, like a thyristor, and can also be turned off by application of a short negative pulse. Thus, GTOs are very convenient in that they do not require separate commutation circuits to be turned on and off.

Power BJTs can reach ratings up to 1200 V and 400 A, and they operate in much the same way as a conventional BJT. Power BJTs are used in power converter applications at frequencies up to around 10 kHz. **Power MOSFETs** can operate at somewhat higher frequencies (a few to several tens of kHz), but are limited in power (typically up to 1000 V, 50 A). **Insulated-gate bipolar transistors** (IGBTs) are voltage-controlled (because of their insulated gate, reminiscent of insulated-gate FETs) power transistors that offer superior speed with respect to BJTs but are not quite as fast as power MOSFETs.

Classification of Power Electronic Circuits

The devices that will be discussed in the present chapter find application in a variety of **power electronic circuits**. This section will briefly summarize the principal types of power electronic circuits and will qualitatively describe their operation. The following sections will describe the devices and their operation in these circuits in more detail.

One possible classification of power electronic circuits is given in Table 5.8.1. Many of the types of circuits are similar to circuits that were introduced in earlier chapters. Voltage regulators were introduced in Section 5.7. Power electronic switches function exactly like the transistor switches described in Section 5.7; their function is to act as voltage- or current-controlled switches to turn AC or DC supplies on and

TABLE 5.8.1 Power Electronic Circuits

Circuit Type	Essential Features
Voltage regulators	Regulate a DC supply to a fixed voltage output
Power amplifiers	Large-signal amplification of voltages and currents
Switches	Electronic switches (for example, transistor switches)
Diode rectifier	Converts fixed AC voltage (single- or multiphase) to fixed DC voltage
AC-DC converter (controlled rectifier)	Converts fixed AC voltage (single- or multiphase) to variable DC voltage
AC-AC converter (AC voltage controller)	Converts fixed AC voltage to variable AC voltage (single- or multiphase)
DC-DC converter (chopper)	Converts fixed DC voltage to variable DC voltage
DC-AC converter (inverter)	Converts fixed DC voltage to variable AC voltage (single- or multiphase)

off. Transistor power amplifiers are the high-power version of the BJT and MOSFET amplifiers mentioned in Section 5.7.

Diode rectifiers were discussed in Section 5.7 in their single-phase form; similar rectifiers can also be designed to operate with three-phase sources. The operation of a single-phase full-wave rectifier was summarized in Figure 5.8.2. AC-DC converters are also rectifiers, but they take advantage of the controlled properties of thyristors. The thyristor gate current can be timed to "fire" conduction at variable times, resulting in a variable DC output, as illustrated in Figure 5.8.2, which shows the circuit and behavior of a single-phase AC-DC converter. This type of converter is very commonly used as a supply for DC electric motors. In Figure 5.8.2 α is the firing angle of thyristor T_1, where the device starts to conduct.

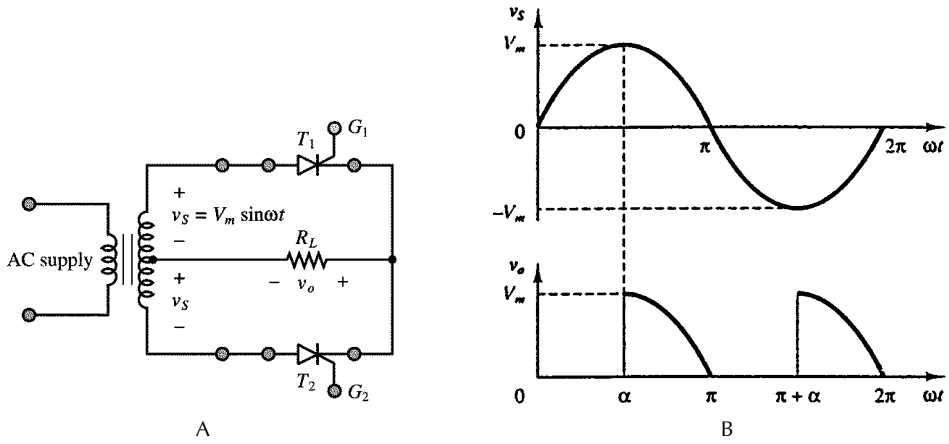

FIGURE 5.8.2 AC-DC converter circuit and waveform.

AC-AC converters are used to obtain a variable AC voltage from a fixed AC source. Figure 5.8.3 shows a triac-based AC-AC converter, which takes advantage of the bidirectional capability of triacs to control the rms value of an alternating voltage. Note in particular that the resulting AC waveform is no longer a pure sinusoid even though its fundamental period (frequency) is unchanged. A DC-DC converter, also known as a *chopper*, or *switching regulator*, permits conversion of a fixed DC source to a variable DC supply. Figure 5.8.4 shows how such an effect may be obtained by controlling the base-emitter voltage of a bipolar transistor, enabling conduction at the desired time. This results in the conversion of the DC input voltage to a variable-duty-cycle output voltage, whose average value can be controlled by selecting the "on" time of the transistor. DC-DC converters find application as variable voltage supplies for DC electric motors used in electric vehicles.

Finally, DC-AC supplies, or inverters, are used to convert a fixed DC supply to a variable AC supply; they find application in AC motor control. The operation of these circuits is rather complex; it is illustrated

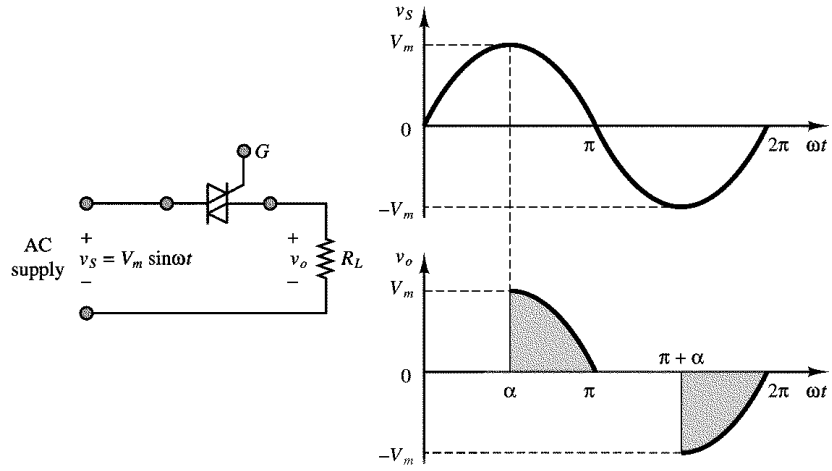

FIGURE 5.8.3 AC-AC converter circuit and waveform.

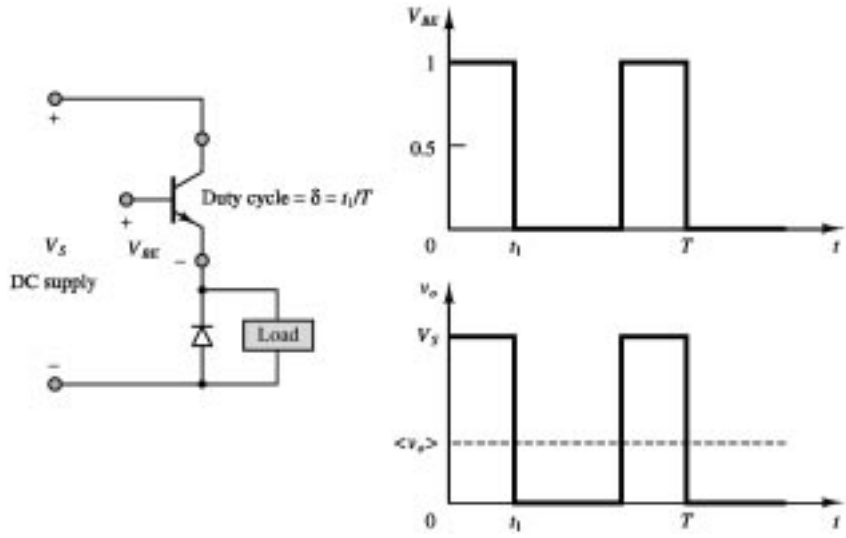

FIGURE 5.8.4 DC-DC converter circuit and waveform.

conceptually in the waveforms of Figure 5.8.5, where it is shown that by appropriately switching two pairs of transistors it is possible to generate an alternating current waveform (square wave).

Each of the circuits of Table 5.8.1 will now be analyzed in greater detail.

Rectifiers and Controlled Rectifiers (AC-DC Converters)

Thyristors and Controlled Rectifiers

In a number of applications, it is useful to be able to externally control the amount of current flowing from an AC source to the load. A family of power semiconductor devices called **controlled rectifiers** allows for control of the rectifiers state by means of a third input, called the gate. Figure 5.8.6 depicts the appearance of a **thyristor**, or **silicon-controlled rectifier** (SCR), illustrating how the physical structure of this device consists of four layers, alternating *p*-type and *n*-type material. Note that the circuit symbol for the thyristor suggests that this device acts as a diode, with provision for an additional external control signal.

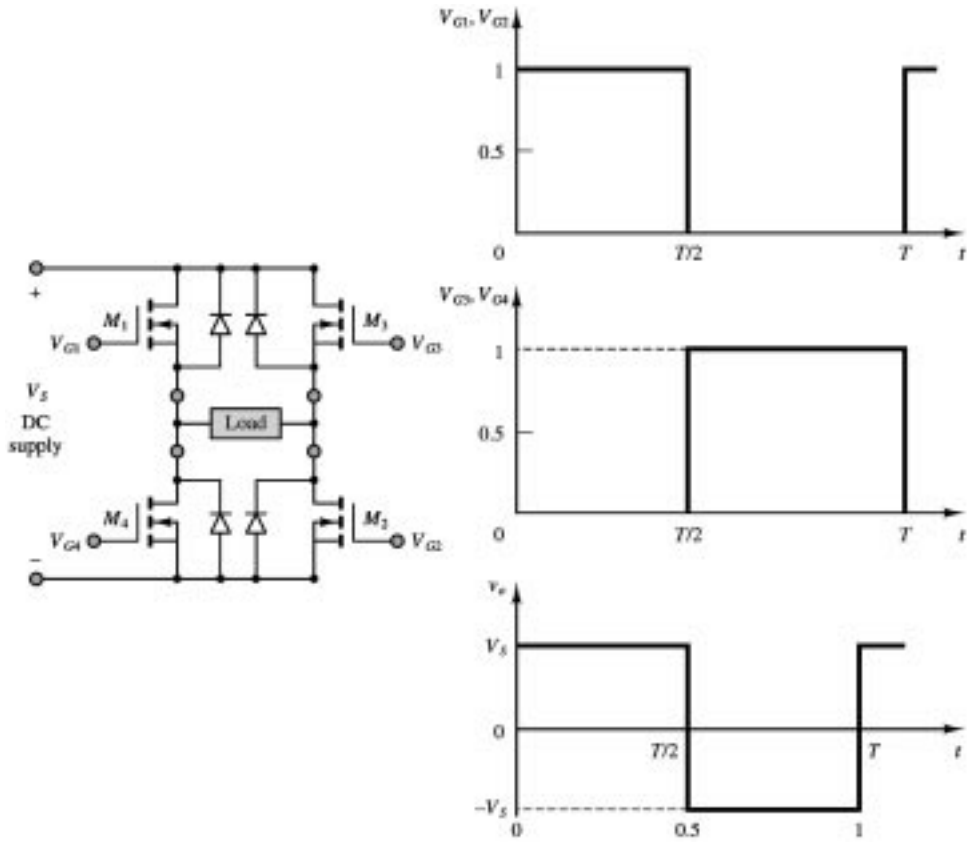

FIGURE 5.8.5 DC-AC converter circuit and waveform.

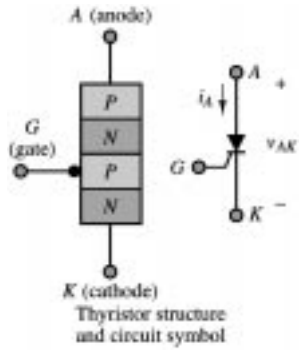

FIGURE 5.8.6 Thyristor structure and circuit symbol.

The operation of the thyristor can be explained in an intuitive fashion as follows. When the voltage v_{AK} is negative (i.e., providing reverse bias), the thyristor acts just like a conventional *pn* junction in the off state. When v_{AK} is forward-biased *and* a small amount of current is injected into the gate, the thyristor conducts forward current. The thyristor then continues to conduct (even in the absence of gate current), provided that v_{AK} remains positive. Figure 5.8.7 depicts the *i-v* curve for the thyristor. Note that the thyristor has two stable states, determined by the bias v_{AK} and by the gate current. In summary, the thyristor acts as a diode with a control gate that determines the time when conduction begins.

A somewhat more accurate description of thyristor operation may be provided if we realize that the four-layer *pnpn* device can be modeled as a *pnp* transistor connected to an *npn* transistor. Figure 5.8.8 clearly shows that, physically, this is a realistic representation. Note that the anode current, i_A, is equal

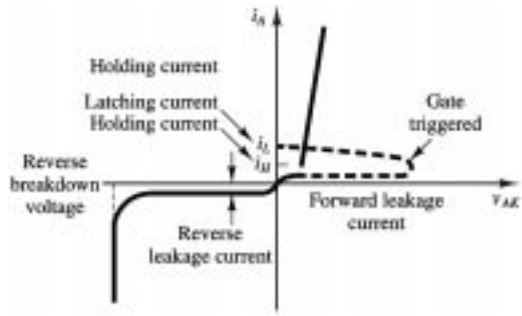

FIGURE 5.8.7 Thyristor *i-v* characteristic.

to the emitter current of the *pnp* transistor (labeled Q_p) and the base current of Q_p is equal to the collector current of the *npn* transistor, Q_n. Likewise, the base current of Q_n is the sum of the gate current and the collector current of Q_p. The behavior of this transistor model is explained as follows. Suppose, initially, i_G and i_{B_n} are both zero. Then it follows that Q_n is in cutoff, and therefore $i_{C_n} = 0$. But if $i_{C_n} = 0$, then the base current going into Q_p is also zero and Q_p is also in cutoff, and $i_{C_n} = 0$, consistent with our initial assumption. Thus, this is a stable state, in the sense that unless an external condition perturbs the thyristor, it will remain off.

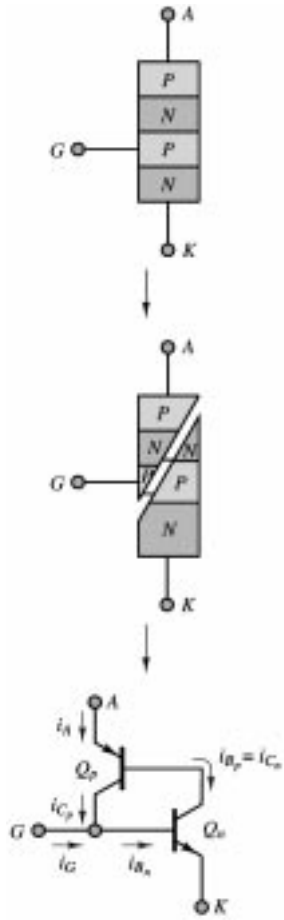

FIGURE 5.8.8 Thyristor two-transistor model.

Now, suppose a small pulse of current is injected at the gate. Then $i_{B_n} > 0$ and Q_n starts to conduct, provided, of course, that $v_{AK} > 0$. At this point, i_{C_n}, and therefore i_{B_p}, must be greater than zero, so that Q_p conducts. It is important to note that once the gate current has turned Q_n on, Q_p also conducts, so that $i_{C_p} > 0$. Thus, even though i_G may cease, once this "on" state is reached, $i_{C_p} = i_{B_n}$ continues to drive Q_n so that the on state is also self-sustaining. The only condition that will cause the thyristor to revert to the off state is the condition in which v_{AK} becomes negative; in this case, both transistors return to the cutoff state.

In a typical controlled rectifier application, the device is used as a half-wave rectifier that conducts only after a trigger pulse is applied to the gate. Without concerning ourselves with how the trigger pulse is generated, we can analyze the general waveforms for the circuit of Figure 5.8.9 as follows. Let the voltage v_{trigger} be applied to the gate of the thyristor at $t = \tau$. The voltage v_{trigger} can be a short pulse, provided by a suitable trigger-timing circuit (Section 5.11 will discuss timing and switching circuits). At $t = \tau$, the thyristor begins to conduct, and it continues to do so until the AC source enters its negative cycle. Figure 5.8.10 depicts the relevant waveforms.

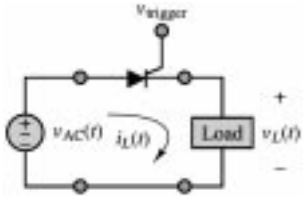

FIGURE 5.8.9 Controlled rectifier circuit.

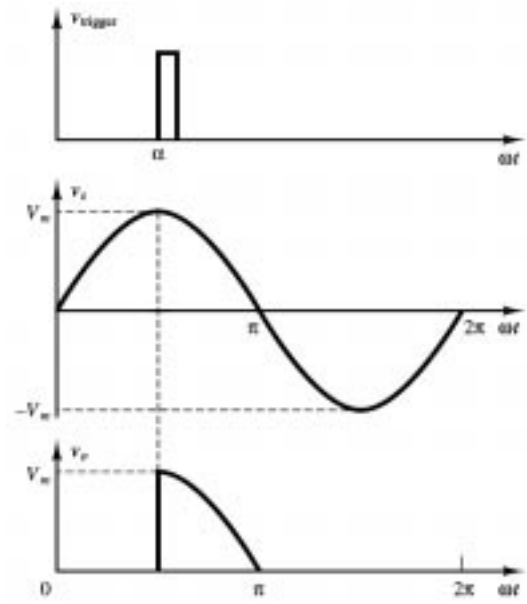

FIGURE 5.8.10 Half-wave controlled rectifier waveforms.

Note how the DC load voltage is controlled by the firing time τ, according to the following expression:

$$\langle v_L \rangle = V_L = \frac{1}{T}\int_{\tau}^{T/2} v_{\text{AC}}(t)\, dt \tag{5.8.1}$$

where T is the period of $v_{AC}(t)$, Now, if we let

$$v_{AC}(t) = A\sin\omega t \tag{5.8.2}$$

we can express the average (DC) value of the load voltage

$$V_L = \frac{1}{T}\int_{\tau}^{T/2} A\sin\omega t\, dt = (1+\cos\omega t)\frac{A}{2\pi} \tag{5.8.3}$$

in terms of the **firing angle**, α, defined as

$$\alpha = \omega t \tag{5.8.4}$$

By evaluating the integral of Equation (5.8.3), we can see that the (DC) load voltage amplitude depends on the firing angle, α:

$$V_L = (1+\cos\alpha)\frac{A}{2\pi} \tag{5.8.5}$$

Electric Motor Drives

The advent of high-power semiconductor devices has made it possible to design effective and relatively low-cost electronic supplies that take full advantage of the capabilities of the devices introduced in this chapter. Electronic power supplies for DC and AC motors have become one of the major fields of application of power electronic devices. The last section of this chapter is devoted to an introduction to two families of power supplies, or **electric drives: choppers**, or **DC-DC converters**; and **inverters**, or **DC-AC converters**. These circuits find widespread application in the control of AC and DC motors in a variety of applications and power ranges.

Before we delve into the discussion of the electronic supplies, it will be helpful to introduce the concept of quadrants of operation of a drive. Depending on the direction of current flow and on the polarity of the voltage, an electronic drive can operate in one of four possible modes, as indicated in Figure 5.8.11.

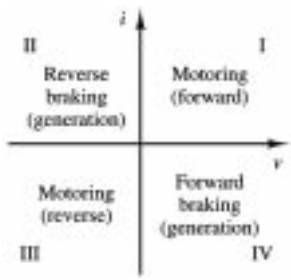

FIGURE 5.8.11 The four quadrants of an electric drive.

Choppers (DC-DC Converters)

As the name suggests, a DC-DC converter is capable of converting a fixed DC supply to a variable DC supply. This feature is particularly useful in the control of the speed of a DC motor (described in greater detail in Section 5.12). In a DC motor, shown schematically in Figure 5.8.12, the developed torque, T_m, is proportional to the current supplied to the motor **armature**, I_a, while the **electromotive force** (emf), E_a, which is the voltage developed across the armature, is proportional to the speed of rotation of the motor, ω_m. A DC motor is an electromechanical energy-conversion system; that is, it converts electrical to mechanical energy (or vice versa if it is used as a generator); if we recall that the product of torque and speed is equal to power in the mechanical domain, and that current times voltage is equal to power in the electrical domain, we conclude that in the ideal case of complete energy conversion, we have

$$E_a \times I_a = T_m \times \omega_m \tag{5.8.6}$$

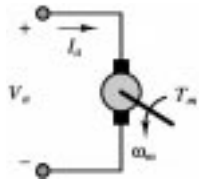

FIGURE 5.8.12 DC motor.

Naturally, such ideal energy conversion cannot take place; however, we can see that there is a correspondence between the four-electrical quadrants of Figure 5.8.11 and the mechanical power output of the motor: namely, if the voltage and current are both positive or both negative, the electrical power will be positive, and so will the mechanical power. This corresponds to the **forward** (*i, v* both positive) and **reverse** (*i,v* both negative) **motoring** operation. Forward motoring corresponds to quadrant I, and reverse motoring to quadrant III in Figure 5.8.12. If the voltage and current are of opposite polarity (quadrants II and IV), electrical energy is flowing back to the electric drive; in mechanical terms this corresponds to a braking condition. Operation in the fourth quadrant can lead to **regenerative braking**, so called because power is generated by making current flow back to the source. This mode could be useful, for example, to recharge a battery supply, because the braking energy can be regenerated by returning it to the electric supply.

A simple circuit that can accomplish the task of providing a variable DC supply from a fixed DC source is the **step-down chopper (buck converter)**, shown in Figure 5.8.13. The circuit consists of a "chopper" switch, denoted by the symbol *S*, and a free-wheeling diode. The switch can be any of the power switches described in this chapter, for example, a power BJT or MOSFET, or a thyristor; see, for example, the BJT switch of Figure 5.8.4. The circuit to the right of the diode is a model of a DC motor, including the inductance and resistance of the armature windings and the effect of the back emf E_a. When the switch is turned on (say, at $t = 0$), the supply V_s is connected to the load and $v_o = V_s$. The load current, i_o, is determined by the motor parameters. When the switch is turned off, the load current continues to flow through the free-wheeling diode, but the output voltage is now $v_o = 0$. At time T, the switch is turned on again, and the cycle repeats.

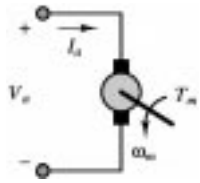

FIGURE 5.8.13 Step-down chopper (buck converter).

Figure 5.8.14 depicts the v_o and i_o waveforms. The average value of the output voltage, $\langle v_o \rangle$, is given by the expression

$$\langle v_o \rangle = \frac{t_1}{T} V_S = \delta V_S \tag{5.8.7}$$

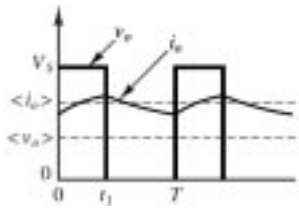

FIGURE 5.8.14 Step-down chopper waveforms.

where δ is the **duty cycle** of the chopper. The step-down chopper has a useful range,

$$0 \le \langle v_o \rangle \le V_S \tag{5.8.8}$$

It is also possible to increase the range of a DC-DC converter to above the supply voltage by making use of the energy-storage properties of an inductor; the resulting circuit is shown in Figure 5.8.15. When the chopper switch, *S*, is on, the supply current flows through the inductor and the closed switch, storing energy in the inductor; the output voltage, v_o, is zero, since the switch is a short circuit. When the switch is open, the supply current will flow through the load via the diode; but the inductor voltage is negative during the transient following the opening of the switch and therefore adds to the source voltage: the energy stored in the inductor while the switch was closed is now released and transferred to the load. This stored energy makes it possible for the output voltage to be higher than the supply voltage for a finite period of time.

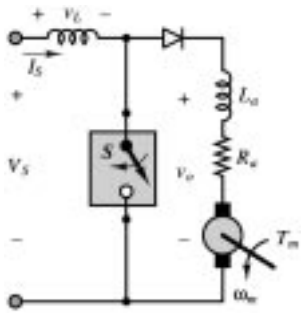

FIGURE 5.8.15 Step-up chopper (boost converter).

Let t_1 once again be the time during which the chopper conducts; neglecting for the moment the ripple in the supply current, the energy stored in the inductor during this period is

$$W_i = V_S I_S t_1 \tag{5.8.9}$$

When the chopper is off, the energy released to the load is

$$W_i = \left(\langle v_o \rangle - V_S\right) I_S \left(T - t_1\right) \tag{5.8.10}$$

If the system is lossless, the two energy expressions must be equal:

$$V_S I_S t_1 = \left(\langle v_o \rangle - V_S\right) I_S \left(T - t_1\right) \tag{5.8.11}$$

and we can determine the average output voltage to be

$$\langle v_o \rangle = V_S \frac{t_1 + T - t_1}{T - t_1} = V_S \frac{T}{T - t_1} = V_S \frac{1}{1 - \delta} \tag{5.8.12}$$

Since the duty cycle, δ, is always less than 1, the theoretical range of the supply is

$$V_S \le \langle v_o \rangle < \infty \tag{5.8.13}$$

The waveforms for the boost converter are shown in Figure 5.8.16.

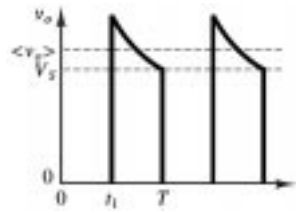

FIGURE 5.8.16 Step-up chopper output voltage waveform.

A step-up chopper can also be used to provide regenerative braking: if the "supply" voltage is the motor armature voltage and the output voltage is the fixed DC supply (battery) voltage, then power can be made to flow from the motor to the DC supply (i.e., recharging the battery). This configuration is shown in Figure 5.8.17.

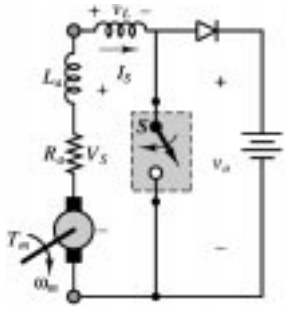

FIGURE 5.8.17 Step-up chopper used for regenerative braking.

Finally, the operation of the step-down and step-up choppers can be combined into a **two-quadrant chopper**, shown in Figure 5.8.18. The circuit shown schematically in Figure 5.8.18 can provide both regenerative braking and motoring operation in a DC motor. When switch S_2 is open and switch S_1 serves as a chopper, the circuit operates as a step-down chopper, precisely as was described earlier in this section (convince yourself of this by redrawing the circuit with S_2 and D_2 replaced by open circuits). Thus, the drive and motor operate in the first quadrant (motoring operation). The output voltage, v_o, will switch between V_S and zero, as shown in Figure 5.8.14, and the load current will flow in the direction indicated by the arrow in Figure 5.8.18 diode D_1 free-wheels whenever S_1 is open. Since both output voltage and current are positive, the system operates in the first quadrant.

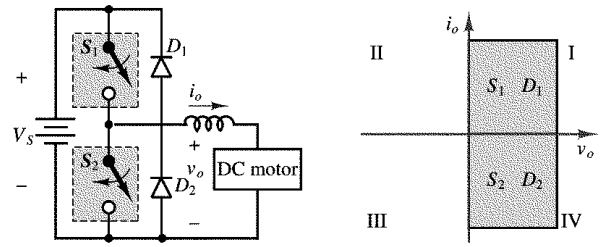

FIGURE 5.8.18 Two-quadrant chopper.

When switch S_1 is open and switch S_2 serves as a chopper, the circuit resembles a step-up chopper. The source is the motor emf, E_a, and the load is the battery; this is the situation depicted in Figure 5.8.17. The current will now be negative, since the sum of the motor emf and the voltage across the inductor (corresponding to the energy stored during the "on" cycle of S_2) is greater than the battery voltage. Thus, the drive operates in the fourth quadrant.

Inverters (DC-AC Converters)

As will be explained in Section 5.12, variable-speed drives for AC motors require a multiphase variable-frequency, variable-voltage supply. Such drives are called *DC-AC converters*, or *inverters*. Inverter circuits can be quite complex, so the objective of this section is to present a brief introduction to the subject, with the aim of illustrating the basic principles. A **voltage source inverter** (VSI) converts the output of a fixed DC supply (e.g., a battery) to a variable-frequency AC supply. Figure 5.8.19 depicts a **half-bridge VSI**; once again, the switches can be either bipolar or MOS transistors, or thyristors. The operation of this circuit is as follows. When switch S_1 is turned on, the output voltage is in the positive half-cycle, and $v_o = V_S/2$. The switching sequence of S_1 and S_2 is shown in Figure 5.8.20. It is important that each switch be turned off before the other is turned on; otherwise, the DC supply would be short-circuited. Since the load is always going to be inductive in the case of a motor drive, it is important to observe that the load current, i_o, will lag the voltage waveform, as shown in Figure 5.8.20. As shown in this figure, there will be some portions of the cycle in which the voltage is positive but the current is negative. The function of diodes D_1 and D_2 is precisely to conduct the load current whenever it is of direction opposite to the polarity of the voltage. Without these diodes, there would be no load current in this case. Figure 5.8.20 also shows which element is conducting in each portion of the cycle.

A full-bridge version of the VSI can also be designed as shown in Figure 5.8.21; the associated output voltage waveform is shown in Figure 5.8.22. A 3-phase VSI is shown in Figure 5.8.23.

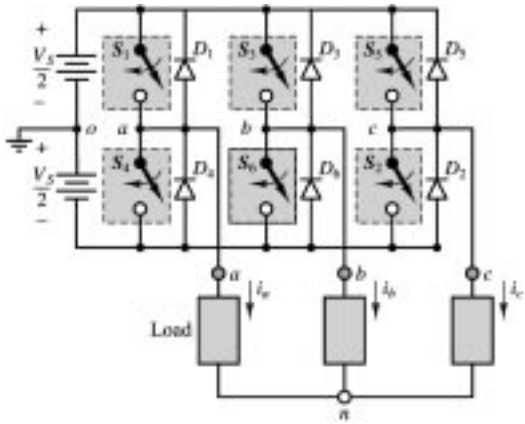

FIGURE 5.8.23 Three-phase voltage source inverter.

5.9 Operational Amplifiers

In this section we will analyze the properties of a general-purpose amplifier circuit known as the *operational amplifier.*

The Operational Amplifier

An **operational amplifier** is an **integrated circuit**, that is, a large collection of individual electrical and electronic circuits integrated on a single silicon wafer. An operational amplifier — or op-amp — can perform a great number of operations, such as addition, filtering, or integration, which are all based on the properties of ideal amplifiers and of ideal circuit elements. The introduction of the operational amplifier in integrated circuit form marked the beginning of a new era in modern electronics. Since the introduction of the first IC op-amp, the trend in electronic instrumentation has been to move away from the discrete (individual-component) design of electronic circuits, toward the use of integrated circuits for a large number of applications. This statement is particularly true for applications of the type the nonelectrical engineer is likely to encounter: op-amps are found in most measurement and instrumentation applications, serving as extremely versatile building blocks for any application that requires the processing of electrical signals.

In the following pages, simple circuit models of the op-amp will be introduced. The simplicity of the models will permit the use of the op-amp as a circuit element, or building block, without the need to describe its internal workings in detail. Integrated circuit technology has today reached such an advanced stage of development that it can be safely stated that for the purpose of many instrumentation applications, the op-amp can be treated as an ideal device. Following the introductory material presented in this chapter, more advanced instrumentation applications will be explored in Section 5.11.

The Open-Loop Model

The ideal operational amplifier behaves very much as an ideal **differential amplifier**, that is, a device that amplifies the difference between two input voltages. Operational amplifiers are characterized by near-infinite input resistance and very small output resistance. As shown in Figure 5.9.1 the output of the op-amp is an amplified version of the difference between the voltages present at the two inputs:

$$v_{\text{out}} = A_{V(OL)}\left(v^{+} - v^{-}\right) \tag{5.9.1}$$

The input denoted by a positive sign is called the **noninverting input** (or terminal), while that represented with a negative sign is termed the **inverting input** (or terminal). The amplification factor, or gain, $A_{V(OL)}$, is called the **open-loop voltage gain** and is quite large by design, typically of the order of 10^5 to 10^7; it will soon become apparent why a large open-loop gain is a desirable characteristic. Together with the high input resistance and low output resistance, the effect of a large amplifier open-loop voltage gain, $A_{V(OL)}$, is such that op-amp circuits can be designed to perform very nearly as ideal voltage or current amplifiers. In effect, to analyze the performance of an op-amp circuit, only one assumption will be needed: that the current flowing into the input circuit of the amplifier is zero, or

$$i_{\text{in}} = 0 \tag{5.9.2}$$

This assumption is justified by the large input resistance and large open-loop gain of the operational amplifier. The model just introduced will be used to analyze three amplifier circuits in the next part of this section.

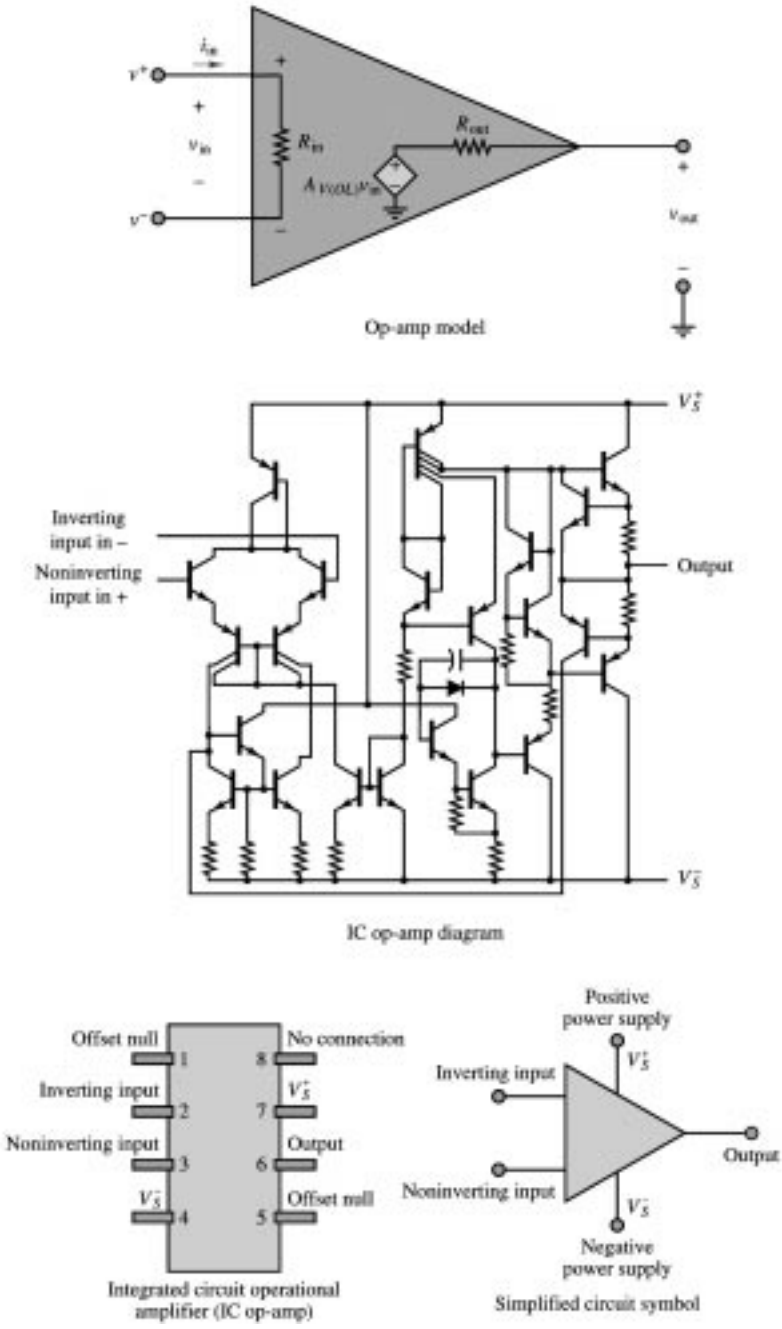

FIGURE 5.9.1 Operational amplifier model symbols, and circuit diagram.

The Operational Amplifier in the Closed-Loop Mode

The Inverting Amplifier. One of the more popular circuit configurations of the op-amp, because of its simplicity, is the so-called inverting amplifier, shown in Figure 5.9.2.

$$v_S = -v_{\text{out}}\left(\frac{1}{R_F/R_S} + \frac{1}{A_{V(OL)}R_F/R_S} + \frac{1}{A_{V(OL)}}\right) \tag{5.9.3}$$

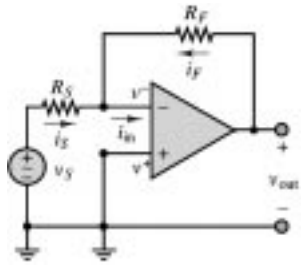

FIGURE 5.9.2 Inverting amplifier.

If the open-loop gain of the amplifier, $A_{V(OL)}$, is sufficiently large, the terms $1/(A_{V(OL)}R_F/R_S)$ and $1/A_{V(OL)}$, are essentially negligible, compared with $1/(R_F/R_S)$. As stated earlier, typical values of $A_{V(OL)}$ range from 10^5 to 10^7, and thus it is reasonable to conclude that, to a close approximation, the following expression describes the closed-loop gain of the inverting amplifier:

$$v_{\text{out}} = -\frac{R_F}{R_S}v_S \quad \text{Inverting amplifier closed-loop gain} \tag{5.9.4}$$

Next, we show that by making an additional assumption it is possible to simplify the analysis considerably. Consider that, as was shown for the inverting amplifier, the inverting terminal voltage is given by

$$v^- = -\frac{v_{\text{out}}}{A_{V(OL)}} \tag{5.9.5}$$

Clearly, as $A_{V(OL)}$ approaches infinity, the inverting-terminal voltage is going to be very small (practically, of the order of microvolts). It may then be assumed that *in the inverting amplifier*, v^- is virtually zero:

$$v^- \approx 0 \tag{5.9.6}$$

This assumption prompts an interesting observation (which may not yet appear obvious at this point): the effect of the feedback connection from output to inverting input is to force the voltage at the inverting input to be equal to that at the noninverting input.

This is equivalent to stating that for an op-amp *with negative feedback*,

$$v^- \approx v^+ \tag{5.9.7}$$

The analysis of the operational amplifier can now be greatly simplified if the following two assumptions are made:

1. $i_{in} = 0$
2. $v^- = v^+$ (5.9.8)

This technique will be tested in the next subsection by analyzing a noninverting amplifier configuration.

A useful op-amp circuit that is based on the inverting amplifier is the **op-amp summer**, or **summing amplifier**. This circuit, shown in Figure 5.9.3, is used to add signal sources. The primary advantage of using the op-amp as a summer is that the summation occurs independently of load and source impedances, so that sources with different internal impedances will not interact with each other.

$$v_{out} = -\sum_{n=1}^{N} \frac{R_F}{R_{S_n}} v_{S_n} \tag{5.9.9}$$

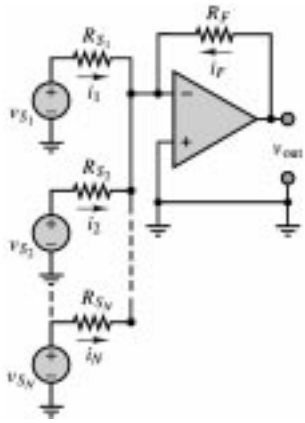

FIGURE 5.9.3 Summing amplifier.

That is, the output consists of the weighted sum of N input signal sources, with the weighting factor for each source equal to the ratio of the feedback resistance to the source resistance.

The Noninverting Amplifier. To avoid the negative gain (i.e., phase inversion) introduced by the inverting amplifier, a **noninverting amplifier** configuration is often employed. A typical noninverting amplifier is shown in Figure 5.9.4; note that the input signal is applied to the noninverting terminal this time.

$$\frac{v_{out}}{v_S} = 1 + \frac{R_F}{R_S} \quad \text{Noninverting amplifier closed-loop gain}$$

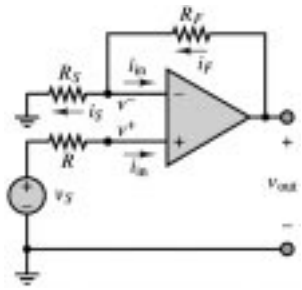

FIGURE 5.9.4 Noninverting amplifier.

The Differential Amplifier. The third closed-loop model examined in this chapter is a combination of the inverting and noninverting amplifiers; it finds frequent use in situations where the difference between two signals needs to be amplified. The basic **differential amplifier** circuit is shown in Figure 5.9.5,

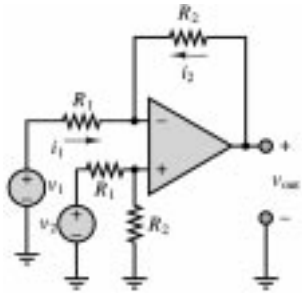

FIGURE 5.9.5 Differential amplifier.

where the two sources, v_1 and v_2, may be independent of each other, or may originate from the same process, as they do in Example 5.9.1.

The following expression for the output voltage is obtained:

$$v_{\text{out}} = R_2\left[\frac{-v_1}{R_1} + \frac{1}{R_1 + R_2}v_2 + \frac{R_2}{R_1\left(R_1 + R_2\right)}v_2\right]$$

$$= \frac{R_2}{R_1}\left(v_2 - v_1\right)$$

In practice, it is often necessary to amplify the difference between two signals that are both corrupted by noise or some other form of interference. In such cases, the differential amplifier provides an invaluable tool in amplifying the desired signal while rejecting the noise. Example 5.9.1 provides a realistic look at a very common application of the differential amplifier.

Example 5.9.1 An EKG Amplifier

This example illustrates the principle behind a two-lead electrocardiogram (EKG) measurement. The desired cardiac waveform is given by the difference between the potentials measured by two electrodes suitably placed on the patient's chest, as shown in Figure 5.9.6. A healthy, noise-free EKG waveform, $v_1 - v_2$, is shown in Figure 5.9.7.

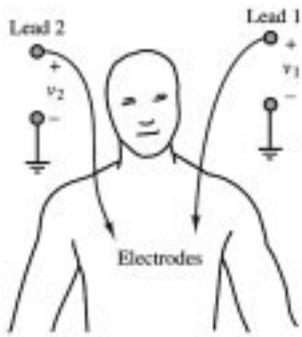

FIGURE 5.9.6 Two-lead electrocardiogram.

FIGURE 5.9.7 EKG waveform.

Unfortunately, the presence of electrical equipment powered by the 60-Hz, 110-VAC line current causes undesired interference at the electrode leads: the lead wires act as antennas and pick up some of the 60-Hz signal in addition to the desired EKG voltage. In effect, instead of recording the desired EKG signals, v_1 and v_2, the two electrodes provide the following inputs to the EKG amplifier, shown in Figure 5.9.8.

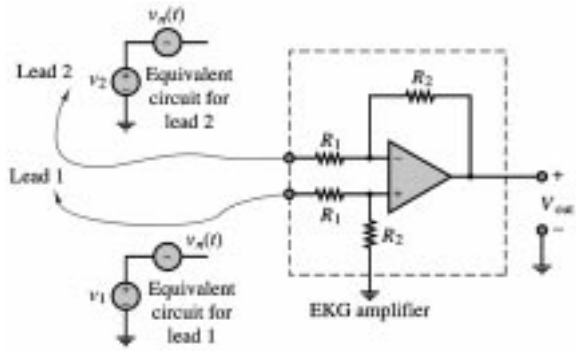

FIGURE 5.9.8 EKG amplifier.

Lead 1:

$$v_1(t) + v_n(t) = v_1(t) + V_n \cos\left(377t + \phi_n\right)$$

Lead 2:

$$v_2(t) + v_n(t) = v_2(t) + V_n \cos\left(377t + \phi_n\right)$$

The interference signal, $V_n \cos(377t + \phi n)$, is approximately the same at both leads, because the electrodes are chosen to be identical (e.g., they have the same lead lengths) and are in close proximity to each other. Further, the nature of the interference signal is such that it is common to both leads, since it is a property of the environment the EKG instrument is embedded in. On the basis of the analysis presented earlier, then,

$$v_{\text{out}} = \frac{R_2}{R_1}\left[\left(v_1 + v_n(t)\right) - \left(v_2 + v_n(t)\right)\right]$$

or

$$v_{\text{out}} = \frac{R_2}{R_1}\left(v_1 - v_2\right)$$

Thus, the differential amplifier nullifies the effect of the 60-Hz interference, while amplifying the desired EKG waveform.

The preceding example introduced the concept of so-called **common-mode** and **differential-mode signals**. In the EKG example, the desired differential-mode EKG signal was amplified by the op-amp while the common-mode disturbance was canceled. Thus, the differential amplifier provides the ability to reject common-mode signal components (such as noise or undesired DC offsets) while amplifying the differential-mode components. This is a very desirable feature in instrumentation systems. In practice, rejection of the common-mode signal is not always complete: some of the common-mode signal

component will always appear in the output. This fact gives rise to a figure of merit called the *common-mode rejection ratio*, which is discussed later in this section.

Often, to provide impedance isolation between bridge transducers and the differential amplifier stage, the signals v_1 and v_2 are amplified separately. This technique gives rise to the so-called **instrumentation amplifier** (IA), shown in Figure 5.9.9. Example 5.9.2 illustrates the calculation of the closed-loop gain for a typical instrumentation amplifier.

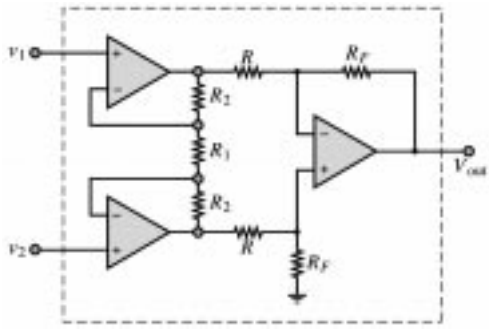

FIGURE 5.9.9 Instrumentation amplifier.

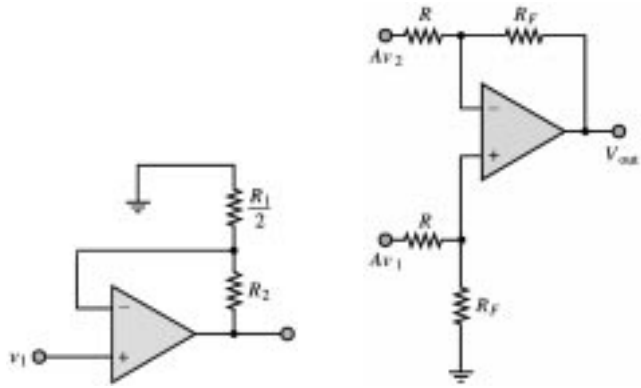
Example 5.9.2 Instrumentation Amplifier

In this example, we compute the closed-loop gain of the instrumentation amplifier of Figure 5.9.9.

Solution. To carry out the desired analysis as easily as possible, it is helpful to observe that resistor R_1 is shared by the two input amplifiers. This corresponds to having each amplifier connected to a resistor equal to $R_1/2$, as shown in Figure 5.9.10(a). Because of the symmetry of the circuit, one can view the shared resistor as being connected to ground in the center, so that the circuit takes the form of a noninverting amplifier, with closed-loop gain given by

$$A = 1 + \frac{2R_2}{R_1} \tag{5.9.10}$$



a b

FIGURE 5.9.10 (a) and (b).

Thus, each of the input voltages is amplified by this gain, and the overall gain of the instrumentation amplifier can then be computed by considering that the voltage difference $(Av_1 - Av_2)$ is then amplified by the differential amplifier stage, with gain R_F/R, as shown in Figure 5.9.10(b):

$$v_{out} = \frac{R_F}{R}\left(Av_1 - v_2\right) = \frac{R_F}{R}\left(1 + \frac{2R_2}{R_1}\right)\left(v_1 - v_2\right) \tag{5.9.11}$$

Active Filters

The class of filters one can obtain by means of op-amp designs is called **active filters**, because op-amps can provide amplification (gain) in addition to the filtering effects already studied in Section 5.6 for passive circuits (i.e., circuits comprising exclusively resistors, capacitors, and inductors).

The easiest way to see how the frequency response of an op-amp can be shaped (almost) arbitrarily is to replace the resistors R_F and R_S in Figures 5.9.2 and 5.9.4 with impedances Z_F and Z_S, as shown in Figure 5.9.11. It is a straightforward matter to show that in the case of the inverting amplifier, the expression for the closed loop gain is given by

$$\frac{\mathbf{V}_{\text{out}}}{\mathbf{V}_S}(j\omega) = -\frac{Z_F}{Z_S} \tag{5.9.12}$$

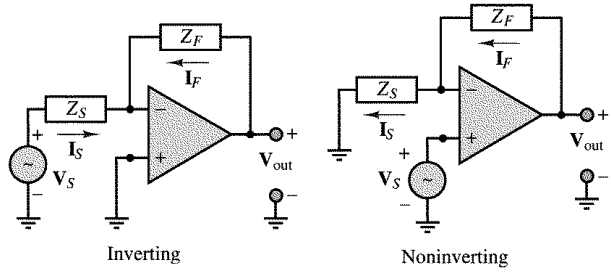


FIGURE 5.9.11 Op-amp circuits employing complex impedances.

whereas for the noninverting case, the gain is

$$\frac{\mathbf{V}_{\text{out}}}{\mathbf{V}_S}(j\omega) = 1 + \frac{Z_F}{Z_S} \tag{5.9.13}$$

where Z_F and Z_S can be arbitrarily complex impedance functions and where $\mathbf{V}_S$, $\mathbf{V}_{\text{out}}$, $\mathbf{I}_F$, and $\mathbf{I}_S$ are all phasors. Thus, it is possible to shape the frequency response of an ideal op-amp filter simply by selecting suitable ratios of feedback impedance to source impedance. The simplest op-amp low-pass filter is shown in Figure 5.9.12. The closed-loop gain $A_{LP}(j\omega)$ is then computed to be

$$A_{LP}(j\omega) = -\frac{Z_F}{Z_S} = -\frac{R_F/R_S}{1 + j\omega C_F R_F}$$

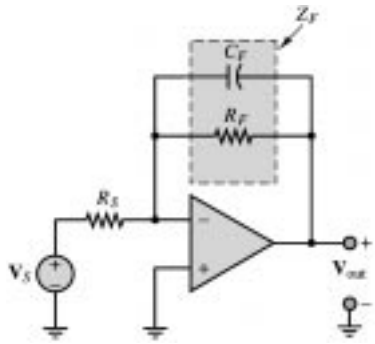

FIGURE 5.9.12 Active low-pass filter.

It should be apparent that the response of this op-amp filter is just an amplified version of that of the passive filter. Figure 5.9.13 depicts the amplitude response of the active low-pass filter (in the figure, $R_F/R_S = 10$ and $1/R_FC_F = 1$) in two different graphs; the first two plots the amplitude ratio $\mathbf{V}_{out}/\mathbf{V}_S$ vs. radian frequency, ω, on a logarithmic scale, while the second plots the amplitude ratio $20 \log_{10} (\mathbf{V}_{out}/\mathbf{V}_S)$ (in units of dB), also vs. ω on a logarithmic scale.

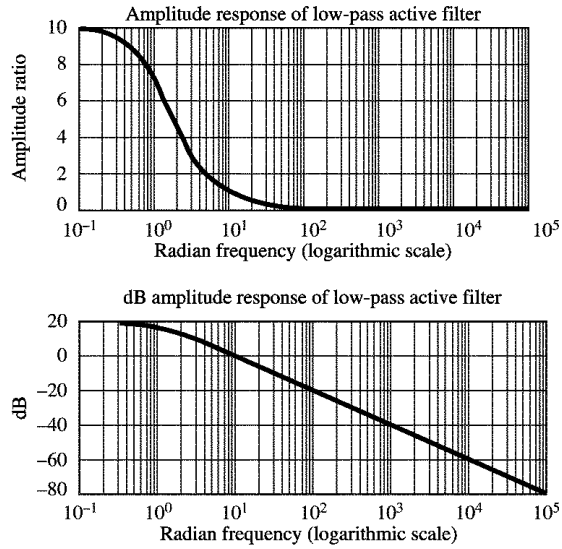

FIGURE 5.9.13 Normalized response of active low-pass filter.

A high-pass active filter can easily be obtained by using the circuit shown in Figure 5.9.14. The following gain function for the op-amp circuit can be derived:

$$A_{HP}(j\omega) = -\frac{Z_F}{Z_S} = -\frac{R_F}{R_S + 1/j\omega C_S} = -\frac{j\omega C_S R_F}{1 + j\omega R_S C_S} \tag{5.9.14}$$

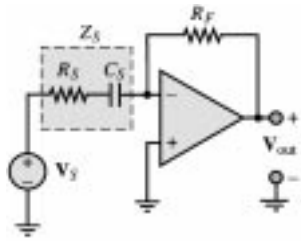

FIGURE 5.9.14 Active high-pass filter.

The high-pass response is depicted in Figure 5.9.15 in both linear and dB plots (in the figure, $R_F/R_S = 10$, $1/R_SC = 1$).

The band-pass filter of Figure 5.9.16 can be shown to have the following frequency response:

$$A_{BP}(j\omega) = -\frac{Z_F}{Z_S} = -\frac{j\omega C_S R_F}{(1 + j\omega C_F R_F)(1 + j\omega C_S R_S)} \tag{5.9.15}$$

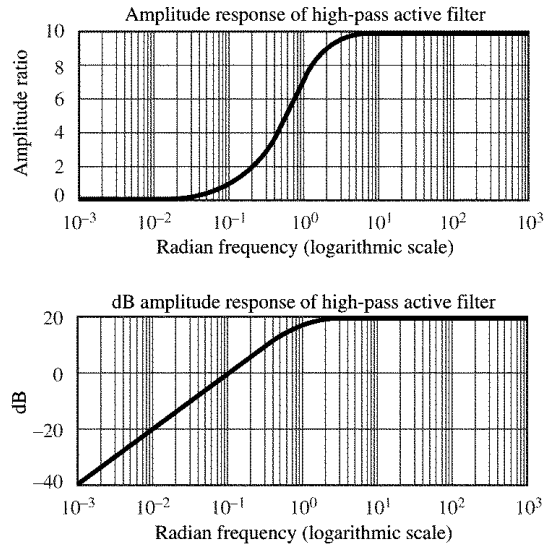

FIGURE 5.9.15 Normalized response of active high-pass filter.

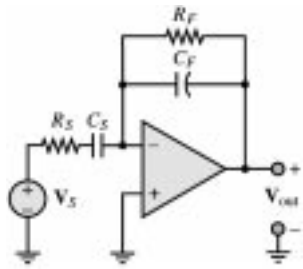

FIGURE 5.9.16 Active band-pass filter.

The form of the op-amp response we just obtained should not appear as a surprise. It is very similar (although not identical) to the product of the low-pass and high-pass responses:

$$A_{LP}(j\omega) = -\frac{R_F/R_S}{1 + j\omega C_F R_F} \tag{5.9.16}$$

$$A_{HP}(j\omega) = -\frac{j\omega C_S R_F}{1 + j\omega R_S C_S} \tag{5.9.17}$$

In particular, the denominator of $A_{BP}(j\omega)$ is exactly the product of the denominators of $A_{LP}(j\omega)$ and $A_{HP}(j\omega)$. It is particularly enlightening to rewrite $A_{LP}(j\omega)$ in a slightly different form, after making the observation that each *RC* product corresponds to some "critical" frequency:

$$\omega_1 = \frac{1}{R_F C_S} \quad \omega_{LP} = \frac{1}{R_F C_F} \quad \omega_{HP} = \frac{1}{R_S C_S} \tag{5.9.18}$$

It is easy to verify that for the case where

$$\omega_{HP} > \omega_{LP} \tag{5.9.19}$$

the response of the op-amp filter may be represented as shown in Figure 5.9.17 in both linear and dB plots (in the figure, $\omega_1 = 1$, $\omega_{HP} = 1000$, $\omega_{HP} = 10$). The dB plot is very revealing, for its shows that, in effect, the band-pass response is the graphical superposition of the low-pass and high-pass responses shown earlier. The two 3-dB (or cutoff) frequencies are the same as in $A_{LP}(j\omega)$, $1/R_FC_F$; and in $A_{HP}(j\omega)$, $1/R_SC_S$. The third frequency, $\omega_1 = 1/R_FC_S$, represents the point where the response of the filter crosses the 0-dB axis (rising slope). Since 0 dB corresponds to a gain of 1, this frequency is called the **unity gain frequency**.

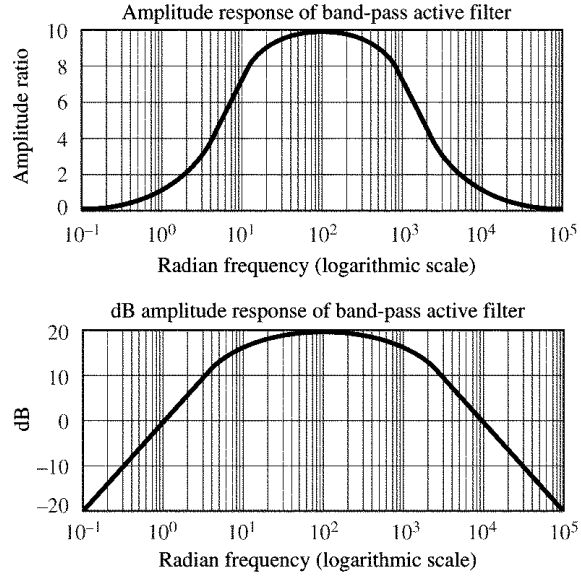

FIGURE 5.9.17 Normalized response of active band-pass filter.

The ideas developed thus far can be employed to construct more complex functions of frequency. In fact, most active filters one encounters in practical applications are based on circuits involving more than one or two energy-storage elements. By constructing suitable functions for Z_F and Z_S, it is possible to realize filters with greater frequency selectivity (i.e., sharpness of cutoff), as well as flatter band-pass or band-rejection functions (that is, filters that either allow or reject signals in a limited band of frequencies). A few simple applications are investigated in the homework problems. One remark that should be made in passing, though, pertains to the exclusive use of capacitors in the circuits analyzed thus far.

Integrator and Differentiator Circuits

The Ideal Integrator

Consider the circuit of Figure 5.9.18, where $v_s(t)$ is an arbitrary function of time (e.g., a pulse train, a triangular wave, or a square wave). The op-amp circuit shown provides an output that is proportional to the integral of $v_s(t)$.

$$v_{\text{out}} = -\frac{1}{R_SC_F}\int_{-\infty}^{t} v_S(t')\,dt' \tag{5.9.20}$$

This equation states that the output voltage is the integral of the input voltage.

There are numerous applications of the op-amp integrator, most notably the **analog computer**. The following example illustrates the operation of the op-amp integrator.

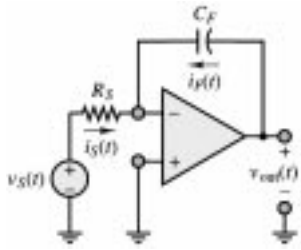

FIGURE 5.9.18 Op-amp integrator.

Example 5.9.3 Charge Amplifiers

One of the most common families of transducers for the measurement of force, pressure, and acceleration is that of **piezoelectric transducers**. These transducers contain a piezoelectric crystal, a crystal that generates an electric charge in response to deformation. Thus, if a force is applied to the crystal (leading to a displacement), a charge is generated within the crystal. If the external force generates a displacement x_i, then the transducer will generate a charge q according to the expression

$$q = K_p x_i$$

Figure 5.9.19 depicts the basic structure of the piezoelectric transducer and a simple circuit model. The model consists of a current source in parallel with a capacitor, where the current source represents the rate of change of the charge generated in response to an external force and the capacitance is a consequence of the structure of the transducer, which consists of a piezoelectric crystal (e.g., quartz or Rochelle salt) sandwiched between conducting electrodes (in effect, this is a parallel-plate capacitor).

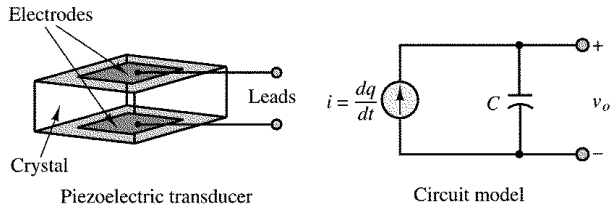

FIGURE 5.9.19 Piezolectric transducer.

Although it is possible, in principle, to employ a conventional voltage amplifier to amplify the transducer output voltage, v_o, given by

$$v_o = \frac{1}{C}\int i\,dt = \frac{1}{C}\int \frac{dq}{dt}\,dt = \frac{q}{C} = \frac{K_p x_i}{C}$$

it is often advantageous to use a **charge amplifier**. The charge amplifier is essentially an integrator circuit, as shown in Figure 5.9.20 characterized by an extremely high input impedance. The high impedance is essential; otherwise, the charge generated by the transducer would leak to ground through the input resistance of the amplifier.

Because of the high input impedance, the input current into the amplifier is negligible; further, because of the high open-loop gain of the amplifier, the inverting-terminal voltage is essentially at ground potential. Thus, *the voltage across the transducer is effectively zero*. As a consequence, to satisfy KCL, the feedback current, $i_F(t)$ must be equal and opposite to the transducer current, i:

$$i_F(t) = -i$$

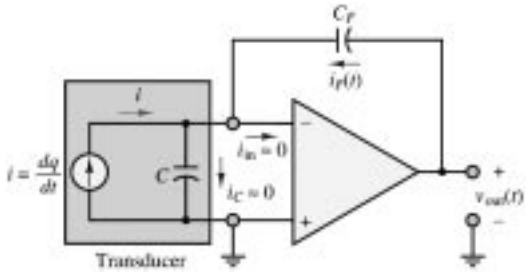

FIGURE 5.9.20 Charge amplifier.

and since

$$v_{\text{out}}(t) = \frac{1}{C_F} i_F(t)\, dt$$

it follows that the output voltage is proportional to the charge generated by the transducer, and therefore to the displacement:

$$v_{\text{out}}(t) = \frac{1}{C_F}\int -i\, dt = \frac{1}{C_F}\int -\frac{dq}{dt}\, dt = -\frac{q}{C_F} = -\frac{K_p x_i}{C_F}$$

Since the displacement is caused by an external force or pressure, this sensing principle is widely adopted in the measurement of force and pressure.

The Ideal Differentiator

Using an argument similar to that employed for the integrator, we can derive a result for the ideal differentiator circuit of Figure 5.9.21. The relationship between input and output is obtained by observing that

$$i_S(t) = C_S \frac{dv_S(t)}{dt} \tag{5.9.21}$$

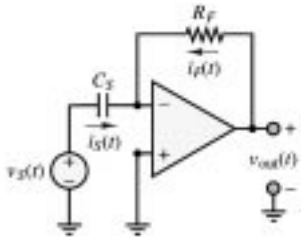

FIGURE 5.9.21 Op-amp differentiators.

and

$$i_F(t) = \frac{v_{\text{out}}(t)}{R_F} \tag{5.9.22}$$

so that the output of the differentiator circuit is proportional to the derivative of the input:

$$v_{\text{out}}(t) = -R_F C_S \frac{dv_S(t)}{dt} \tag{5.9.23}$$

Although mathematically attractive, the differentiation property of this op-amp circuit is seldom used in practice, because differentiation tends to simplify any noise that may be present in a signal.

Physical Limitations of Op-Amps

Thus far, the operational amplifier has been treated an ideal device, characterized by infinite input resistance, zero output resistance, and infinite open-loop voltage gain. Although this model is adequate to represent the behavior of the op-amp in a large number of applications, it is important to realize that practical operational amplifiers are not ideal devices, but exhibit a number of limitations that should be considered in the design of instrumentation. In particular, in dealing with relatively large voltages and currents, and in the presence of high-frequency signals, it is important to be aware of the nonideal properties of the op-amp. In the present section, we examine the principal limitations of the operational amplifier.

Voltage Supply Limits

The effect of limiting supply voltages is that amplifiers are capable of amplifying signals *only within the range of their supply voltages*;

$$V_S^- < v_{\text{out}} < V_S^+ \tag{5.9.24}$$

For most op-amps, the limit is actually approximately 1.5 V less than the supply voltages.

Frequency Response Limits

Another property of all amplifiers that may pose severe limitations to the op-amp is their finite bandwidth. We have so far assumed, in our ideal op-amp model, that the open-loop gain is a very large constant. In reality, $A_{V(OL)}$ is a function of frequency and is characterized by a low-pass response. For a typical op-amp,

$$A_{V(OL)}(j\omega) = \frac{A_0}{1 + j\omega/\omega_0} \tag{5.9.25}$$

The finite bandwidth of the practical op-amp results in a fixed **gain-bandwidth product** for any given amplifier. The effect of a constant gain-bandwidth product is that as the closed-loop gain of the amplifier is increased, its 3-dB bandwidth is proportionally reduced, until, in the limit, if the amplifier were used in the open-loop mode, its gain would be equal to A_0 and its 3-dB bandwidth would be equal to ω_0. Thus, *the product of gain and bandwidth in any given op-amp is constant*. That is,

$$A_0 \times \omega_0 = A_1 \times \omega_1 = A_2 \times \omega_2 = K \tag{5.9.26}$$

as is shown in Figure 5.9.22.

Input Offset Voltage

Another limitation of practical op-amps results because even in the absence of any external inputs, it is possible that an **offset voltage** will be present at the input of an op-amp. This voltage is usually denoted by $\pm V_{os}$ and it is caused by mismatches in the internal circuitry of the op-amp. The offset voltage appears as a differential input voltage between the inverting and noninverting input terminals. The presence of an additional input voltage will cause a DC bias error in the amplifier output, which can be modeled as shown in Figure 5.9.23.

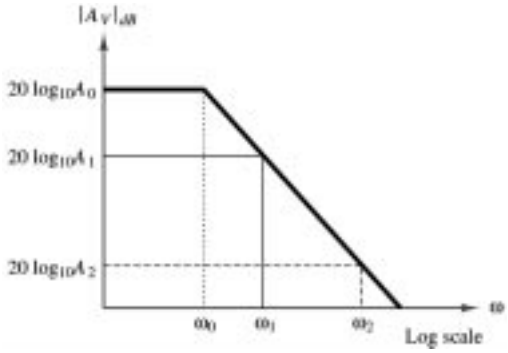

FIGURE 5.9.22

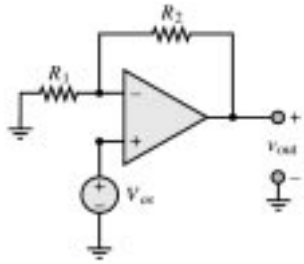

FIGURE 5.9.23 Op-amp input offset voltage.

Input Bias Currents

Another nonideal characteristic of op-amps results from the presence of small input bias currents at the inverting and noninverting terminals. Once again, these are due to the internal construction of the input stage of an operational amplifier. Figure 5.9.24 illustrates the presence of nonzero input bias currents (I_B) going into an op-amp.

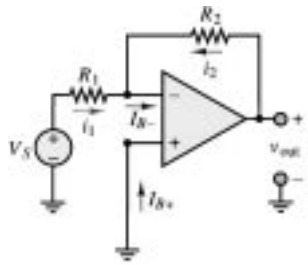

FIGURE 5.9.24

Typical values of I_B depend on the semiconductor technology employed in the construction of the op-amp. Op-amps with bipolar transistor input stages may see input bias currents as large as 1 μA, while for FET input devices, the input bias currents are less than 1 nA. Since these currents depend on the internal design of the op-amp, they are not necessarily equal. One often designates the **input offset current** I_{os} as

$$I_{os} = I_{B+} - I_{B-} \tag{5.9.27}$$

The latter parameter is sometimes more convenient from the standpoint of analysis.

Output Offset Adjustment

Both the offset voltage and the input offset current contribute to an output offset voltage $V_{\text{out},os}$. Some op-amps provide a means for minimizing $V_{\text{out},os}$. For example, the μA741 op-amp provides a connection for this procedure. Figure 5.9.25 shows a typical pin configuration for an op-amp in an eight-pin dual-

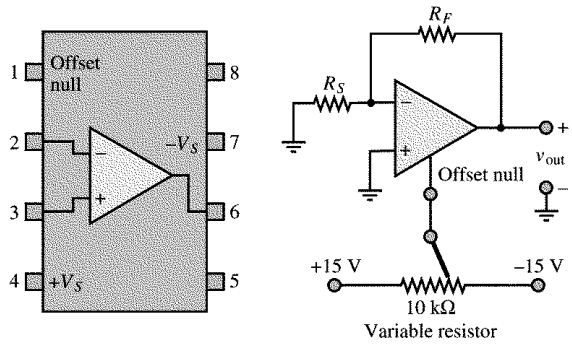

FIGURE 5.9.25 Output off-set voltage adjustment.

in-line package (DIP) and the circuit used for nulling the output offset voltage. The variable resistor is adjusted until v_{out} reaches a minimum (ideally, 0 V). Nulling the output voltage in this manner removes the effect of both input offset voltage and current on the output.

Slew Rate Limit

Another important restriction in the performance of a practical op-amp is associated with rapid changes in voltage. The op-amp can produce only a finite rate of change at its output. This limit rate is called the **slew rate**. Consider an ideal step input, where at $t = 0$ the input voltage is switched from zero to V volts. Then we would expect the output to switch from 0 to $A \cdot V$ volts, where A is the amplifier gain. However, $v_{out}(t)$ can change at only a finite rate; thus,

$$\left|\frac{dv_{out}(t)}{dt}\right|_{max} = S_0 = \text{Slew rate} \tag{5.9.28}$$

Figure 5.9.26 shows the response of an op-amp to an ideal step change in input voltage, Here S_0, the slope of $v_{out}(t)$, represents the slew rate.

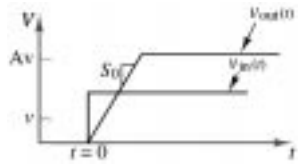

FIGURE 5.9.26 Slew rate limit in op-amps.

Short-Circuit Output Current

Recall the model for the op-amp, which represented the internal circuits of the op-amp in terms of an equivalent input resistance, R_{in}, and a controlled voltage source, $A_V\, v_{in}$. In practice, the internal source is not ideal, because it cannot provide an infinite amount of current (either to the load or to the feedback connection, or both). The immediate consequence of this nonideal op-amp characteristic is that the maximum output current of the amplifier is limited by the so-called short-circuit output current, I_{SC}:

$$\left|I_{out}\right| < I_{SC} \tag{5.9.29}$$

To further explain this point, consider that the op-amp needs to provide current to the feedback path (in order to "zero" the voltage differential at the input) and to whatever load resistance, R_L, may be connected to the output. Figure 5.9.27 illustrates this idea for the case of an inverting amplifier, where I_{SC} is the load current that would be provided to a short-circuit load ($R_L = 0$).

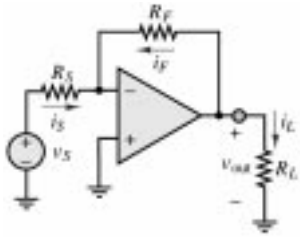

FIGURE 5.9.27

Common-Mode Rejection Ratio (CMRR)

Example 5.9.2 introduced the notion of differential-mode and common-mode signals. If we define A_{dm} as the **differential-mode gain** and A_{cm} as the **common-mode gain** of the op-amp, the output of an op-amp can then be expressed as follows:

$$v_{\text{out}} = A_{dm}\left(v_2 - v_1\right) + A_{cm}\left(\frac{v_2 - v_1}{2}\right) \tag{5.9.30}$$

Under ideal conditions, A_{cm} should be exactly zero, since the differential amplifier should completely reject common-mode signals. The departure from this ideal condition is a figure of merit for a differential amplifier and is measured by defining a quantity called the **common-mode rejection ratio** (CMRR). The CMRR is defined as the ratio of the differential-mode gain to the common-mode gain and should ideally be infinite:

$$\text{CMRR} = \frac{A_{dm}}{A_{cm}}$$

The CMRR is often expressed in units of decibels (dB).

5.10 Digital Circuits

The objective of this section is to discuss the essential features of digital logic circuits, which are at the heart of digital computers.

Analog and Digital Signals

One of the fundamental distinctions in the study of electronic circuits (and in the analysis of any signals derived from physical measurements) is that between analog and digital signals. As discussed in the preceding chapter, an **analog signal** is an electrical signal whose value varies in analogy with a physical quantity (e.g., temperature, force, or acceleration). For example, a voltage proportional to a measured variable pressure or to a vibration naturally varies in an analog fashion. Figure 5.10.1 depicts an arbitrary analog function of time, $f(t)$. We note immediately that for each value of time, t, $f(t)$ can take one value among any of the values in a given range. For example, in the case of the output voltage of an op-amp, we expect the signal to take any value between $+V_{sat}$ and $-V_{sat}$, where V_{sat} is the supply-imposed saturation voltage.

FIGURE 5.10.1 Analog signal.

A **digital signal**, on the other hand, can take only a *finite number of values*. This is an extremely important distinction, as will be shown shortly. An example of a digital signal is a signal that allows display of a temperature measurement on a digital readout. Let us hypothesize that the digital readout is three digits long and can display numbers from 0 to 100, and let us assume that the temperature sensor is correctly calibrated to measure temperatures from 0 to 100°F. Further, the output of the sensor ranges from 0 to 5 V, where 0 V corresponds to 0°F and 5 V to 100°F. Therefore, the calibration constant of the sensor is $k_T = (100° - 0°)/(5 - 0) = 20°/V$. Clearly, the output of the sensor is an analog signal; however, the display can show only a finite number of readouts (101, to be precise). Because the display itself can only take a value out of a discrete set of states — the integers from 0 to 100 — we call it a digital display, indicating that the variable displayed is expressed in digital form.

Now, each temperature on the display corresponds to a *range of voltages:* each digit on the display represents one hundredth of the 5-V range of the sensor, or 0.05 V = 50 m V. Thus, the display will read 0 if the sensor voltage is between 0 and 49 mV, 1 if it is between 50 and 99 mV, and so on. Figure 5.10.2 depicts the staircase function relationship between the analog voltage and the digital readout. This **quantization** of the sensor output voltage is, in effect, an approximation. If one wished to know the temperature with greater precision, a greater number of display digits could be employed.

The most common digital signals are binary signals. A **binary signal** is a signal that can take only one of two discrete values and is therefore characterized by transitions between two states. Figure 5.10.3 displays a typical binary signal. In binary arithmetic (which we discuss in the next section), the two discrete values f_1 and f_0 are represented by the numbers 1 and 0. In binary voltage waveforms, these values are represented by two voltage levels. For example, in the TTL convention, these values are (nominally) 5 and 0 V, respectively; in CMOS circuits, these values can vary substantially. Other conventions are also used, including reversing the assignment — for example, by letting a 0-V level represent a logic 1 and a 5-V level represent a logic 0. Note that in a binary waveform, knowledge of the transition between one stage and another (e.g., from f_0 to f_1 at $t = t_2$) is equivalent to knowledge of

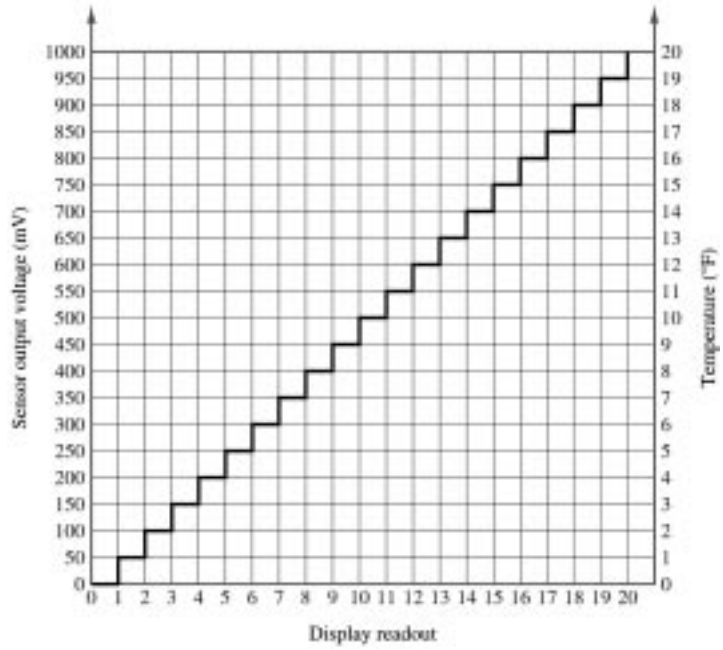

FIGURE 5.10.2 Digital representation of an analog signal.

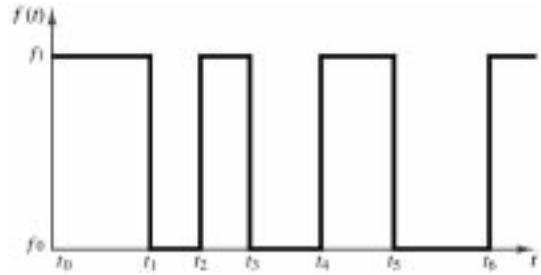

FIGURE 5.10.3 A binary signal.

the state. Thus, digital logic circuits can operate by detecting transitions between voltage levels. The transitions are often called **edges** and can be positive (f_0 to f_1) or negative (f_1 to f_0). Virtually all of the signals handled by a computer are binary. From here on, whenever we speak of digital signals, you may assume that the text is referring to signals of the binary type, unless otherwise indicated.

The Binary Number System

The binary number system is a natural choice for representing the behavior of circuits that operate in one of two states (on or off, 1 or 0, or the like). The diode and transistor gates and switches studied in Section 5.7 fall in this category. Table 5.10.1 shows the correspondence between decimal and binary number systems for decimal numbers up to 16.

Table 5.10.1 shows that it takes four binary digits, also called **bits**, to represent the decimal numbers up to 15. Usually, the rightmost bit is called the **least significant bit**, or LSB, and the leftmost bit is called the **most significant bit**, or MSB. Since binary numbers clearly require a larger number of digits than decimal numbers, the digits are usually grouped in sets of four, eight, or sixteen. Four bits are usually termed a **nibble**, eight bits are called a **byte**, and sixteen bits (or two bytes) form a **word**.

TABLE 5.10.1 Conversion from Decimal to Binary

Addition and Subtraction

The operations of addition and subtraction are based on the simple rules shown in Table 5.10.2. Figure 5.10.4 provides three examples.

TABLE 5.10.2 Rules for Addition

FIGURE 5.10.4 Examples of binary addition.

The procedure for subtracting binary numbers is based on the rules of Table 5.10.3. A few examples of binary subtraction are given in Figure 5.10.5, with their decimal counterparts.

TABLE 5.10.3 Rules for Subtraction

0 – 0 = 0
1 – 0 = 1
1 – 1 = 0
0 – 1 = 1 (with a borrow of 1)

Multiplication and Division

Whereas in the decimal system the multiplication table consists of $10^2 = 100$ entries, in the binary system we only have $2^2 = 4$ entries. Table 5.10.4 represents the complete multiplication table for the binary number system.

Decimal	Binary	Decimal	Binary	Decimal	Binary
9	1001	16	10000	6.25	110.01
−5	−101	−3	−11	−4.50	−100.10
4	0100	13	01101	1.75	001.11

TABLE 5.10.4 Rules for Multiplication

$0 \times 0 = 0$
$0 \times 1 = 0$
$1 \times 0 = 0$
$1 \times 1 = 1$

Division in the binary system is also based on rules analogous to those of the decimal system, with the two basic laws given in Table 5.10.5. Once again, we need be concerned with only two cases, and just as in the decimal system, division by zero is not contemplated.

TABLE 5.10.5 Rules for Division

$0 \div 1 = 0$
$1 \div 1 = 1$

Conversion from Decimal to Binary

The conversion of a decimal number to its binary equivalent is performed by successive division of the decimal number by 2, checking for the remainder each time. Figure 5.10.6 illustrates this idea with an example.

Remainder
$49 \div 2 = 24 + 1$
$24 \div 2 = 12 + 0$
$12 \div 2 = 6 + 0$
$6 \div 2 = 3 + 0$
$3 \div 2 = 1 + 1$
$1 \div 2 = 0 + 1$
$49_{10} = 110001_2$

FIGURE 5.10.6 Example of conversion from decimal to binary.

The same technique can be used for converting decimal fractional numbers to their binary form, provided that the whole number is separated from the fractional part and each is converted to binary form (separately), with the results added at the end. Figure 5.10.7 outlines this procedure by converting the number 37.53 to binary form.

Complements and Negative Numbers

To simplify the operation of subtraction in digital computers, **complements** are used almost exclusively. In practice, this corresponds to replacing the operation $X - Y$ with operation $X + (-Y)$. This procedure results in considerable simplification, since the computer hardware need include only adding circuitry. Two types of complements are used with binary numbers: the **one's complement** and the **two's complement**.

The one's complement of an n-bit binary number is obtained by subtracting the number itself from $(2^n - 1)$. Two examples are as follows:

Remainder
$37 \div 2 = 18 + 1$
$18 \div 2 = 9 + 0$
$9 \div 2 = 4 + 1$
$4 \div 2 = 2 + 0$
$2 \div 2 = 1 + 0$
$1 \div 2 = 0 + 1$
$37_{10} = 100101_2$

$2 \times 0.53 = 1.06 \rightarrow 1$
$2 \times 0.06 = 0.12 \rightarrow 0$
$2 \times 0.12 = 0.24 \rightarrow 0$
$2 \times 0.24 = 0.48 \rightarrow 0$
$2 \times 0.48 = 0.96 \rightarrow 0$
$2 \times 0.96 = 1.92 \rightarrow 1$
$2 \times 0.92 = 1.84 \rightarrow 1$
$2 \times 0.84 = 1.68 \rightarrow 1$
$2 \times 0.68 = 1.36 \rightarrow 1$
$2 \times 0.36 = 0.72 \rightarrow 0$
$2 \times 0.72 = 1.44 \rightarrow 1$
$0.53_{10} = 0.10000111101$

FIGURE 5.10.7 Conversion from decimal to binary.

$$a = 0101$$

$$\text{One's complement of } a = \left(2^4 - 1\right) - a$$

$$= (1111) - (0101)$$

$$= 1010$$

$$b = 101101$$

$$\text{One's complement of } b = \left(2^6 - 1\right) - b$$

$$= (111111) - (101101)$$

$$= 010010$$

The two's complement of n-bit binary number is obtained by subtracting the number itself from 2^n. Two's complements of the same numbers a and b used in the preceding illustration are computed as follows:

$$a = 0101$$

$$\text{Two's complement of } a = 2^4 - a$$

$$= (10000) - (0101)$$

$$= 1011$$

$$b = 101101$$

$$\text{Two's complement of } b = 2^6 - b$$

$$= (1000000) - (101101)$$

$$= 010011$$

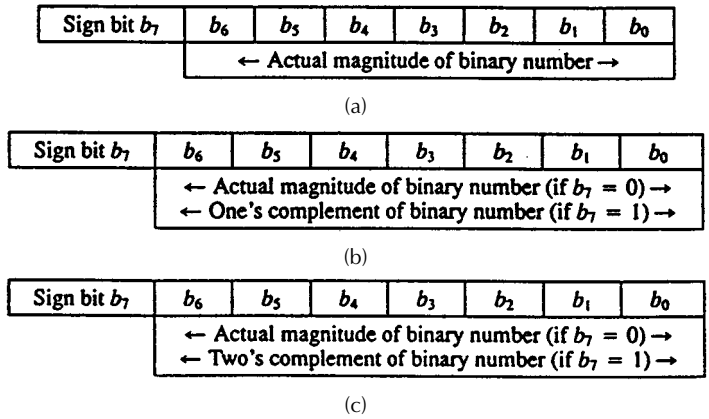

FIGURE 5.10.8 (a) Eight-bit sign-magnitude binary number; (b) eight-bit one's complement binary number; (c) eight-bit two's complement binary number.

Different conventions exist in the binary system to represent whether a number is negative or positive. These are summarized in Figure 5.10.8.

The Hexadecimal System

It should be apparent by now that representing numbers in base 2 and base 10 systems is purely a matter of convenience, given a specific application. Another base frequently used is the **hexadecimal system**, a direct derivation of the binary number system. In the hexadecimal (or hex) code, the bits in a binary number are subdivided into groups of four. Since there are 16 possible combinations for a four-bit number, the natural digits in the decimal system (0 through 9) are insufficient to represent a hex digit. To solve this problem, the first six letters of the alphabet are used, as shown in Table 5.10.6. Thus, in hex code, an eight-bit word corresponds to just two digits; for example:

$$1010\ 0111_2 = A7_{16}$$

$$0010\ 1001_2 = 29_{16}$$

Binary Codes

In this subsection, we describe two common binary codes that are often used for practical reasons. The first is a method of representing decimal numbers in digital logic circuits that is referred to as **binary-coded decimal**, or BCD, **representation**. In effect, the simplest BCD representation is just a sequence of four-bit binary numbers that stops after the first ten entries, as shown in Table 5.10.7. There are also other BCD codes, all reflecting the same principle: that each decimal digit is represented by a fixed-length binary word. One should realize that although this method is attractive because of its direct correspondence with the decimal system, it is not efficient. Consider, for example, the decimal number 68. Its binary representation by direct conversion is the seven-bit number 1000100. On the other hand, the corresponding BCD representation would require eight bits:

$$68_{10} = 01101000_{\text{BCD}}$$

TABLE 5.10.7 BCD Code

0	0000

9	1001

Another code that finds many applications is the **Gray code**. This is simply a reshuffling of the binary code with the property that any two consecutive numbers differ only by one bit. Table 5.10.8 illustrates the three-bit Gray code. The Gray code can be very useful in practical applications, because in counting up or down according to this code, the binary representation of a number changes only one bit at a time.

Boolean Algebra

The mathematics associated with the binary number system (and with the more general field of logic) is called *Boolean algebra*. The variables in a Boolean, or logic, expression can take only one of two values, usually represented by the numbers 0 and 1. These variables are sometimes referred to as true (1) and false (0). This convention is normally referred to as **positive logic**. There is also a **negative logic** convention in which the roles of logic 1 and logic 0 are reversed. In this book we shall employ only positive logic.

Analysis of **logic functions**, that is, functions of logical (Boolean) variables, can be carried out in terms of truth tables. A truth table is a listing of all the possible values each of the Boolean variables

can take, and of the corresponding value of the desired function. In the following paragraphs we shall define the basic logic functions upon which Boolean algebra is founded, and we shall describe each in terms of a set of rules and a truth table; in addition, we shall also introduce **logic gates**. Logic gates are physical devices that can be used to implement logic functions. Elementary logic gates were introduced in Section 5.7.

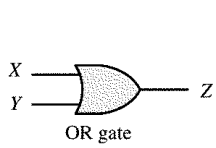
AND and OR Gates

The basis of **Boolean algebra** lies in the operations of **logical addition**, or the **OR** operation; and **logical multiplication**, or the **AND** operation. Both of these find a correspondence in simple logic gates, as we shall presently illustrate. Logical addition, although represented by the symbol +, differs from conventional algebraic addition, as shown in the last rule listed in Table 5.10.9. Note that this rule also differs from the last rule of binary addition studied in the previous section. Logical addition can be represented by the logic gate called an **OR gate**, whose symbol and whose inputs and outputs are shown in Figure 5.10.9. The OR gate represents the following logical statement:

TABLE 5.10.9 Rules for Logical Addition (OR)

$0 + 0 = 0$
$0 + 1 = 1$
$1 + 0 = 1$
$1 + 1 = 1$

If either X or Y is true (1), then Z is true (1) (5.10.1)



X	Y	Z
0	0	0
0	1	1
1	0	1
1	1	1

Truth table

FIGURE 5.10.9 Logical addition and the OR gate.

This rule is embodied in the electronic gates discussed in Chapter 9, in which a logic 1 corresponds, say, to a 5-V signal and a logic 0 to a 0-V signal.

Logical multiplication is denoted by the center dot (·) and is defined by the rules of Table 5.10.10. Figure 5.10.10 depicts the **AND gate**, which corresponds to this operation. The AND gate corresponds to the following logical statement:

TABLE 5.10.10 Rules for Logical Multiplication (AND)

$0 \cdot 0 = 0$
$0 \cdot 1 = 0$
$1 \cdot 0 = 0$
$1 \cdot 1 = 1$

If both X and Y are true (1), then Z is true (1) (5.10.2)

One can easily envision logic gates (AND and OR) with an arbitrary number of inputs; three- and four-input gates are not uncommon.

The rules that define a logic function are often represented in tabular form by means of a **truth table**. Truth tables for the AND and OR gates are shown in Figures 5.10.9 and 5.10.10. A truth table is nothing more than a tabular summary of all of the possible outputs of a logic gate, given all the possible input

Truth table

FIGURE 5.10.10 Logical multiplication and the AND gate.

values. If the number of inputs is 3, the number of possible combinations grows from 4 to 8, but the basic idea is unchanged. Truth tables are very useful in defining logic functions. A typical logic design problem might specify requirements such as "the output Z shall be logic 1 only when the condition (X = 1 AND Y = 1) OR (W = 1) occurs, and shall be logic 0 otherwise." The truth table for this particular logic function is shown in Figure 5.10.11 as an illustration. The design consists, then, of determining the combination of logic gates that exactly implements the required logic function. Truth tables can greatly simplify this procedure.

Logic gate realization of the statement "the output Z shall be logic 1 only when the condition (X = 1 AND Y = 1) OR (W = 1) occurs, and shall be logic 0 otherwise."

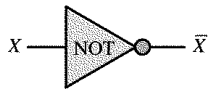
Solution using logic gates

FIGURE 5.10.11 Example of logic function implementation with logic gates.

The AND and OR gates form the basis of all logic design in conjunction with the **NOT gate**. The NOT gate is essentially an inverter, and it provides the complement of the logic variable connected to its input. The complement of a logic variable X is denoted by $\overline{X}$. The NOT gate has only one input, as shown in Figure 5.10.12



NOT gate

X	$\overline{X}$
1	0
0	1

Truth table for NOT gate

FIGURE 5.10.12 Complements and the NOT gate.

To illustrate the use of the NOT gate, or inverter, we return to the design example of Figure 5.10.11, where we required that the output of a logic circuit be Z = 1 only if X = 0 AND Y = 1 OR if W = 1. We recognize that except for the requirement X = 0, this problem would be identical if we stated it as follows: "The output Z shall be logic 1 only when the condition ($\overline{X}$ = 1 AND Y = 1) OR (W = 1) occurs, and shall be logic 0 otherwise." If we use an inverter to convert X to $\overline{X}$, we see that the required

condition becomes $\overline{X}$ = 1 AND Y = 1) OR (W = 1). The formal solution to this elementary design exercise is illustrated in Figure 5.10.13.

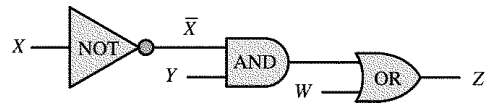
(Required logic function)

Truth table



Solution using logic gates

FIGURE 5.10.13 Solution of a logic problem using logic gates.

In the course of the discussion of logic gates, extensive use will be made of truth tables to evaluate logic expressions. A set of basic rules will facilitate this task. Table 5.10.11 lists some of the rules of Boolean algebra:

TABLE 5.10.11 Rules of Boolean Algebra

1.	$0 + X = X$	
2.	$1 + X = 1$	
3.	$X + X = X$	
4.	$X + \overline{X} = 1$	
5.	$0 \cdot X = 0$	
6.	$1 \cdot X = X$	
7.	$X \cdot X = X$	
8.	$X \cdot \overline{X} = 0$	
9.	$\overline{\overline{X}} = X$	
10.	$X + Y = Y + X$	Commutative law
11.	$X \cdot Y = Y \cdot X$	
12.	$X + (X + Z) = (X + Y) + Z$	Associative law
13.	$X \cdot (Y \cdot Z) = (X \cdot Y) \cdot Z$	
14.	$X \cdot (Y + Z) = X \cdot Y + X \cdot Z$	Distributive law
15.	$X + X \cdot Z = X$	Absorption law
16.	$X \cdot (X + Y) = X$	
17.	$(X + Y) \cdot (X + Z) = X + Y \cdot Z$	
18.	$X + \overline{X} \cdot Y = X + Y$	
19.	$X \cdot Y + Y \cdot Z + \overline{X} \cdot Z = X \cdot Y + \overline{X} \cdot Z$	

To complete the introductory material on Boolean algebra, a few paragraphs need to be devoted to two very important theorems, called **De Morgan's theorems**. These are stated here in the form of logic functions:

$$\left(\overline{X + Y}\right) = \overline{X} \cdot \overline{Y} \tag{5.10.3}$$

$$\left(\overline{X \cdot Y}\right) = \overline{X} + \overline{Y} \tag{5.10.4}$$

These two laws state a very important property of logic functions: any logic function can be implemented using only OR and NOT gates, or using only AND and NOT gates.

De Morgan's laws can easily be visualized in term of logic gates, as shown in Figure 5.10.14. The associated truth tables are proof of these theorems.

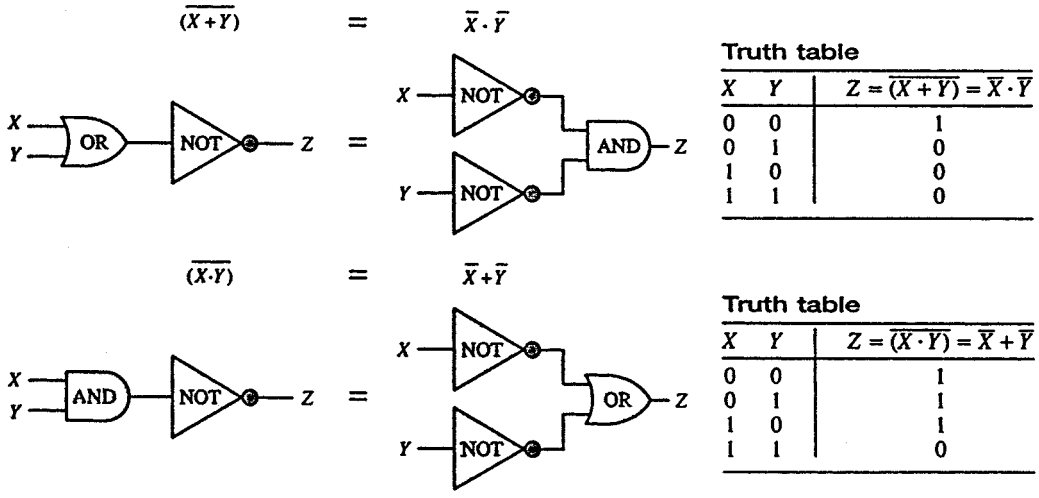


FIGURE 5.10.14 De Morgan's laws.

The importance of De Morgan's laws is in the statement of the **duality** that exists between AND and OR operations: any function can be realized by just one of the two basic operations, plus the complement operation. This gives rise to two families of logic functions: **sums of products** and **products of sums**, as shown in Figure 5.10.15. Any logical expression can be reduced to either one of these two forms. Although the two forms are equivalent, it may well be true that one of the two has a simpler implementation (fewer gates). Example 5.10.1 illustrates this point.

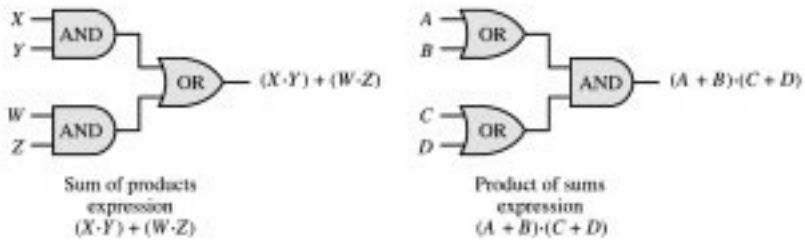

FIGURE 5.10.15 Sun-of-products and product-of-sums logic functions.

Example 5.10.1

Use De Morgan's theorem to realize the function $y = A + (B \cdot C)$ as a product-of-sums expression, and implement it using AND, OR, and NOT gates.

Solution. Knowing that $\overline{\overline{y}} = y$, we can apply the first of De Morgan's laws to the complement of the function y to obtain the expression

$$\overline{y} = \overline{A + (B \cdot C)} = \overline{A} \cdot \left(\overline{B \cdot C}\right) = \overline{A} \cdot \left(\overline{B} + \overline{C}\right)$$

Thus,

$$\overline{y} = y = \overline{A} \cdot \left(\overline{B} + \overline{C}\right)$$

Using logic gates, we can then implement the function as shown in Figure 5.10.16

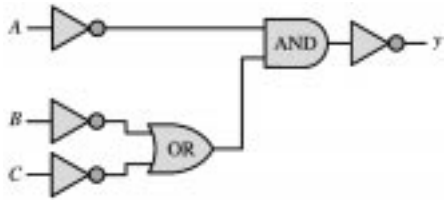

FIGURE 5.10.16 Figure for Example 5.10.1.

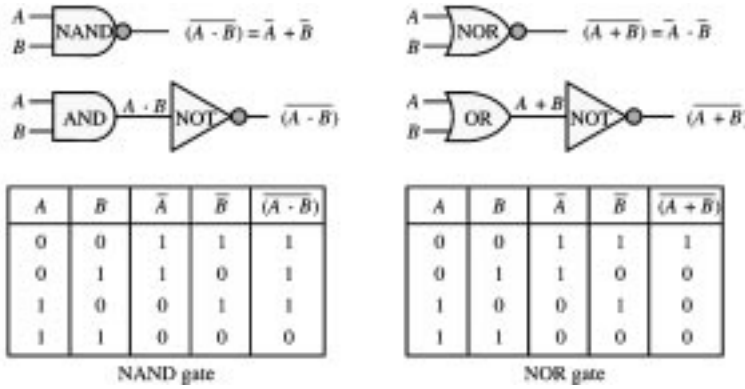
NAND and NOR Gates

In addition to the AND and OR gates we have just analyzed, the complementary forms of these gates, called NAND and NOR, are very commonly used in practice. In fact, NAND and NOR gates form the basis of most practical logic circuits. Figure 5.10.17 depicts these two gates and illustrates how they can be easily interpreted in terms of AND, OR, and NOT gates by virtue of De Morgan's laws. You can readily verify that the logic function implemented by the NAND and NOR gates corresponds, respectively, to AND and OR gates followed by an inverter. It is very important to note that, by De Morgan's laws, the NAND gate performs a *logical addition* on the *complements* of the inputs. while the NOR gate performs a *logical multiplication* on the *complements* of the inputs. Functionally, then, any logic function could be implemented with either NOR or NAND gates only.



A	B	$\overline{A}$	$\overline{B}$	$\overline{(A \cdot B)}$
0	0	1	1	1
0	1	1	0	1
1	0	0	1	1
1	1	0	0	0

NAND gate

A	B	$\overline{A}$	$\overline{B}$	$\overline{(A + B)}$
0	0	1	1	1
0	1	1	0	0
1	0	0	1	0
1	1	0	0	0

NOR gate

FIGURE 5.10.17 Equivalence of NAND and NOR gates with AND and OR gates.

In the next section we shall learn how to systematically approach the design of logic functions. First, we provide a few examples to illustrate logic design with NAND and NOR gates.

Example 5.10.2

Realize the following function using only NAND and NOR gates:

$$y = \overline{\left(\overline{A \cdot B}\right) + C}$$

Solution. Since the term in parentheses appears as a complement product, it can be obtained by means of a NAND gate. Further, once the function $\overline{(A \cdot B)}$ has been realized, we can see that y is the

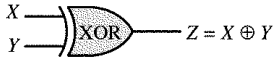
complemented sum of two terms — that is, it can be obtained directly with a NOR gate. The resulting logic circuit is shown in Figure 5.10.18.

Can you find another solution to this problem that employs only two gates?

FIGURE 5.10.18 Figure for Example 5.10.2.

The XOR (Exclusive OR) Gate

It is rather common practice for a manufacturer of integrated circuits to provide common combinations of logic circuits in a single integrated circuit package. An example of this idea is provided by the **exclusive OR** (XOR) **gate**, which provides a logic function similar, but not identical, to the OR gate we have already studied. The XOR gate acts as an OR gate, except when its inputs are all logic 1s; in this case, the output is a logic 0 (thus the term *exclusive)*. Figure 5.10.19 shows the logic circuit symbol adopted for this gate, and the corresponding truth table. The logic function implemented by the XOR gate is the following: "either *X* or *Y*, but not both." This description can be extended to an arbitrary number of inputs.



X	Y	Z
0	0	0
0	1	1
1	0	1
1	1	0

Truth table

FIGURE 5.10.19 XOR gate.

The symbol adopted for the exclusive OR operation is ⊕, and so we shall write

$$Z = X \oplus Y$$

to denote this logic operation. The XOR gate can be obtained by a combination of the basic gates we are already familiar with. For example, if we observe that the XOR function corresponds to $Z = X \oplus Y = (X + Y) \cdot X \cdot \overline{(X + Y)}$, we can realize the XOR gate by means of the circuit shown in Figure 5.10.20.

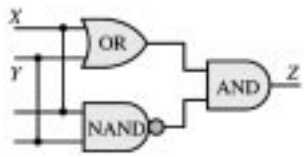


FIGURE 5.10.20 Realization of an XOR gate.

Karnaugh Maps and Logic Design

In examining the design of logic functions by means of logic gates, we have discovered that more than one solution is usually available for the implementation of a given logic expression. It should also be clear by now that some combinations of gates can implement a given function more efficiently than others. How can we be assured of having chosen the most efficient realization? Fortunately, there is a procedure that utilizes a map describing all possible combinations of the variables present in the logic function of interest. This map is called a **Karnaugh map**, after its inventor. Figure 5.10.21 depicts the appearance of Karnaugh maps for two-, three-, and four-variable expressions in two different forms. As can be seen, the row and column assignments for two or more variables are arranged so that all adjacent terms change by only one bit. For example, in the three- or four-variable map, the columns next to

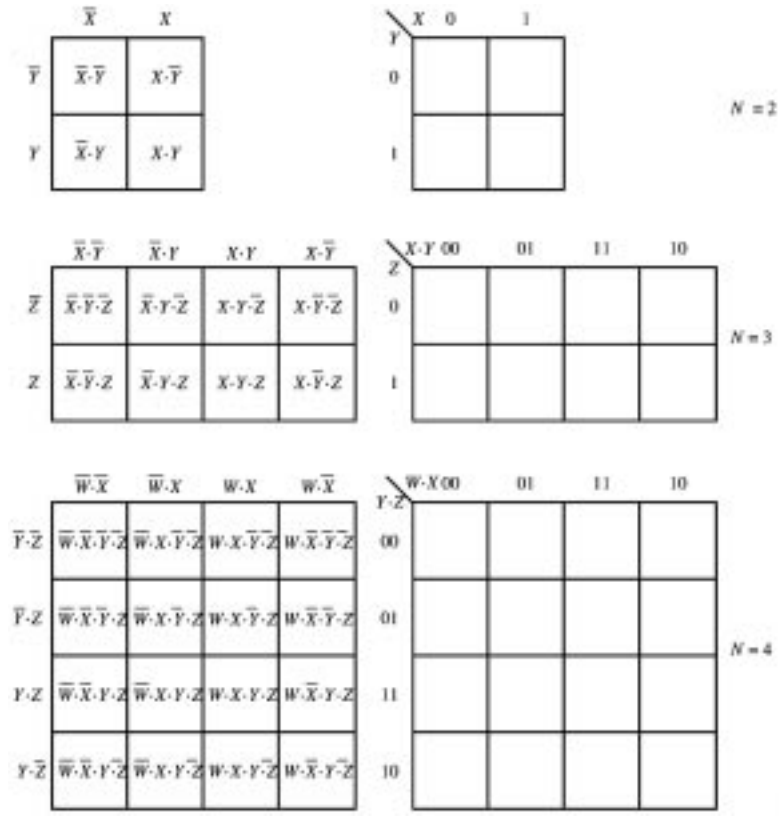

FIGURE 5.10.21 Two-, three-, and four-variable Karnaugh maps.

column 01 are columns 00 and 10. Also note that each map consists of 2^N **cells**, where N is the number of logic variables.

Each cell in a Karnaugh map contains a **minterm**, that is, a product of the N variables that appear in our logic expression (in either uncomplemented or complemented form). For example, for the case of three variables ($N = 3$), there are $2^3 = 8$ such combination, or minterms: $\overline{X} \cdot \overline{Y} \cdot \overline{Z}$, $\overline{X} \cdot \overline{Y} \cdot Z$, $\overline{X} \cdot Y \cdot \overline{Z}$, $\overline{X} \cdot Y \cdot Z$, $X \cdot \overline{Y} \cdot \overline{Z}$, $X \cdot \overline{Y} \cdot Z$, $X \cdot Y \cdot \overline{Z}$, and $X \cdot Y \cdot Z$. The content of each cell — that is, the minterm — is the product of the variables appearing at the corresponding vertical and horizontal coordinates. For example, in the three-variable map, $X \cdot Y \cdot \overline{Z}$ appears at the intersection of $X \cdot Y$ and $\overline{Z}$. The map is filled by placing a value of 1 for any combination of variables for which the desired output is a 1. For example, consider the function of three variables for which we desire to have an output of 1 whenever the variables X, Y, and Z have the following values:

$$\begin{array}{lll} X = 0 & Y = 1 & Z = 0 \\ X = 0 & Y = 1 & Z = 1 \\ X = 1 & Y = 1 & Z = 0 \\ X = 1 & Y = 1 & Z = 1 \end{array}$$

The same truth table is shown in Figure 5.10.22 together with the corresponding Karnaugh map.

The Karnaugh map provides an immediate view of the values of the function in graphical form. Further, the arrangement of the cells in the Karnaugh map is such that any two adjacent cells contain minterms that vary in only one variable. This property, as will be verified shortly, is quite useful in the design of logic functions by means of logic gates, especially if we consider the map to be continuously

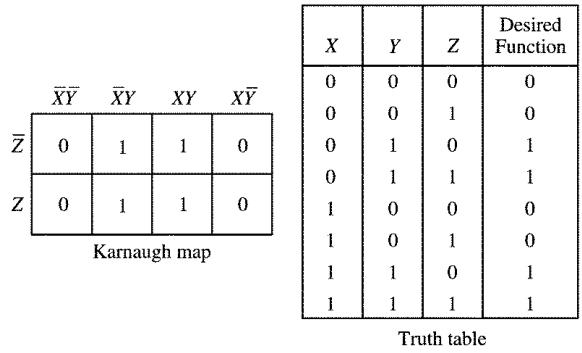

FIGURE 5.10.22 Truth table and Karnaugh map representations of a logic function.

wrapping around itself, as if the top and bottom, and right and left edges were touching each other. For the three-variable map given in Figure 5.10.21, for example, the cell $X \cdot \overline{Y} \cdot \overline{Z}$ is adjacent to $\overline{X} \cdot \overline{Y} \cdot \overline{Z}$ if we "roll" the map so that the right edge touches the left. Note that these two cells differ only in the variable X, a property we earlier claimed adjacent cells have.

Shown in Figure 5.10.23 is a more complex, four-variable logic function which will serve as an example in explaining how Karnaugh maps can be used directly to implement a logic function. First, we define a subcube as a set of 2^m adjacent cells, for $m = 1, 2, 3, \ldots, N$. Thus, a subcube can consist of 1, 2, 4, 8, 16, 32, … cells. All possible subcubes for the four-variable map of Figure 5.10.23 are shown in Figure 5.10.24. Note that there are no four-cell subcubes in this particular case. Note also that there is some overlap between subcubes.

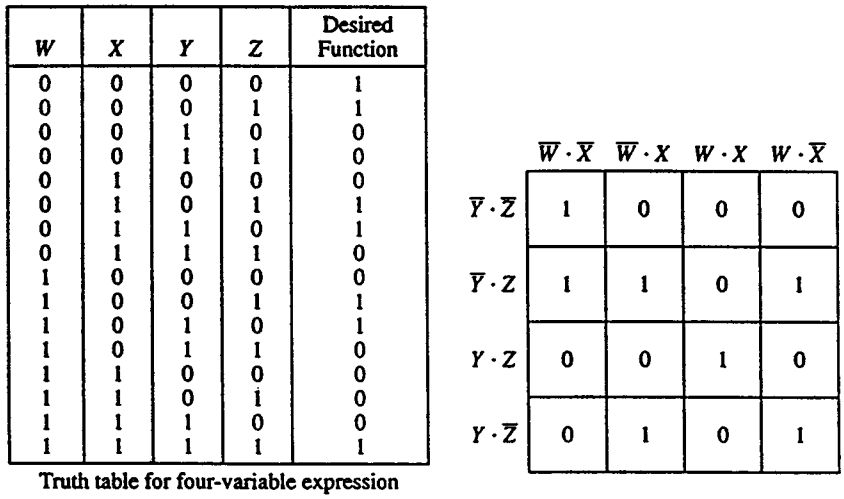

FIGURE 5.10.23 Karnaugh map for a four-variable expression.

Sum-of-Products Realizations

Although not explicitly stated, the logic functions of the preceding section were all in sum-of-products form. As you know, it is also possible to realize logic functions in product-of-sums form. This section discusses the implementation of logic functions in sum-of-products form and gives a set of design rules. The next section will do the same for product-of-sums form logical expressions. The following rules are a useful aid in determining the minimal sum-of-products expression:

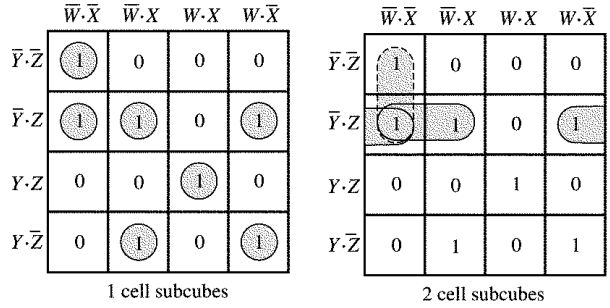

FIGURE 5.10.24 One- and two-cell subcubes for the Karnaugh map of Figure 5.10.23.

1. Begin with isolated cells. These must be used as they are, since no simplification is possible.
2. Find all cells that are adjacent to only one other cell, forming two-cell subcubes.
3. Find cells that form four-cell subcubes, eight-cell subcubes, and so forth.
4. The minimal expression is formed by the collection of the *smallest number of maximal subcubes.*

The following examples illustrate the application of these principles to a variety of problems.

Product-of-Sums Realizations

Thus far, we have exclusively worked with sum-of-products expressions, that is, logic functions of the form $A \cdot B + C \cdot D$. We know, however, that De Morgan's laws state that there is an equivalent form that appears as a product of sums, for example, $(W + Y) \cdot (Y + Z)$. The two forms are completely equivalent, logically, but one of the two forms may lead to a realization involving a smaller number of gates. When using Karnaugh maps, we may obtain the product-of-sums form very simply by following these rules:

1. Solve for the 0s exactly as for the 1s in sum-of-products expressions.
2. Complement the resulting expression.

The same principles stated earlier apply in covering the map with subcubes and determining the minimal expression. The following examples illustrate how one form may result in a more efficient solution than the other.

Example 5.10.3

This example illustrates the design of a logic function using both sum-of-products and product-of-sums implementations, thus showing that it may be possible to realize some savings by using one implementation rather than the other.

1. Realize the function *f* by a Karnaugh map using 0s.
2. Realize the function *f* by a Karnaugh map using 1s.

x	y	z	f
0	0	0	0
0	0	1	1
0	1	0	1
0	1	1	1
1	0	0	1
1	0	1	1
1	1	0	0
1	1	1	0

Solution.

1. Using 0s, we obtain the Karnaugh map of Figure 5.10.25, leading to the product-of-sums expression

$$f = (x + y + z) \cdot (\bar{x} + \bar{y})$$

which requires five gates.

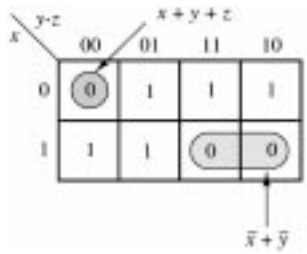

FIGURE 5.10.25 Figure for Example 5.10.3.

2. If 1s are used, as shown in Figure 5.10.26, a sum-of-products expression is obtained, of the form

$$f = \bar{x} \cdot y + x \cdot \bar{y} + \bar{y} \cdot z$$

which requires seven gates.

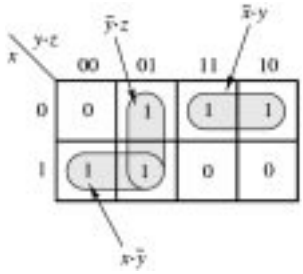

FIGURE 5.10.26 Figure for Example 5.10.3.

Example 5.10.4 Safety Circuit for Operation of a Stamping Press

In this example, the techniques illustrated in the preceding example will be applied to a practical situation. To operate a stamping press, an operator must press two buttons (b_1 and b_2) 1 m apart from each other and away from the press (this ensures that the operator's hands cannot be caught in the press). When the buttons are pressed, the logical variables b_1 and b_2 are equal to 1. Thus, we can define a new variable $A = b_1 \cdot b_2$; when $A = 1$, the operator's hands are safely away from the press. In addition to the safety requirement, however, other conditions must be satisfied before the operator can activate the press. The press is designed to operate on one of two workpieces, part I and part II, but not both. Thus, acceptable logic states for the press to be operated are "part I is in the press, but not part II" and "part II is in the press, but not part I." If we denote the presence of part I in the press by the logical variable $B = 1$ and the presence of part II by the logical variable $C = 1$, we can then impose additional requirements on the operation of the press. For example, a robot used to place either part in the press could activate a pair of switches (corresponding to logical variables B and C) indicating which part, if any, is in the press. Finally, in order for the press to be operable, it must be "ready", meaning that it has to have completed any previous stamping operation. Let the logical variable $D = 1$ represent the ready condition. We have now represented the operation of the press in terms of four logical variables, summarized in the truth

table of Table 5.10.12. Note that only two combinations of the logical variables will result in operation of the press: $ABCD = 1011$ and $ABCD = 1101$. You should verify that these two conditions correspond to the desired operation of the press. Using a Karnaugh map, realize the logic circuitry required to implement the truth table shown.

TABLE 5.10.12 Conditions for Operation of Stamping Press

(*A*) $b_1 \cdot b_2$	(*B*) Part I is in Press	(*C*) Part II is in Press	(*D*) Press is Operable	Press Operation 1 = Pressing; 0 = Not Pressing
0	0	0	0	0
0	0	0	1	0
0	0	1	0	0
0	0	1	1	0
0	1	0	0	0
0	1	0	1	0
0	1	1	0	0
0	1	1	1	0
1	0	0	0	0
1	0	0	1	0
1	0	1	0	0
1	0	1	1	1
1	1	0	0	0
1	1	0	1	1
1	1	1	0	0
1	1	1	1	0

Note: ↑ Both buttons (b_1, b_2) must be pressed for this to be a 1.

Solution. Table 5.10.12 can be converted to a Karnaugh map, as shown in Figure 5.10.27. Since there

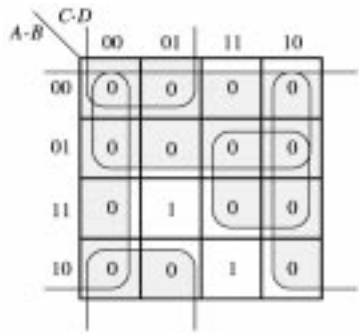

FIGURE 5.10.27 Figure for Example 5.10.4.

are many more 0s than 1s in the table, the use of 0s in covering the map will lead to greater simplification. This will result in a product-of-sums expression. The four subcubes shown in Figure 5.10.27 yield the equation

$$A \cdot D \cdot (C + B) \cdot (\overline{C} + \overline{B})$$

By De Morgan's law, this equation is equivalent to

$$A \cdot D \cdot (C + B) \cdot \overline{(C \cdot B)}$$

which can be realized by the circuit of Figure 5.10.28.

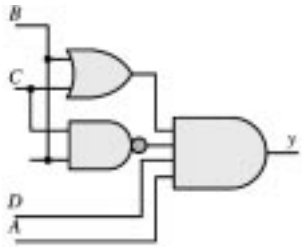

FIGURE 5.10.28 Figure for Example 5.10.4.

For the purpose of comparison, the corresponding sum-of-products circuit is shown in Figure 5.10.29. Note that this circuit employs a greater number of gates and will therefore lead to a more expensive design.

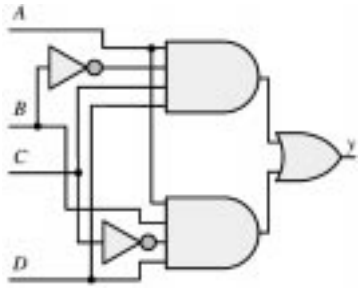

FIGURE 5.10.29 Figure for Example 5.10.4.

Don't Care Conditions

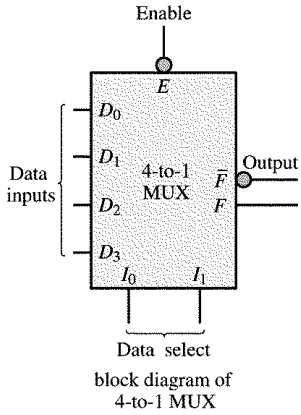
Another simplification technique may be employed whenever the value of the logic function to be implemented can be either a 1 or a 0. This condition may result from the specification of the problem and is not uncommon. Whenever it does not matter whether a position in the map is filled by a 1 or a 0, we use a so-called **don't care** entry, denoted by an x. Then the don't care can be used as either a 1 or a 0, depending on which results in a greater simplification (i.e., helps in forming the smallest number of maximal subcubes).

Combinational Logic Modules

The basic logic gates described in the previous section are used to implement more advanced functions and are often combined to form logic modules, which, thanks to modern technology, are available in compact integrated circuit (IC) packages. In this section and the next, we discuss a few of the more common **combinational logic modules**, illustrating how these can be used to implement advanced logic function.

Multiplexers

Multiplexers, or **data selectors**, are combinational logic circuits that permit the selection of one of many inputs. A typical multiplexer (MUX) has 2^n **data lines**, n **address lines**, and one output. In addition, other control inputs (e.g., enables) may exist. Standard, commercially available MUXs allow for n up to 4; however, two or more MUXs can be combined if a greater range is needed. The MUX allows for one of 2^n inputs to be selected as the data output; the selection of which input is to appear at the output is made by way of the address lines. Figure 5.10.30 depicts the block diagram of a four-input MUX. The input data lines are labeled D_0, D_1, D_2, and D_3; the **data select**, or address, **lines** are labeled I_0 and I_1; and the output is available in both complemented and uncomplemented form, and is thus labeled F, or $\overline{F}$. Finally, an **enable** input, labeled E, is also provided, as a means of enabling or disabling the MUX: if $E = 1$, the MUX is disabled; if $E = 0$, it is enabled. The negative logic (MUX off when $E = 1$



I_1	I_0	F
0	0	D_0
0	1	D_1
1	0	D_2
1	1	D_3

Truth table of 4-to-1 MUX

FIGURE 5.10.30 4:1 MUX.

and on when $E = 0$) is represented by the small "bubble" at the enable input, which represents a complement operation (just as at the output of NAND and NOR gates). The enable input is useful whenever one is interested in a cascade of MUXs; this would be of interest if we needed to select a line from a large number, say $2^8 = 256$. Then two 4-input MUXs could be used to provide the data selection of 1 of 8.

The material described in the previous sections is quite adequate to describe the internal workings of a multiplexer. Figure 5.10.31 shows the internal construction of 4:1 MUX using exclusively NAND gates (inverters are also used, but the reader will recall that a NAND gate can act as an inverter if properly connected).

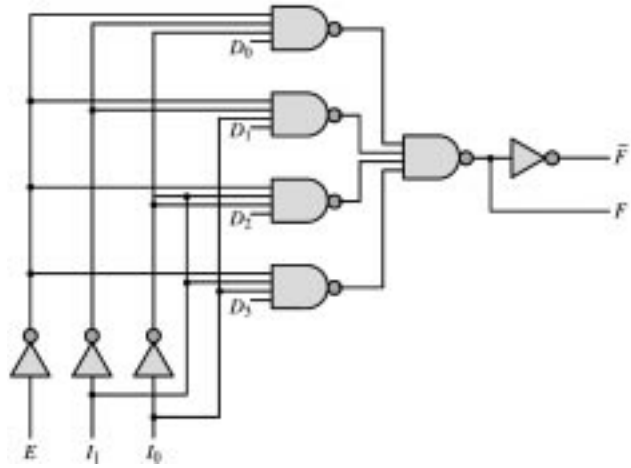


FIGURE 5.10.31 Internal structure of the 4:1 MUX.

In the design of digital systems (for example, microcomputers), a single line is often required to carry two or more different digital signals. However, only one signal at a time can be placed on the line. A MUX will allow us to select, at different instants, the signal we wish to place on this single line. This property is shown here for a 4:1 MUX. Figure 5.10.32 depicts the functional diagram of a 4:1 MUX, showing four data lines, D_0 through D_3, and two select lines, I_0 and I_1.

The data selector function of a MUX is best understood in terms of Table 5.10.13. In this truth table, the x's represent don't care entries. As can be seen from the truth table, the output selects one of the data lines depending on the values of I_1 and I_0, assuming that I_0 is the least significant bit. As an example,

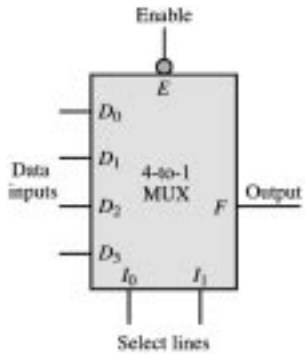

FIGURE 5.10.32 Functional diagram of four-input MUX.

TABLE 5.10.13

I_1	I_0	D_3	D_2	D_1	D_0	F
0	0	x	x	x	0	0
0	0	x	x	x	1	1
0	1	x	x	0	x	0
0	1	x	x	1	x	1
1	0	x	0	x	x	0
1	0	x	1	x	x	1
1	1	0	x	x	x	0
1	1	1	x	x	x	1

$I_1I_0 = 10$ selects D_2, which means that the output, F, will select the value of the data line D_2. Therefore $F = 1$ if $D_2 = 1$ and $F = 0$ if $D_2 = 0$.

Read-Only Memory (ROM)

Another common technique for implementing logic functions uses a **read-only memory**, or ROM. As the name implies, a ROM is a logic circuit that holds in storage ("memory") information — in the form of binary numbers — that cannot be altered but can be "read" by a logic circuit. A ROM is an array of memory cells, each of which can store either a 1 or a 0. The array consists of $2^m \times n$ cells, where n is the number of bits in each word stored in ROM. To access the information stored in ROM, m address lines are required. When an address is selected, in a fashion similar to the operation of the MUX, the binary word corresponding to the address selected appears at the output, which consists of n bits, that is, the same number of bits as the stored words. In some sense, a ROM can be thought of as a MUX that has an output consisting of a word instead of a single bit.

Figure 5.10.33 depicts the conceptual arrangement of a ROM with $n = 4$ and $m = 2$. The ROM table has been filled with arbitrary 4-bit words, just for the purpose of illustration. In Figure 5.10.33, if one were to select an enable input of 0 (i.e., on) and values for the address lines of $I_0 = 0$ and $I_1 = 1$, the output word would be $W_2 = 0110$, so that $b_0 = 0$, $b_1 = 1$, $b_2 = 1$, $b_3 = 0$. Depending on the content of the ROM and the number of address and output lines, one could implement an arbitrary logic function.

Unfortunately, the data stored in read-only memories must be entered during fabrication and cannot be altered later. A much more convenient type of read-only memory is the **erasable programmable read-only memory** (EPROM), the content of which can be easily programmed and stored and may be changed if needed. EPROMs find use in many practical applications because of their flexibility in content and ease of programming. The following example illustrates the use of an EPROM to perform the linearization of a nonlinear function.

Example 5.10.5 EPROM-Based Lookup Table

One of the most common applications of EPROMs is the *arithmetic lookup table*. A lookup table is similar in concept to the familiar multiplication table and is used to store precomputed values of certain

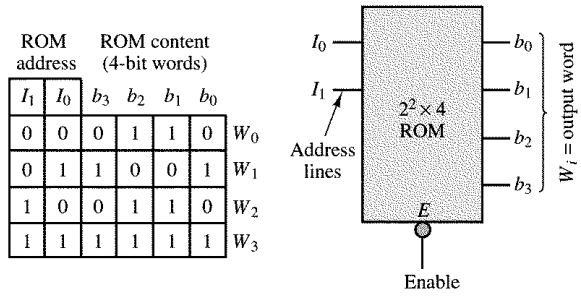

FIGURE 5.10.33 Read-only memory.

functions, eliminating the need for actually computing the function. A practical application of this concept is present in every automobile manufactured in the U.S. since the early 1980s, as part of the exhaust emission control system. In order for the catalytic converter to minimize the emissions of exhaust gases (especially hydrocarbons, oxides of nitrogen, and carbon monoxide), it is necessary to maintain the *air-to-fuel ratio* (A/F) as close as possible to the stoichiometric value, that is, 14.7 parts of air for each part of fuel. Most modern-day engines are equipped with fuel injection systems that are capable of delivering accurate amounts of fuel to each individual cylinder; thus, the task of maintaining an accurate A/F amounts to measuring the mass of air that is aspirated into each cylinder and computing the corresponding mass of fuel. Many automobiles are equipped with a *mass airflow sensor*, capable of measuring the mass of air drawn into each cylinder during each engine cycle. Let the output of the mass airflow sensor be denoted by the variable M_A, and let this variable represent the mass of air (in g) actually entering a cylinder during a particular stroke. It is then desired to compute the mass of fuel, M_F (also expressed in g), required to achieve an A/F of 14.7. This computation is simply

$$M_F = \frac{M_A}{14.7}$$

Although the above computation is a simple division, its actual calculation in a low-cost digital computer (such as would be used on an automobile) is rather complicated. It would be much simpler to tabulate a number of values of M_A, to precompute the variable M_F, and then to store the result of this computation into an EPROM. If the EPROM address were made to correspond to the tabulated values of air mass and the content at each address to the corresponding fuel mass (according to the precomputed values of the expression $M_F = M_A/14.7$), it would not be necessary to perform the division by 14.7. For each measurement of air mass into one cylinder, an EPROM address is specified and the corresponding content is read. The content at the specific address is the mass of fuel required by the particular cylinder.

In practice, the fuel mass needs to be converted into a time interval corresponding to the duration of time during which the fuel injector is open. This final conversion factor can also be accounted for in the table. Suppose, for example, that the fuel injector is capable of injecting K_F g of fuel per second; then the time duration, T_F, during which the injector should be open in order to inject M_F g of fuel into the cylinder is given by

$$T_F = \frac{M_F}{K_F} \text{s}$$

Therefore, the complete expression to be precomputed and stored in the EPROM is

$$T_F = \frac{M_A}{14.7 \times K_F} \text{s}$$

Figure 5.10.34 illustrates this process graphically.

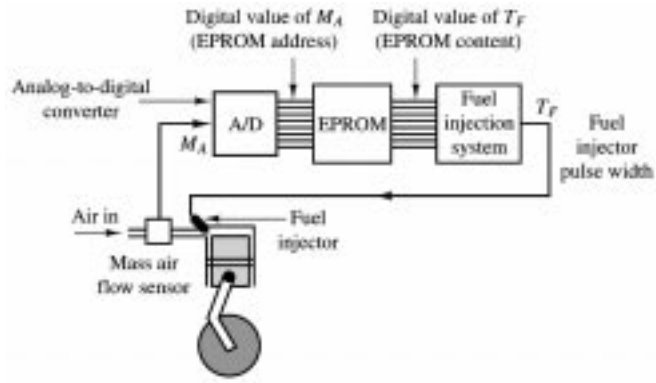

FIGURE 5.10.34 Use of EPROM lookup table in automotive fuel injection system.

To provide a numerical illustration, consider a hypothetical engine capable of aspirating air in the range $0 < M_A < 0.51$ g and equipped with fuel injectors capable of injecting at the rate of 1.36 g/sec. Thus, the relationship between T_F and M_A is

$$T_F = 50 \times M_A \text{ msec} = 0.05 M_A \text{ sec}$$

If the digital value of M_A is expressed in dg (decigrams, or tenths of g), the lookup table of Figure 5.10.35 can be implemented, illustrating the conversion capabilities provided by the EPROM. Note that in order to represent the quantities of interest in an appropriate binary format compatible with the 8-bit EPROM, the units of air mass and of time have been scaled.

M_A(g) × 10^{-2}	Address (digital value of M_A)	Content (digital value of T_F)	T_F(ms) × 10^{-1}
0	00000000	00000000	0

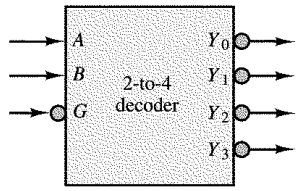
Decorders and Read and Write Memory

Decoders, which are commonly used for applications such as address decoding or memory expansion, are combinational logic circuits as well. Our reason for introducing decoders is to show some of the internal organization of semiconductor memory devices.

Figure 5.10.36 shows the truth table for a 2:4 decoder. The decoder has an enable input, $\overline{G}$, and select inputs, B and A. It also has four outputs, Y_0 through Y_3. When the enable input is logic 1, all decoder outputs are forced to logic 1 regardless of the select inputs.

This simple description of decoders permits a brief discussion of the internal organization of an SRAM (**static random-access** or **read and write memory**). SRAM is internally organized to provide memory with high speed (i.e., short access time), a large bit capacity, and low cost. The memory array in this memory device has a column length equal to the number of words, W, and a row length equal to the



Inputs			Outputs			
Enable	Select					
$\overline{G}$	A	B	Y_0	Y_1	Y_2	Y_3
1	**X**	**X**	1	1	1	1
0	0	0	0	1	1	1
0	0	1	1	0	1	1
0	1	0	1	1	0	1
0	1	1	1	1	1	0

FIGURE 5.10.36 2:4 decoder.

number of bits per word, N. To select a word, an n-to-W decoder is needed. Since the address inputs to the decoder select only one of the decoder's outputs, the decoder selects one word in the memory array. Figure 5.10.37 shows the internal organization of a typical SRAM.

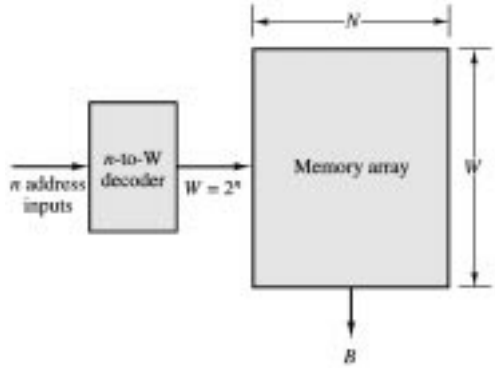


FIGURE 5.10.37 Internal organization of SRAM.

Thus, to choose the desired word from the memory array, the proper address inputs are required. As an example, if the number of words in the memory array is 8, a 3:8 decoder is needed. Data sheets for 2:4 and 3:8 decoders from a CMOS family data book are provided at the end of the chapter.

Sequential Logic Modules

Combinational logic circuits provide outputs that are based on a combination of present inputs only. On the other hand, sequential logic circuits depend on present and past input values. Because of this "memory" property, sequential circuits can store information; this capability opens a whole new area of application for digital logic circuits.

Latches and Flip-Flops

The basic information-storage device in a digital circuit is called a **flip-flop**. There are many different varieties of flip-flops; however, all flip-flops share the following characteristics:

1. A flip-flop is a **bistable device**; that is, it can remain in one of two stable states (0 and 1) until appropriate conditions cause it to change state. Thus, a flip-flop can serve as a memory element.
2. A flip-flop has two outputs, one of which is the complement of the other.

RS Flip-Flop. It is customary to depict flip-flops by their block diagram and a name — such as Q or X — representing the output variable. Figure 5.10.38 represents the so-called **RS flip-flop**, which has two inputs, denoted by S and R, and two outputs, Q and $\overline{Q}$. The value of Q is called the *state* of the flip-

flop. If Q =1, we refer to the device as *being in the 1 state*. Thus, we need define only one of the two outputs of the flip-flop. The two inputs, R and S, are used to change the state of the flip-flop, according to the following rules:

1. When $R = S = 0$, the flip-flop remains in its present state (whether 1 or 0).
2. When $S = 1$ and $R = 0$, the flip-flop is *set* to the 1 state (thus, the letter S, for **set**).
3. When $S = 0$ and $R = 1$, the flip-flop is *reset* to the 0 state (thus, the letter R, for **reset**).
4. It is not permitted for both S and R to be equal to 1. (This would correspond to requiring the flip-flop to set and reset at the same time.)

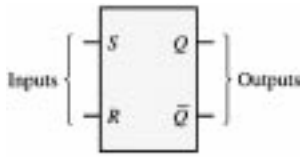

FIGURE 5.10.38 *RS* flip-flop.

The rules just described are easily remembered by noting that 1s on the S and R inputs correspond to the set and reset commands, respectively.

A convenient means of describing the series of transitions that occur as the signals sent to the flip-flop inputs change is the **timing diagram**. A timing diagram is a graph of the inputs and outputs of the *RS* flip-flop (or any other logic device) depicting the transitions that occur over time. In effect, one could also represent these transitions in tabular form; however, the timing diagram provides a convenient visual representation of the evolution of the state of the flip-flop. Figure 5.10.39 depicts a table of transitions for an *RS* flip-flop Q, as well as the corresponding timing diagram.

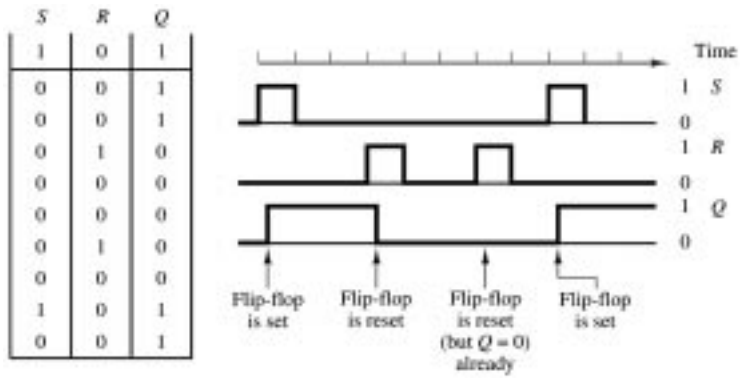

FIGURE 5.10.39 Timing diagram for the *RS* flip-flop.

It is important to note that the *RS* flip-flop is **level-sensitive**. This means that the set and reset operations are completed only after the R and S inputs have reached the appropriate levels. Thus, in Figure 5.10.39 we show the transitions in the Q outputs as occurring with a small delay relative to the transitions in the R and S inputs.

It is instructive to illustrate how an *RS* flip-flop can be constructed using simple logic gates. For example, Figure 5.10.40 depicts a realization of such a circuit consisting of four gates: two inverters and two NAND gates (actually, the same result could be achieved with four NAND gates). Consider the case in which the circuit is in the initial state $Q = 0$ (and therefore $\overline{Q} = 1$). If the input $S = 1$ is applied, the top NOT gate will see inputs $\overline{Q} = 1$ and $\overline{S} = 0$, so that $Q = (\overline{S} \cdot \overline{Q}) = (\overline{0 \cdot 1}) = 1$ — that is, the flip-flop is set. Note that when Q is set to 1, $\overline{Q}$ becomes 0. This, however, does not affect the state of the Q output, since replacing $\overline{Q}$ with 0 in the expression

$$Q = \left(\overline{\overline{S} \cdot \overline{Q}}\right)$$

does not change the result:

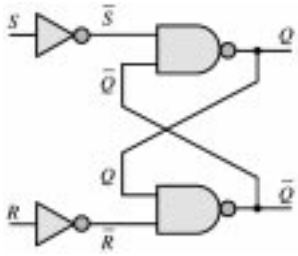

FIGURE 5.10.40 Logic gate implementation of the *RS* flip-flop.

$$Q = \left(\overline{0 \cdot 0}\right) = 1$$

Thus, the cross-coupled feedback from outputs Q and $\overline{Q}$ to the input of the NAND gates is such that the set condition sustains itself. It is straightforward to show (by symmetry) that a 1 input on the R line causes the device to reset (i.e., causes $Q = 0$) and that this condition is also self-sustaining.

An extension of the *RS* flip-flop includes an additional enable input that is *gated* into each of the other two inputs. Figure 5.10.41 depicts an *RS* flip-flop consisting of two NOR gates. In addition, an enable input is connected through two AND gates to the *RS* flip-flop, so that an input to the R and S line will be effective only when the enable input is 1. Thus, any transitions will be controlled by the enable input, which acts as a synchronizing signal. The enable signal may consist of a **clock**, in which case the flip-flop is said to be **clocked** and its operation is said to be **synchronous**.

The same circuit of Figure 5.10.41 can be used to illustrate two additional features of flip-flops: the **preset** and **clear** functions, denoted by the inputs P and C, respectively. When P and C are 0, they do not affect the operation of the flip-flop. Setting $P = 1$ corresponds to setting $S = 1$, and therefore causes the flip-flop to go into the 1 state, thus, the term *preset*: this function allows the user to preset the flip-flop to 1 at any time. When C is 1, the flip-flop is reset, or *cleared* (i.e., Q is made equal to 0). Note that these direct inputs are, in general, asynchronous; therefore, they allow the user to preset or clear the flip-flop at any time. A set of timing waveforms illustrating the function of the enable, preset, and clear inputs is also shown in Figure 5.10.41. Note how transitions occur only when the enable input goes high (unless the preset or clear inputs are used to override the *RS* inputs).

Another extension of the *RS* flip-flop, called the **data latch**, is shown in Figure 5.10.42. In this circuit, the R input is always equal to the inverted S input, so that whenever the enable input is high, the flip-flop is set. This device has the dual advantage of avoiding the potential conflict that might arise if both R and S were high and reducing the number of input connections by eliminating the reset input. This circuit is called a data latch because once the enable input goes low, the flip-flop is latched to the previous value of the input. Thus this device can serve as a basic memory element.

D Flip-Flop. The ***D* flip-flop** is an extension of the data latch that utilizes two *RS* flip-flops, as shown in Figure 5.10.43. In this circuit, a clock is connected to the enable input of each flip-flop. Since Q_1 sees an inverted clock signal, the latch is enabled when the clock waveform goes low. However, since Q_2 is disabled when the clock is low, the output of the D flip-flop will not switch to the 1 state until the clock goes high, enabling the second latch and transferring the state of Q_1 to Q_2. It is important to note that the D flip-flop changes state only on the positive edge of the clock waveform: Q_1 is set on the negative edge of the clock, and Q_2 (and therefore Q) is set on the positive edge of the clock, as shown in the timing diagram of Figure 5.10.43. This type of device is said to be **edge-triggered**. This feature is indicated by the "knife edge" drawn next to the CLK input in the device symbol. The particular device

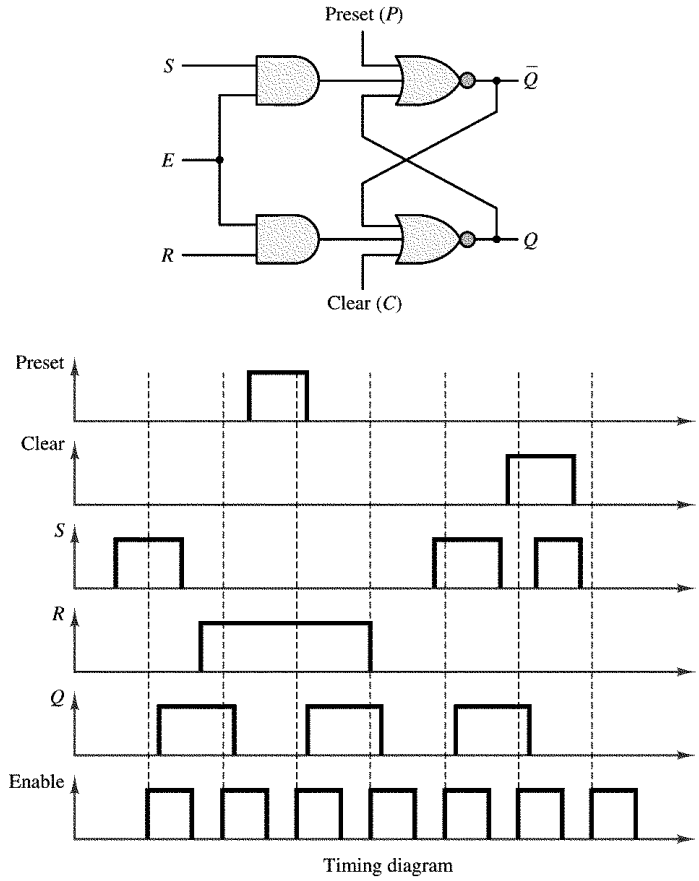

FIGURE 5.10.41 *RS* flip-flop with enable, preset, and clear lines.

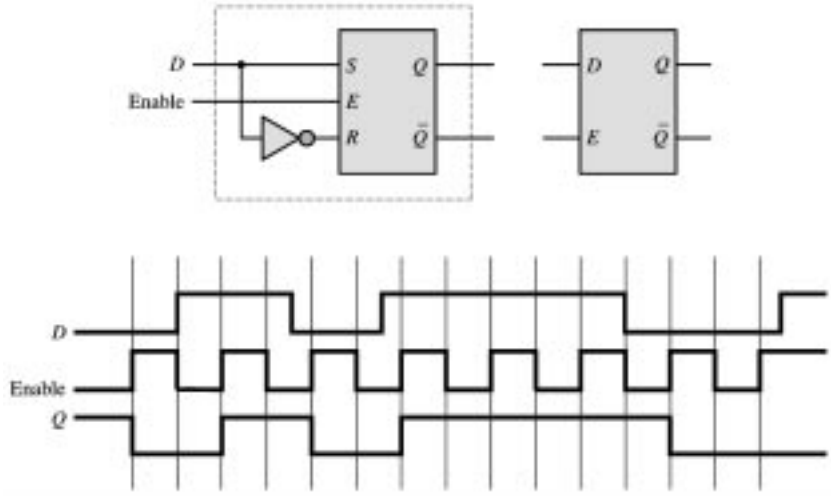

FIGURE 5.10.42 Data latch.

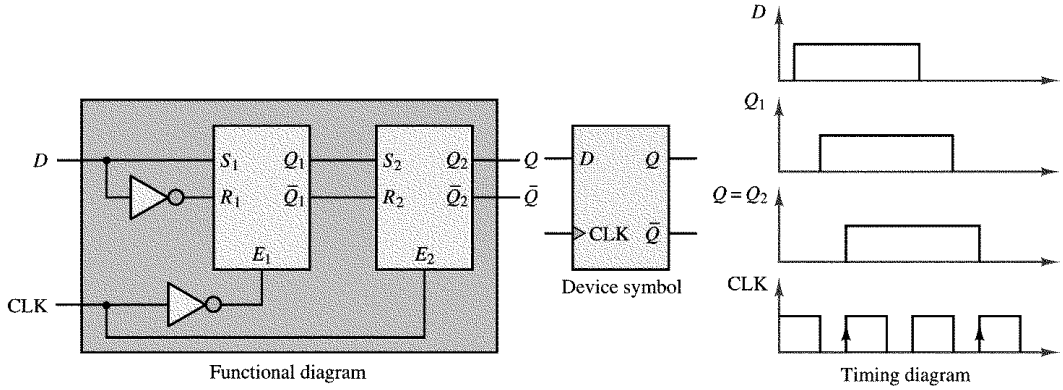

FIGURE 5.10.43 D flip-flop.

described here is said to be positive edge-triggered, or **leading edge-triggered**, since the final output of the flip-flop is set on a positive-going clock transition.

On the basis of the rules stated in this section, the state of the *D* flip-flop can be described by means of the following truth table:

D	CLK	*Q*
0	↑	0
1	↑	1

where the symbol ↑ indicates the occurrence of a positive transition.

JK Flip-Flop. Another very common type of flip-flop is the ***JK* flip-flop**, shown in Figure 5.10.44. The *JK* flip-flop operates according to the following rules:

- When *J* and *K* are both low, no change occurs in the state of the flip-flop.
- When $J = 0$ and $K = \downarrow$, the flip-flop is reset to 0.
- When $J = \downarrow$ and $K = 0$, the flip-flop is set to 1.
- When both *J* and *K* are high, the flip-flop will toggle between states at every transition of the clock input.

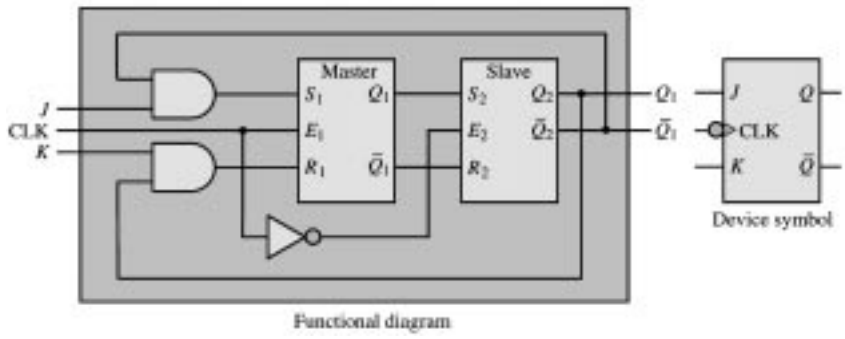

FIGURE 5.10.44 *JK* flip-flop.

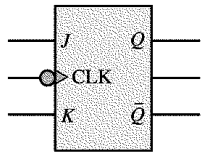
The symbol ↓ denotes a negative transition.

Note that, functionally, the operation of the *JK* flip-flop can also be explained in terms of two *RS* flip-flops. When the clock waveform goes high, the "master" flip-flop is enabled; the "slave" receives the

state of the master upon a negative clock transition. The "bubble" at the clock input signifies that the device is negative or **trailing edge-triggered**. This behavior is similar to that of an *RS* flip-flop, except for the $J = 1, K = 1$ condition, which corresponds to a toggle mode rather than to a disallowed combination of inputs.

Figure 5.10.45 depicts the truth table for the *JK* flip-flop. It is important to note that when both inputs are 0 the flip-flop remains in its previous state at the occurrence of a clock transition; when either input is high and the other is low, the *JK* flip-flop behaves like the *RS* flip-flop, whereas if both inputs are high, the output "toggles" between states every time the clock waveform undergoes a negative transition.



JK flip-flop

J_n	K_n	Q_{n+1}
0	0	Q_n
0	1	0 (reset)
1	0	1 (set)
1	1	$\bar{Q}_n$ (toggle)

FIGURE 5.10.45 Truth table for the *JK* flip-flop.

Digital Counters

One of the more immediate applications of flip-flops is in the design of **counters**. A counter is a sequential logic device that can take one of *N* possible states, stepping through these states in a sequential fashion. When the counter has reached its last state, it resets to zero and is ready to start counting again. For example, a three-bit **binary up counter** would have $2^3 = 8$ possible states, and might appear as shown in the functional block of Figure 5.10.46. The input clock waveform causes the counter to step through the eight states, making one transition for each clock pulse. We shall shortly see that a string of *JK* flip-flops can accomplish this task exactly. The device shown in Figure 5.10.46 also displays a reset input, which forces the counter to equal 0: $b_2b_1b_0 = 000$.

Although binary counters are very useful in many applications, one is often interested in a **decade counter**, that is, a counter that counts from 0 to 9 and then resets. A four-bit binary counter can easily be configured in principle to provide this function by means of simple logic that resets the counter when it has reached the count $1001_2 = 9_{10}$. As shown in Figure 5.10.47, if we connect bits b_3 and b_1 to a four-input AND gate, along with $\bar{b}_2$ and $\bar{b}_0$, the output of the AND gate can be used to reset the counter after a count of 10. Additional logic can provide a "carry" bit whenever a reset condition is reached, which could be passed along to another decade counter, enabling counts up to 99. Decade counters can be cascaded so as to represent decimal digits in succession.

Although the decade counter of Figure 5.10.47 is attractive because of its simplicity, this configuration would never be used in practice because of the presence of **propagation delays**. These delays are caused by the finite response time of the individual transistors in each logic device and cannot be guaranteed to be identical for each gate and flip-flop. Thus, if the reset signal — which is presumed to be applied at exactly the same time to each of the four *JK* flip-flops in the four-bit binary counter — does not cause the *JK* flip-flops to reset at exactly the same time on account of different propagation delays, then the binary word appearing at the output of the counter will change from 1001 to some other number, and the output of the four-input NAND gate will no longer be high. In such a condition, the flip-flops that have not already reset will then not be able to reset, and the counting sequence will be irreparably compromised.

What can be done to obviate this problem? The answer is to use a systematic approach to the design of sequential circuits making use of **state transition diagrams**. This topic is discussed in the references.

A simple implementation of the binary counter we have described in terms of its functional behavior is shown in Figure 5.10.48. The figure depicts a three-bit binary **ripple counter**, which is obtained from a cascade of three *JK* flip-flops. The transition table shown in the figure illustrates how the *Q* output of each state becomes the clock input to the next stage, while each flip-flop is held in the toggle mode. The output transitions assume that the clock, CLK, is a simple square wave (all *JK*s are negative edge-triggered).

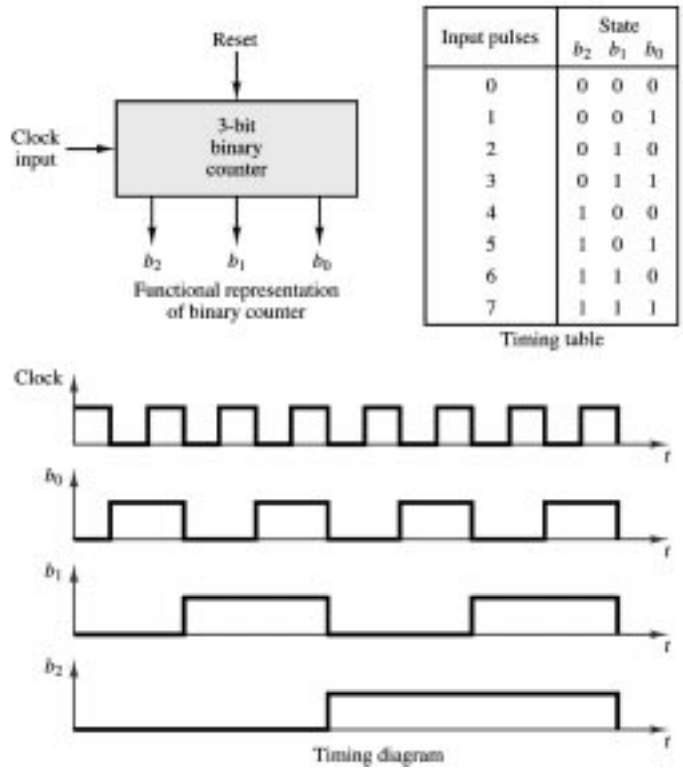


FIGURE 5.10.46 Binary up counter.

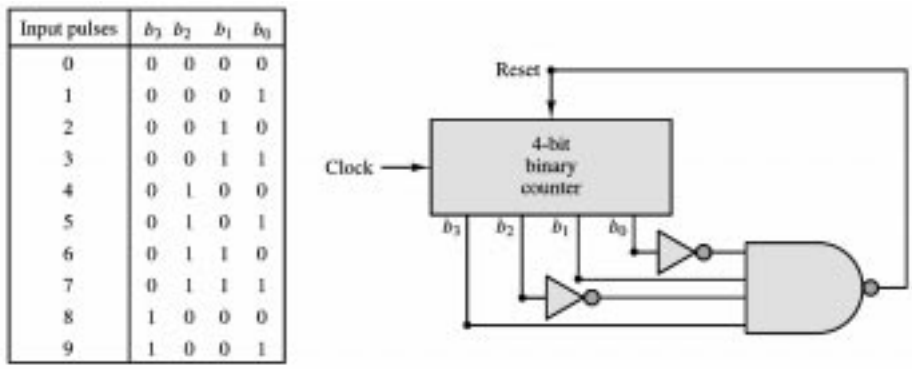

FIGURE 5.10.47 Decade counter.

This 3-bit ripple counter can easily be configured as a divide-by-8 mechanism, simply by adding an AND gate. To divide the input clock rate by 8, one output pulse should be generated for every eight clock pulses. If one were to output a pulse every time a binary 111 combination occurs, a simple AND gate would suffice to generate the required condition. This solution is shown in Figure 5.10.49. Note that the square wave is also included as an input to the AND gate; this ensures that the output is only as wide as the input signal. This application of ripple counters is further illustrated in the following example.

A slightly more complex version of the binary counter is the so-called **synchronous counter**, in which the input clock drives all of the flip-flops simultaneously. Figure 5.10.50 depicts a three-bit synchronous counter. In this figure, we have chosen to represent each flip-flop as a *T* flip-flop. The clocks to all the

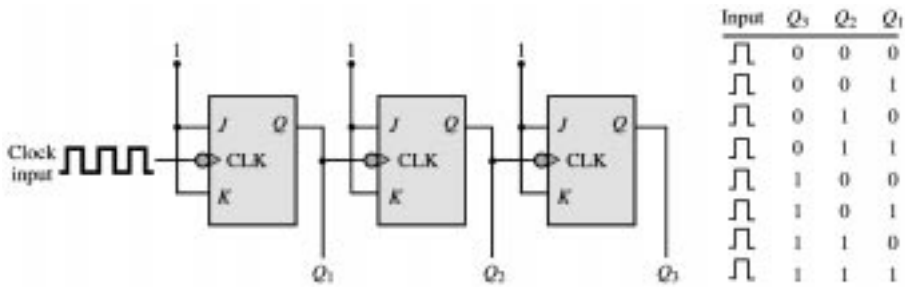

FIGURE 5.10.48 Ripple counter.

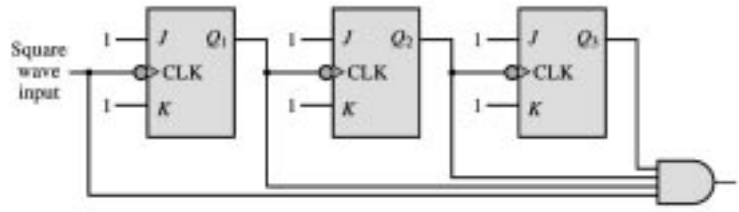

FIGURE 5.10.49 Divide-by-8 circuit.

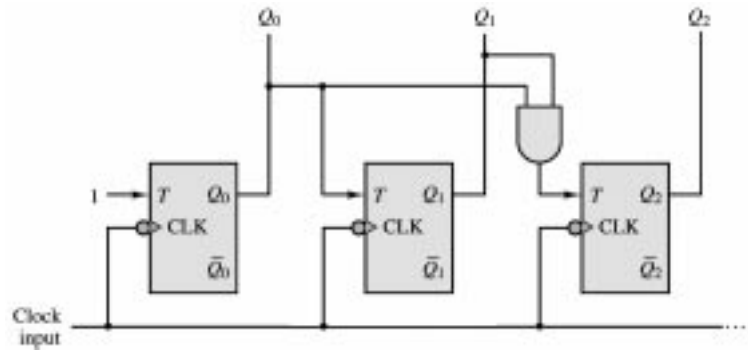

FIGURE 5.10.50 Three-bit synchronous counter.

flip-flops are incremented simultaneously. The reader should verify that Q_0 toggles to 1 first and then Q_1 toggles to 1, and that the AND gate ensures that Q_2 will toggle only after Q_0 and Q_1 have both reached the 1 state ($Q_0 \cdot Q_1 = 1$).

Other common counters are the **ring counter** and the **up-down counter**, which has an additional select input that determines whether the counter counts up or down.

Example 5.10.6 Measurement of Angular Position

One type of angular position encoder is the slotted encoder shown in Figure 5.10.51. This encoder can be used in conjunction with a pair of counters and a high-frequency clock to determine the speed of rotation of the slotted wheel. As shown in Figure 5.10.52, a clock of known frequency is connected to a counter while another counter records the number of slot pulses detected by an optical slot detector as the wheel rotates. Dividing the counter values, one could obtain the speed of the rotating wheel in radians per second. For example, assume a clocking frequency of 1.2 kHz. If both counters are started at zero and at some instant the timer counter reads 2850 and the encoder counter reads 3050, then the speed of the rotating encoder is found to be

$$1200\frac{\text{cycles}}{\text{second}}\cdot\frac{2850\text{ slots}}{3050\text{ cycles}}=1121.3\frac{\text{slots}}{\text{second}}$$

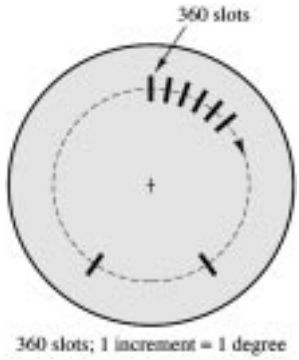

FIGURE 5.10.51

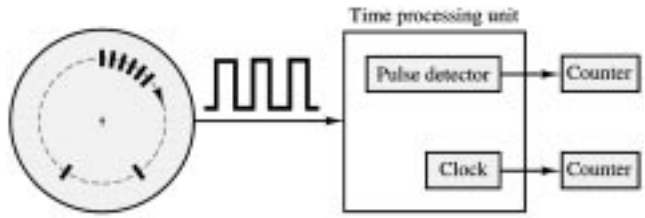

FIGURE 5.10.52 Calculating the speed of rotation of the slotted wheel.

and

$$1121.3\text{ slots/sec}\times 1^\circ\text{ per slot}\times 2\pi/360\text{ rad/degree}=19.6\text{ rad/sec}$$

If this encoder is connected to a rotating shaft, it is possible to measure the angular position and velocity of the shaft. Such shaft encoders are used in measuring the speed of rotation of electric motors, machine tools, engines, and other rotating machinery. A typical application of the slotted encoder is to compute the ignition and injection timing in an automotive engine. In an automotive engine, information related to speed is obtained from the camshaft and the flywheel, which have known reference points. The reference points determine the timing for the ignition firing points and fuel injection pulses and are identified by special slot patterns on the camshaft and crankshaft. Two methods are used to detect the special slots (reference points): *period measurement with additional transition detection* (PMA, and *period measurement with missing transition detection* (PMM). In the PMA method, an additional slot (reference point) determines a known reference position on the crankshaft or camshaft. In the PMM method, the reference position is determined by the absence of a slot. Figure 5.10.53 illustrates a typical PMA pulse sequence, showing the presence of an additional pulse. The additional slot may be used to determine the timing for the ignition pulses relative to a known position of the crankshaft. Figure 5.10.54 depicts a typical PMM pulse sequence. Because the period of the pulses is known, the additional slot of the missing slot can be easily detected and used as a reference position. How would you implement these pulse sequences using ring counters?

Registers

A register consists of a cascade of flip-flops that can store binary data, one bit in each flip-flop. The simplest type of register is the parallel input–parallel output register shown in Figure 5.10.55. In this register, the "load" input pulse, which acts on all clocks simultaneously, causes the parallel inputs $b_0b_1b_2b_3$

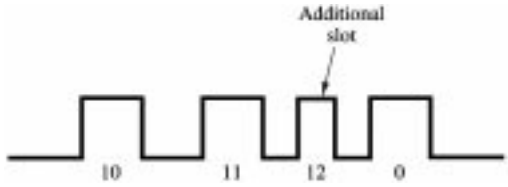

FIGURE 5.10.53 PMA pulse sequence.

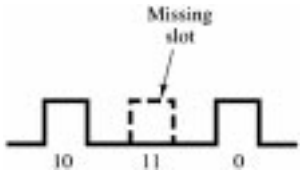

FIGURE 5.10.54 PMA pulse sequence.

to be transferred to the respective flip-flops. The *D* flip-flop employed in this register allows the transfer from b_n to Q_n to occur very directly. Thus, *D* flip-flops are very commonly used in this type of application. The binary word $b_3b_2b_1b_0$ is now "stored", each bit being represented by the state of a flip-flop. Until the "load" input is applied again and a new word appears at the parallel inputs, the register will preserve the stored word.

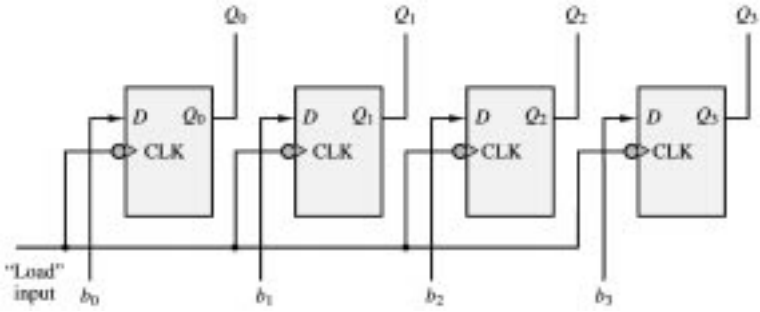

FIGURE 5.10.55 Four-bit parallel register.

The construction of the parallel register presumes that the *N*-bit word to be stored is available in parallel form. However, it is often true that a binary word will arrive in serial form, that is, one bit at a time. A register that can accommodate this type of logic signal is called a **shift register**. Figure 5.10.56 illustrates how the same basic structure of the parallel register applies to the shift register, except that the input is now applied to the first flip-flop and shifted along at each clock pulse. Note that this type of register provides both a serial and a parallel output.

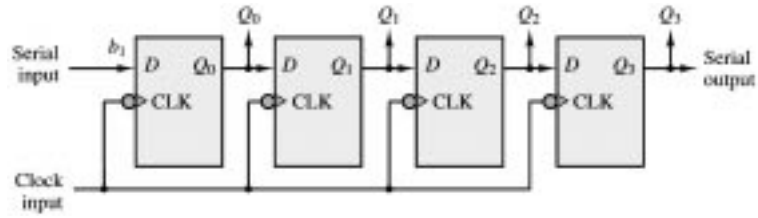

FIGURE 5.10.56 Four-bit shift register.

5.11 Measurements and Instrumentation

Measurement Systems and Transducers

Measurement Systems

In virtually every engineering application there is a need for measuring some physical quantities, such as forces, stresses, temperatures, pressures, flows, or displacements. These measurements are performed by physical devices called **sensors** or **transducers**, which are capable of converting a physical quantity to a more readily manipulated electrical quantity. Most sensors, therefore, convert the change of a physical quantity (e.g., humidity, temperature) to a corresponding (usually proportional) change in an electrical quantity (e.g., voltage or current). Often, the direct output of the sensor requires additional manipulation before the electrical output is available in a useful form. For example, the change in resistance resulting from a change in the surface stresses of a material — the quantity measured by the resistance strain gauges described in Section 5.2 — must first be converted to a change in voltage through a suitable circuit (the Wheatstone bridge) and then amplified from the millivolt to the volt level. The manipulations needed to produce the desired end result are referred to as *signal conditioning*. The wiring of the sensor to the signal conditioning circuitry requires significant attention to *grounding* and *shielding* procedures, to ensure that the resulting signal is as free from noise and interference as possible. Very often, the conditioned sensor signal is then converted to *digital* form and recorded in a computer for additional manipulation, or is displayed in some form. The apparatus used in manipulating a sensor output to produce a result that can be suitably displayed or stored is called a **measurement system**. Figure 5.11.1 depicts a typical computer-based measurement system in block diagram form.

FIGURE 5.11.1 Measurement system.

Sensor Classification

There is no standard and universally accepted classification of sensors. Depending on one's viewpoint, sensors may be grouped according to their physical characteristics (e.g., electronic sensors, resistive sensors), or by the physical variable or quantity measured by the sensor (e.g., temperature, flow rate). Other classifications are also possible. Table 5.11.1 presents a partial classification of sensors grouped according to the variable sensed; we do not claim that the table is complete, but we can safely state that most of the engineering measurements of interest to the reader are likely to fall in the categories listed in Table 5.11.1. Also included in the table are section or example references to sensors described in this chapter.

A sensor is usually accompanied by a set of specifications that indicate its overall effectiveness in measuring the desired physical variable. The following definitions will help the reader understand sensor data sheets:

Accuracy: Conformity of the measurement to the true value, usually in percent of full-scale reading
Error: Difference between measurement and true value, usually in percent of full-scale reading
Precision: Number of significant figures of the measurement
Resolution: Smallest measurable increment
Span: Linear operating range
Range: The range of measurable values
Linearity: Conformity to an ideal linear calibration curve, usually in percent of reading or of full-scale reading (whichever is greater)

Motion and Dimensional Measurements

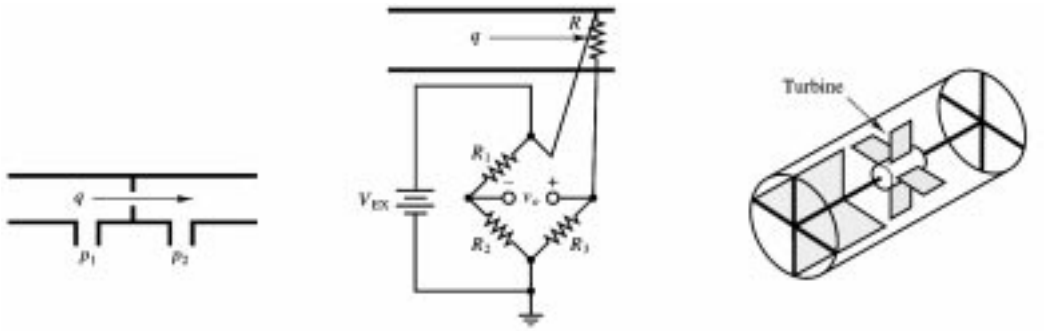
The measurement of motion and dimension is perhaps the most commonly encountered engineering measurement. Measurements of interest include absolute position, relative position (displacement), velocity, acceleration, and jerk (the derivative of acceleration). These can be either translational or rotational measurements; usually, the same principle can be applied to obtain both kinds of measurements. These measurements are often based on changes in elementary properties, such as changes in the resistance of an element (e.g., strain gauges, potentiometers), in an electric field (e.g., capacitive sensors), or in a magnetic field (e.g., inductive, variable-reluctance, or eddy current sensors). Other mechanisms may be based on special materials (e.g., piezoelectric crystals), or on optical signals and imaging systems.

Force, Torque, and Pressure Measurements

Another very common class of measurements is that of pressure and force, and the related measurement of torque. Perhaps the single most common family of force and pressure transducers comprises those based on strain gauges (e.g., load cells, diaphragm pressure transducers). Also very common are piezoelectric transducers. Capacitive transducers again find application in the measurement of pressure.

Flow Measurementrs

In many engineering applications it is desirable to sense the flow rate of a fluid, whether compressible (gas) or incompressible (liquid). The measurement of fluid flow rate is a complex subject; in this section we simply summarize the concepts underlying some of the most common measurement techniques. Shown in Figure 5.11.2 are three different types of flow rate sensors. The sensor in Figure 5.11.2(a) is based on **differential pressure measurement** and on a **calibrated orifice**: the relationship between



Differential-pressure flowmeter: A calibrated orifice and a pair of pressure transducers permit the measurement of flow rate. (a)

Hot-wire anemometer: A heated wire is cooled by the gas flow. The resistance of the wire changes with temperature. (b)

Turbine flowmeter: Fluid flow induces rotation of the turbine; measurement of turbine velocity provides an indication of flow rate. (c)

FIGURE 5.11.2 Devices for the measurement of flow.

pressure across the orifice, $p_1 - p_2$, and flow rate through the orifice, q, is predetermined through the calibration; therefore, measuring the differential pressure is equivalent to measuring flow rate.

The sensor in Figure 5.11.2(b) is called a **hot-wire anemometer**, because it is based on a heated wire that is cooled by the flow of a gas. The resistance of the wire changes with temperature, and a Wheatstone bridge circuit converts this change in resistance to a change in voltage. Also commonly used are **hot-film anemometers**, where a heated film is used in place of the more delicate wire. A very common application of the latter type of sensor is in automotive engines, where control of the air-to-fuel ratio depends on measurement of the engine intake mass airflow rate.

Figure 5.11.2(c) depicts a **turbine flowmeter**, in which the fluid flow causes a turbine to rotate; the velocity of rotation of the turbine (which can be measured by a noncontact sensor — e.g., a magnetic pickup) is related to the flow velocity.

Besides the techniques discussed in this chapter, many other techniques exist for measuring fluid flow, some of significant complexity.

Temperature Measurements

One of the most frequently measured physical quantities is temperature. The need to measure temperature arises in just about every field of engineering. This subsection is devoted to summarizing two common temperature sensors — the **thermocouple** and the **resistance temperature detector** (RTD) — and their related signal conditioning needs.

Thermocouples. A thermocouple is formed by the junction of two dissimilar metals. This junction results on an open-circuit **thermoelectric voltage** due to the **Seebeck effect**, named after Thomas Seebeck, who discovered the phenomenon in 1821. Various types of thermocouples exist; they are usually classified according to the data of Table 5.11.2. The Seebeck coefficient shown in the table is specified at a given temperature because the output voltage of a thermocouple, v, has a nonlinear dependence on temperature. This dependence is typically expressed in terms of a polynomial of the following form:

$$T = a_0 + a_1 v + a_2 v^2 + a_3 v^3 + \ldots + a_n v^n \tag{5.11.1}$$

For example, the coefficients of the J thermocouple in the range –100 to + 1000°C are as follows:

$$a_0 = -0.048868252 \qquad a_1 = 19{,}873.14503 \qquad a_2 = -128{,}614.5353$$

$$a_3 = 11{,}569{,}199.78 \qquad a_4 = -264{,}917{,}531.4 \qquad a_5 = 2{,}018{,}441{,}314$$

TABLE 5.11.2 Thermocouple Data

Type	Elements +/–	Seebeck Coefficient (μV/°C)	Range (°C)	Range (mV)
E	Chromel/constantan	58.70 at 0°C	–270 to 1000	–9.835 to 76.358
J	Iron/constantan	50.37 at 0°C	–210 to 1200	–8.096 to 69.536

S	Pt(13%)–Rh/Pt	11.35 at 600°C	–50 to 1768	–0.226 to 21.108

The use of a thermocouple requires special connections, because the junction of the thermocouple wires with other leads (such as voltmeter leads, for example) creates additional thermoelectric junctions that in effect act as additional thermocouples. For example, in the J thermocouple circuit of Figure 5.11.3, junction J_1 is exposed to the temperature to be measured, but junctions J_2 and J_3 also generate a thermoelectric voltage, which is dependent on the temperature at these junctions, that is, the temperature at the voltmeter connections. One would therefore have to know the voltages at these junctions as well, in order to determine the actual thermoelectric voltage at J_1. To obviate this problem, a reference junction at known temperature can be employed; a traditional approach involves the use of a **cold junction**, so called because it consists of an ice bath, one of the easiest means of obtaining a known reference temperature. Figure 5.11.4 depicts a thermocouple measurement using an ice bath. The voltage measured in Figure 5.11.4 is dependent on the temperature difference $T_1 - T_{ref}$, where $T_{ref} = 0°C$. The connections to the voltmeter are made at an *isothermal block*, kept at a constant temperature; note that the same metal is used in both of the connections to the isothermal block. Thus (still assuming a J thermocouple), there is no difference between the thermoelectric voltages at the two copper-iron junctions; these will add to zero at the voltmeter. The voltmeter will therefore read a voltage proportional to $T_1 - T_{ref}$.

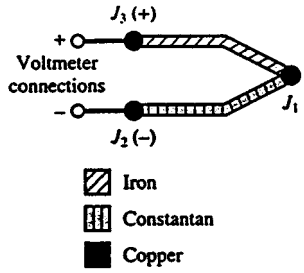

FIGURE 5.11.3 J thermocouple circuit.

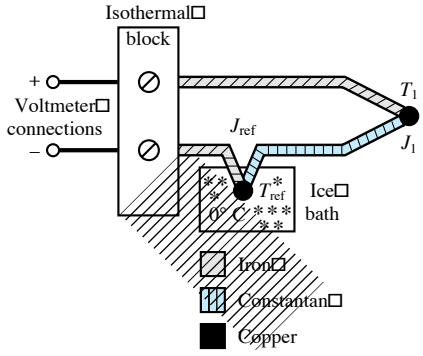

FIGURE 5.11.4 Cold-junction-compensated thermocouple circuit.

An ice bath is not always a practical solution. Other cold junction temperature compensation techniques employ an additional temperature sensor to determine the actual temperature of the junctions J_2 and J_3 of Figure 5.11.3

Resistance Temperature Detectors (RTDs). A resistance temperature detector (RTD) is a variable-resistance device whose resistance is a function of temperature. RTDs can be made with both positive and negative temperature coefficients and offer greater accuracy and stability than thermocouples. **Thermistors** are part of the RTD family. A characteristic of all RTDs is that they are *passive* devices, that is, they do not provide a useful output unless excited by an external source. The change in resistance in an RTD is usually converted to a change in voltage by forcing a current to flow through the device. An indirect result of this method is a **self-heating error**, caused by the $i^2 R$ heating of the device. Self-heating of an RTD is usually denoted by the amount of power that will raise the RTD temperature by 1°C. Reducing the excitation current can clearly help reduce self-heating, but it also reduces the output voltage.

The RTD resistance has a fairly linear dependence on temperature, a common definition of the **temperature coefficient** of an RTD is related to the change in resistance from 0 to 100°C. Let R_0 be the resistance of the device at 0°C and R_{100} the resistance at 100°C. Then the temperature coefficient, α, is defined to be

$$\alpha = \frac{R_{100} - R_0}{100 - 0} \frac{\Omega}{^\circ C} \tag{5.11.2}$$

A more accurate representation of RTD temperature dependence can be obtained by using a nonlinear (cubic) equation and published tables of coefficients. As an example, a platinum RTD could be described either by the temperature coefficient $\alpha = 0.003911$, or by the equation

$$\begin{aligned} R_T &= R_0\left(1 + AT - BT^2 - CT^3\right) \\ &= R_0\left(1 + 3.6962 \times 10^{-3} T - 5.8495 \times 10^{-7} T^2 - 4.2325 \times 10^{-12} T^3\right) \end{aligned} \tag{5.11.3}$$

where the coefficient C is equal to zero for temperatures above 0°C.

Because RTDs have fairly low resistance, they are sensitive to error introduced by the added resistance of the lead wires connected to them; Figure 5.11.5 depicts the effect of the lead resistances, r_L, on the RTD measurement. Note that the measured voltage includes the resistance of the RTD as well as the resistance of the leads. If the leads used are long (greater than 3 m is a good rule of thumb), then the measurement will have to be adjusted for this error. Two possible solutions to the lead problems are the *four-wire* RTD measurement circuit and the *three-wire* Wheatstone bridge circuit, shown in Figure 5.11.6(a) and (b), respectively. In the circuit of Figure 5.11.6(a), the resistance of the lead wires from the excitation, r_{L1} and r_{L4}, may be arbitrarily large, since the measurement is affected by the resistance of only the output lead wires, r_{L2} and r_{L3}, which can be kept small by making these leads short. The circuit of Figure 5.11.6(b) takes advantage of the properties of the Wheatstone bridge to cancel out the unwanted effect of the lead wires while still producing an output dependent on the change in temperature.

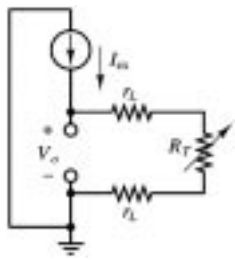

FIGURE 5.11.5 Effect of connection leads on RTD temperature measurement.

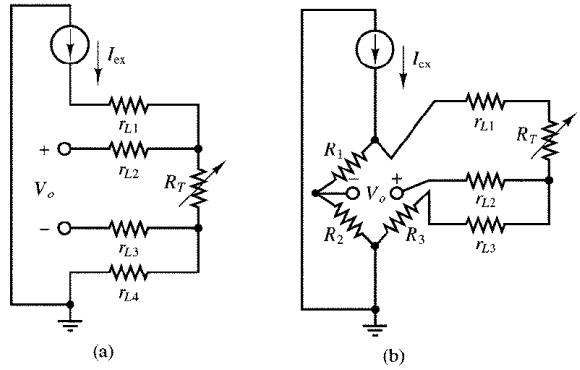

FIGURE 5.11.6 Four-wire RTD circuit (a) and three-wire Wheatstone bridge RTD circuit (b).

Wiring, Grounding, and Noise

The importance of proper circuit connections cannot be overemphasized. Unfortunately, this is a subject that is rarely taught in introductory electrical engineering courses. The present section summarizes some important considerations regarding signal source connections, various types of input configurations, noise sources and coupling mechanisms, and means of minimizing the influence of noise on a measurement.

Signal Sources and Measurement System Configurations

Before proper connection and wiring techniques can be presented, we must examine the difference between **grounded** and **floating signal sources**. Every sensor can be thought of as some kind of signal source; a general representation of the connection of a sensor to a measurement system is shown in Figure 5.11.7(a). The sensor is modeled as an ideal voltage source in series with a source resistance. Although this representation does not necessarily apply to all sensors, it will be adequate for the purposes of the present section. Figures 5.7.11(b) and (c) show two types of signal sources: grounded and floating. A grounded signal source is one in which a ground reference is established — for example, by connecting the *signal low* lead to a case or housing. A floating signal source is one in which neither signal lead is connected to ground; since ground potential is arbitrary, the signal source voltage levels (*signal low* and *signal high*) are at an unknown potential relative to the case ground. Thus, the signal is said to be *floating*. Whether a sensor can be characterized as a grounded or a floating signal source ultimately depends on the connection of the sensor to its case, but the choice of connection may depend on the nature of the source. For example, the thermocouple described earlier is *intrinsically* a floating signal source, since the signal of interest is a difference between voltages. The same thermocouple *could* become a grounded signal source if one or its two leads were directly connected to ground, but this is usually not a desirable arrangement for this particular sensor.

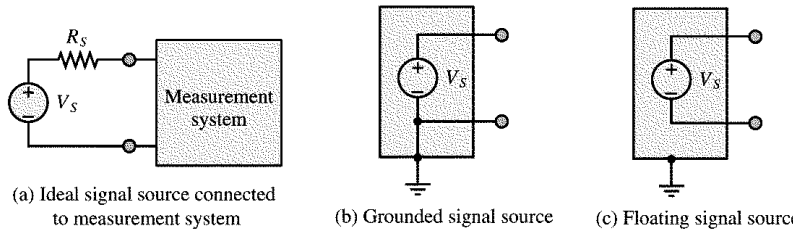

FIGURE 5.11.7 Measurement system and types of signal sources.

In analogy with a signal source, a measurement system can be either **ground-referenced** or **differential**. In a ground-referenced system, the signal low connection is tied to the instrument case ground; in a differential system, neither of the two signal connections is tied to ground. Thus, a differential measurement system is well suited to measuring the difference between two signal levels (such as the output of an ungrounded thermocouple).

One of the potential dangers in dealing with grounded signal sources is the introduction of **ground loops**. A ground loop is an undesired current path caused by the connection of two reference voltages to each other. This is illustrated in Figure 5.11.8, where a grounded signal source is shown connected to a ground-referenced measurement system. Notice that we have purposely denoted the signal source ground and the measurement system ground by two distinct symbols, to emphasize that these are not necessarily at the same potential — as also indicated by the voltage difference ΔV. Now, one might be tempted to tie the two grounds to each other, but this would only result in a current flowing from one ground to the other, through the small (but nonzero) resistance of the wire connecting the two. The net effect of this ground loop would be that the voltage measured by the instrument would include the unknown ground voltage difference ΔV, as shown in Figure 5.11.8. Since this latter voltage is unpredictable, you can see that ground loops can cause substantial errors in measuring systems. In addition, ground loops are the primary cause of conducted noise, as explained later in this section.

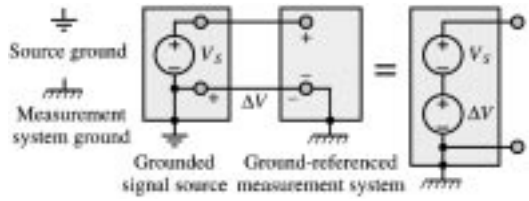

FIGURE 5.11.8 Ground loop in ground-referenced measurement system.

A differential measurement system is often a way to avoid ground loop problems because the signal source and measurement system grounds are not connected to each other, and especially because the signal low input of the measuring instrument is not connected to either instrument case ground. The connection of a grounded signal source and a differential measurement system is depicted in Figure 5.11.9.

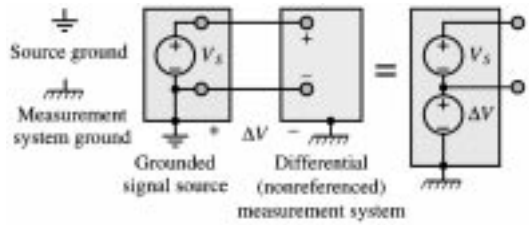

FIGURE 5.11.9 Differential (nonreferenced) measurement system.

If the signal source connected to the differential measurement system is floating, as shown in Figure 5.11.10, it is often a recommended procedure to reference the signal to the instrument ground by means of two identical resistors that can provide a return path to ground for any currents present at the instrument. An example of such input currents could be the input bias currents inevitably present at the input of an operational or instrumentation amplifier.

The simple concepts illustrated in the preceding paragraphs and figures can assist the user and designer of instrumentation systems in making the best possible wiring connections for a given measurement.

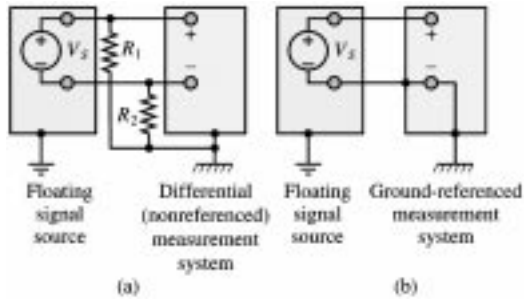

FIGURE 5.11.10 Measuring signals from a floating source: (a) differential input; (b) single-ended input.

Noise Sources and Coupling Mechanisms

Noise — meaning any undesirable signal interfering with a measurement — is an unavoidable element of all measurements. Figure 5.11.11 depicts a block diagram of the three essential stages of a noisy measurement: **a noise source, a noise coupling mechanism**, and a sensor or associated signal-conditioning circuit. Noise sources are always present and are often impossible to eliminate completely; typical sources of noise in practical measurements are the electromagnetic fields caused by fluorescent light fixtures, video monitors, power supplies, switching circuits, and high-voltage (or current) circuits. Many other sources exist, of course, but often the simple sources in our everyday environment are the most difficult to defeat.

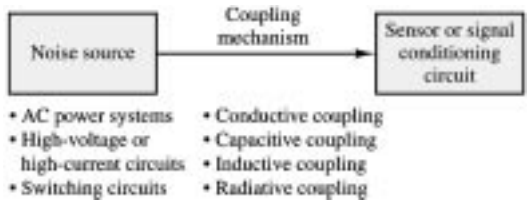

FIGURE 5.11.11 Noise sources and coupling mechanisms.

Figure 5.11.11 also indicates that various coupling mechanisms can exist between a noise source and an instrument. Noise coupling can be conductive; that is, noise currents may actually be conducted from the noise source to the instrument by physical wires. Noise can also be coupled capacitively, inductively and radiatively.

Figure 5.11.12 illustrates how interference can be **conductively coupled** by way of a ground loop. In the figure, a power supply is connected to both a load and a sensor. We shall assume that the load may be switched on and off, and that it carriers substantial currents. The top circuit contains a ground loop: the current i from the supply divides between the load and sensor; since the wire resistance is nonzero, a large current flowing through the load may cause the ground potential at point a to differ from the potential at point b. In this case, the measured sensor output is no longer, v_o, but it is now equal to $v_o + v_{ba}$, where v_{ba} is the potential difference from point b to point a. Now, if the load is switched on and off and its current is therefore subject to large, abrupt changes, these changes will be manifested in the voltage v_{ba} and will appear as noise on the sensor output.

This problem can be cured simply and effectively by providing separate *ground returns* for the load and sensor, thus eliminating the ground loop.

The mechanism of **capacitive coupling** is rooted in electric fields that may be caused by sources of interference. The detailed electromagnetic analysis can be quite complex, but to understand the principle, refer to Figure 5.11.13(a), where a noise source is shown to generate an electric field. If a noise source conductor is sufficiently close to a conductor that is part of the measurement system, the two conductors

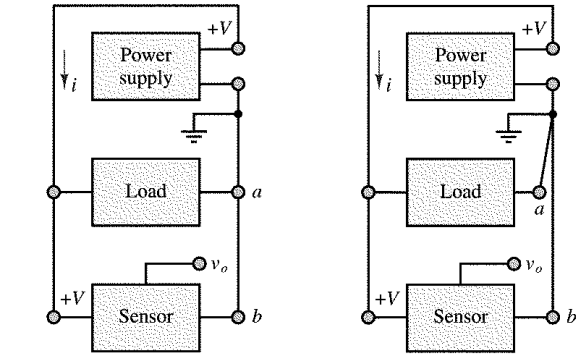

FIGURE 5.11.12 Conductive coupling: ground loop and separate ground returns.

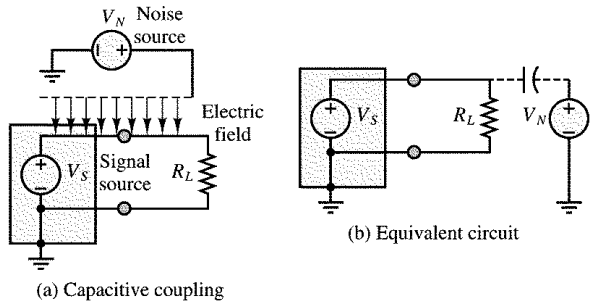

FIGURE 5.11.13 Capacitive coupling and equivalent-circuit representation.

(separated by air, a dielectric) will form a capacitor, through which any time-varying currents can flow. Figure 5.11.13(b) depicts an equivalent circuit in which the noise voltage V_N couples to the measurement circuit through an imaginary capacitor, representing the actual capacitance of the noise path.

The dual of capacitive coupling is **inductive coupling**. This form of noise coupling is due to the magnetic field generated by current flowing through a conductor. If the current is large, the magnetic fields can be significant, and the **mutual inductance** between the noise source and the measurement circuit causes the noise to couple to the measurement circuit. Thus, inductive coupling, as shown in Figure 5.11.14 results when undesired (unplanned) magnetic coupling ties the noise source to the measurement circuit.

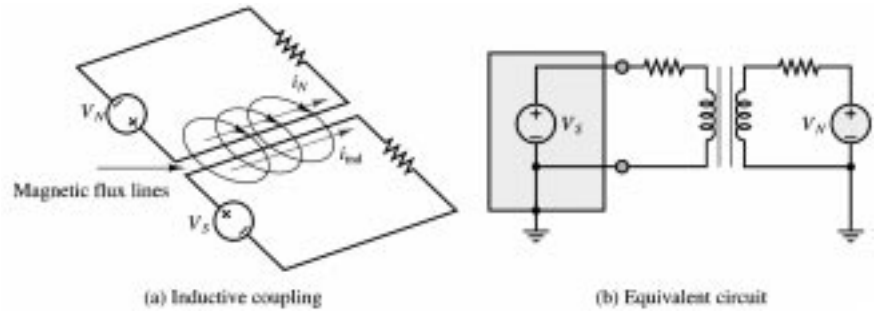

FIGURE 5.11.14 Inductive coupling and equalent-circuit representation.

Noise Reduction

Various techniques exist for minimizing the effect of undesired interference, in addition to proper wiring and grounding procedures. The two most common methods are **shielding** and the use of **twisted-pair wire**. A shielded cable is shown in Figure 5.11.15. The shield is made of a copper braid or of foil and is usually grounded at the source end, *but not at the instrument end*, because this would result in a ground loop. The shield can protect the signal from a significant amount of electromagnetic interference, especially at lower frequencies. Shielded cables with various numbers of conductors are available commercially. However, shielding cannot prevent inductive coupling. The simplest method for minimizing inductive coupling is the use of twisted-pair wire; the reason for using twisted pair is that untwisted wire can offer large loops that can couple a substantial amount of electromagnetic radiation. Twisting drastically reduces the loop area, and with it the interference. Twisted pair is available commercially.

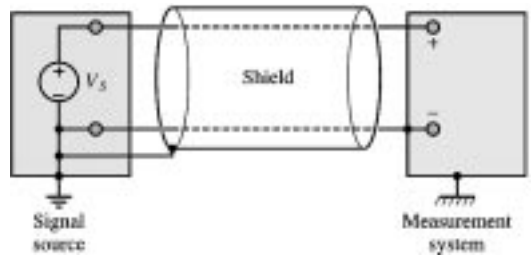

FIGURE 5.11.15 Shielding.

Signal Conditioning

A properly wired, grounded, and shielded sensor connection is a necessary first stage of any well-designed measurement system. The next stage consists of any **signal conditioning** that may be required to manipulate the sensor output into a form appropriate for the intended use. Very often, the sensor output is meant to be fed into a digital computer, as illustrated in Figure 5.11.1. In this case, it is important to condition the signal so that it is compatible with the process of data acquisition. Two of the most important signal-conditioning functions are *amplification* and *filtering*. Both are discussed in the present section.

Instrumentation Amplifiers

An **instrumentation amplifier** (IA) is a differential amplifier with very high input impedance, low bias current, and programmable gain that finds widespread application when low-level signals with large common-mode components are to be amplified in noisy environments. This situation occurs frequently when a low-level transducer signal needs to be preamplified, prior to further signal conditioning (e.g., filtering).

The functional structure of an IC instrumentation amplifier is depicted in Figure 5.11.16. Specifications for a common IC instrumentation amplifier (and a more accurate circuit description) are shown in Figure 5.11.17. Among the features worth mentioning here are the programmable gains, which the user can set by suitably connecting one or more of the resistors labeled R_1 to the appropriate connection. Note that the user may also choose to connect additional resistors to control the amplifier gain, without adversely affecting the amplifier's performance, since R_1 requires no matching. In addition to the pin connection that permits programmable gains, two additional pins are provided, called **sense** and **reference**. These additional connections are provided to the user for the purpose of referencing the output voltage to a signal other than ground, by means of the reference terminal, or of further amplifying the output current (e.g., with a transistor stage), by connecting the sense terminal to the output of the current amplifier.

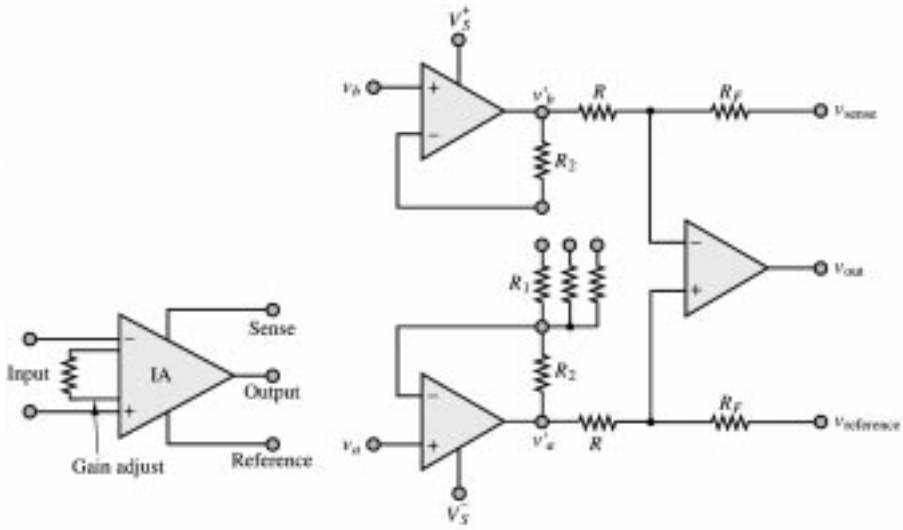

FIGURE 5.11.16 IC instrumentation amplifier.

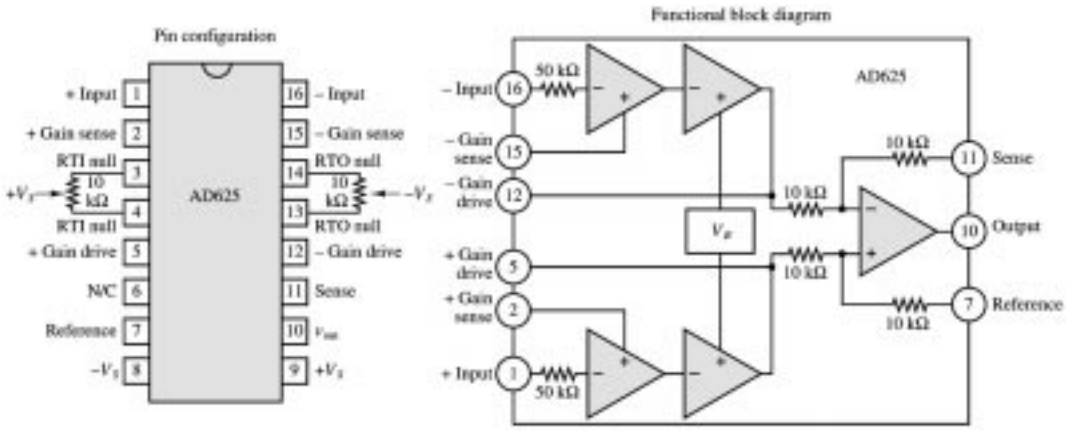

FIGURE 5.11.17 AD625 instrumentation amplifier data sheet.

Active Filters

The need to filter sensor signals that may be corrupted by noise or other interfering or undesired inputs has already been approached in two earlier chapters. In Section 5.6, simple passive filters made of resistors, capacitors, and inductors were analyzed. It was shown that three types of filter frequency response characteristics can be achieved with these simple circuits: low-pass, high-pass, and band-pass. In Section 5.9, the concept of active filters was introduced, to suggest that it may be desirable to exploit the properties of operational amplifiers to simplify filter design, to more easily match source and load impedances, and to eliminate the need for inductors. The aim of this section is to discuss more advanced active filter designs, which find widespread application in instrumentation circuits.

Figure 5.11.18 depicts the general characteristics of a low-pass active filter, indicating that within the pass-band of the filter, a certain deviation from the nominal filter gain, A, is accepted, as indicated by the minimum and maximum pass-band gains, $A + \varepsilon$ and $A - \varepsilon$. The width of the pass-band is indicated by the cutoff frequency, ω_c. On the other hand, the stop-band, starting at the frequency ω_s, does not

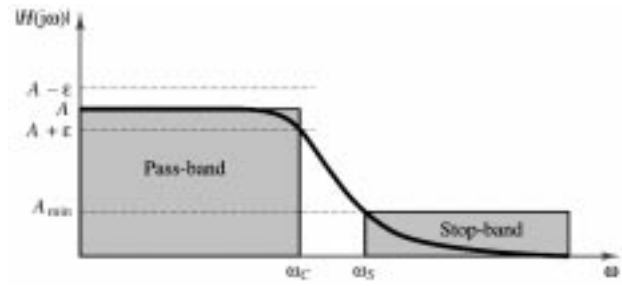

FIGURE 5.11.18 Prototype low-pass filter response.

allow a gain greater than A_{min}. Different types of filter designs achieve different types of frequency responses, which are typically characterized either by having a particularly flat pass-band frequency response (**Butterworth filters**) or by a very rapid transition between pass-band and stop-band (**Chebyshev filters**, and **Cauer**, or **elliptical, filters**), or by some other characteristic, such as a very linear phase response (**Bessel filters**). Achieving each of these properties usually involves trade-offs; for example, a very flat pass-band response will usually result in a relatively slow transition from pass-band to stop-band.

In addition to selecting a filter from a certain family, it is also possible to select the *order* of the filter; this is equal to the order of the differential equation that describes the input-output relationship of a given filter. In general, the higher the order, the faster the transition from pass-band to stop-band (at the cost of greater phase shifts and amplitude distortion, however). Although the frequency response of Figure 5.11.18 pertains to a low-pass filter, similar definitions also apply to the other types of filters.

Butterworth filters are characterized by a *maximally flat* pass-band frequency response characteristic; their response is defined by a magnitude-squared function of frequency:

$$\left|H(j\omega)\right|^2 = \frac{H_0^2}{1+\varepsilon^2\omega^{2n}} \tag{5.11.14}$$

where $\varepsilon = 1$ for maximally flat response and n is the order of the filter. Figure 5.11.19 depicts the frequency response (normalized to $\omega_c = 1$) of first-, second-, third-, and fourth-order Butterworth low-pass filters. The **Butterworth polynomials**, given in Table 5.11.3 in factored form, permit the design of the filter by specifying the denominator as a polynomial in s. For $s = j\omega$, one obtains the frequency response of the filter.

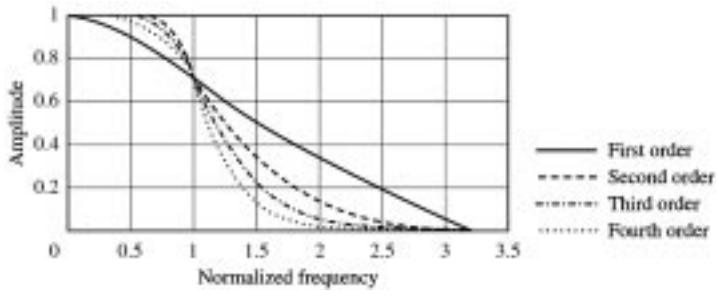

FIGURE 5.11.19 Butterworth low-pass filter frequency response.

Figure 5.11.20 depicts the normalized frequency response of first- to fourth-order low-pass Chebyshev filters ($n = 1$ to 4), for $\varepsilon = 1.06$. Note that a certain amount of ripple is allowed in the pass-band; the

TABLE 5.11.3 Butterworth Polynomials in Quadratic Form

Order, *n*	Quadratic Factors
1	$(s + 1)$
2	$(s^2 + \sqrt{2}s + 1)$
3	$(s + 1)\ (s^2 + s + 1)$
4	$(s^2 + 0.7654s + 1)\ (s^2 + 1.8478s + 1)$
5	$(s + 1)\ (s^2 + 0.6180s + 1)\ (s^2 + 1.6180s + 1)$

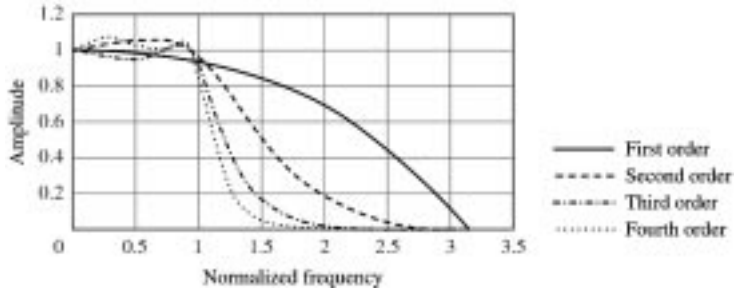

FIGURE 5.11.20 Chebyshev low-pass filter frequency response.

amplitude of the ripple is defined by the parameter ε and is constant throughout the pass-band. Thus, these filters are also called **equiripple filters**. Cauer, or elliptical, filters are similar to Chebyshev filters, except for being characterized by equiripple both in the pass-band and in the stop-band. Design tables exist to select the appropriate order of Butterworth, Chebyshev, or Cauer filter for a specific application.

Three common configurations of second-order active filters, which can be used to implement **second-order** (or **quadratic**) **filter sections** using a single of op-amp, are shown in Figure 5.11.21. These filters are called **constant-*K***, or **Sallen and Key, filters** (after the name of the inventors). The analysis of these active filters, although somewhat more involved than that of the active filters presented in the preceding chapter, is based on the basic properties of the ideal operational amplifier discussed earlier. Consider, for example, the low-pass filter of Figure 5.11.21. The first unusual aspect of the filter is the presence of both negative and **positive feedback**; that is, feedback connections are provided to both the inverting and the noninverting terminals of the op-amp. The analysis method consists of finding expressions for the input terminal voltages of the op-amp, V^+ and V^-, and using these expressions to derive the input-output relationship for the filter. The frequency response of the low-pass filter is given by

$$H(j\omega) = \frac{K\left(1/R_1R_2C_1C_2\right)}{(j\omega)^2 + \left[\frac{1}{R_1C_1} + \frac{1}{R_2C_1} + \frac{1}{R_2C_2}(1-K)\right] + \frac{1}{R_1R_2C_1C_2}} \tag{5.11.5}$$

This frequency response can be expressed in more general form as follows:

$$H(j\omega) = \frac{H_0\omega_C^2}{(j\omega)^2 + (\omega_C/Q)j\omega + \omega_C^2}$$

where

$$H_0 = K \tag{5.11.6}$$

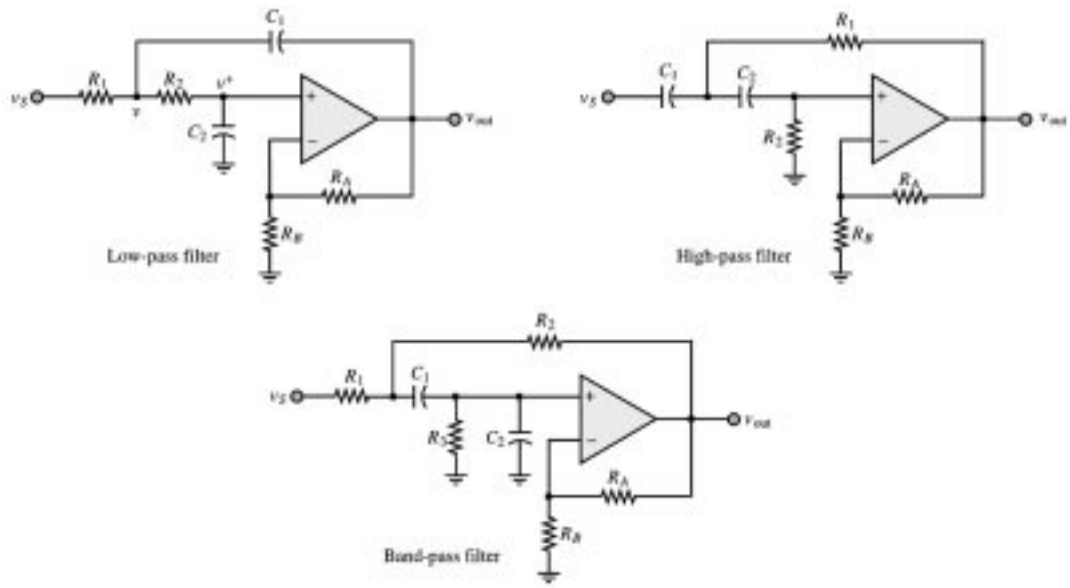

FIGURE 5.11.21 Sallen and Key active filters.

is the DC gain of the filter, and where

$$\omega_C = \sqrt{\frac{1}{R_1 R_2 C_1 C_2}}$$

is the cutoff frequency, and where

$$\frac{1}{Q} = \sqrt{\frac{R_2 C_1 C_2}{R_1 C_1}} + \sqrt{\frac{R_1 C_2}{R_2 C_1}} + (1 - K)\sqrt{\frac{R_1 C_1}{R_2 C_2}} \tag{5.11.17}$$

is the inverse of the **quality factor**, Q. The Q of a filter is related to the overshoot in the transient response of the filter; and to the peaking (i.e., sharpness of the resonant peak) of the frequency response, a high-Q circuit will display more peaking, or overshoot, than a low-Q circuit.

Analog-to-Digital and Digital-to-Analog Conversion

To take advantage of the capabilities of a microcomputer, it is necessary to suitably interface signals to and from external devices with the microcomputer. Such signals may be analog or digital. Depending on the nature of the signal, either an analog or a digital interface circuit will be required. The advantages in memory storage, programming flexibility, and computational power afforded by today's digital computers are such that the instrumentation designer often chooses to convert an analog signal to an equivalent digital representation, to exploit the capabilities of a microprocessor in processing the signal. In many cases, the data converted from analog to digital form remain in digital form for ease of storage, or for further processing. In some instances it is necessary to convert the data back to analog form. The latter condition arises frequently in the context of control system design, where an analog measurement is converted to digital form and processed by a digital computer to generate a control action (e.g., raising or lowering the temperature of a process, or exerting a force or a torque); in such cases, the output of the digital computer is converted back to analog form, so that a continuous signal becomes available to

the actuators. Figure 5.11.22 illustrates the general appearance of a digital measuring instrument and of a digital controller acting on a plant or process.

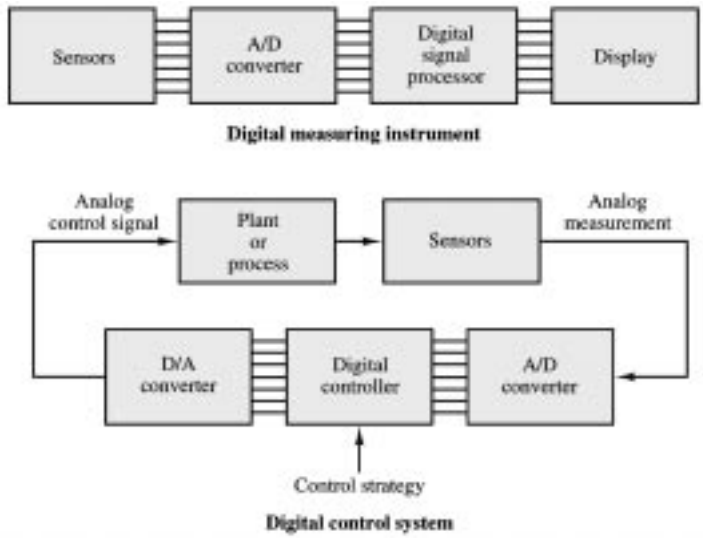

FIGURE 5.11.22 Block diagrams of a digital measuring instrument and a digital control system.

The objective of this section is to describe how the digital-to-analog (D/A) and analog-to-digital (A/D) conversion blocks of Figure 5.11.22 function. After illustrating discrete circuits that can implement simple A/D and D/A converters, we shall emphasize the use of ICs specially made for these tasks. Nowadays, it is uncommon (and impractical) to design such circuits using discrete components: the performance and ease of use of IC packages make them the preferred choice in virtually all applications.

Digital-to-Analog Converters

We discuss digital-to-analog conversion first because it is a necessary part of analog-to-digital conversion in many A/D conversion schemes. A **digital-to-analog converter** (DAC) will convert a binary word to an analog output voltage (or current). The binary word is represented in terms of 1s and 0s, where typically (but not necessarily) 1s correspond to a 5-V level and 0s to a 0-V signal. As an example, consider a four-bit binary word:

$$B = \left(b_3 b_2 b_1 b_0\right)_2 = \left(b_3 \cdot 2^3 + b_2 \cdot 2^2 + b_1 \cdot 2^1 + b_0 \cdot 2^0\right)_{10} \tag{5.11.8}$$

The analog voltage corresponding to the digital word B would be

$$v_a = \left(8b_3 + 4b_2 + 2b_1 + b_0\right)\delta v \tag{5.11.9}$$

where δv is the smallest *step size* by which v_a can increment. This least step size will occur whenever the least significant bit (LSB), b_0, changes from 0 to 1, and is the smallest increment the digital number can make. We shall also shortly see that the analog voltage obtained by the D/A conversion process has a "staircase" appearance because of the discrete nature of the binary signal.

The step size is determined on the basis of each given application and is usually determined on the basis of the number of bits in the digital word to be converted to an analog voltage. We can see that, by extending the previous example for an n-bit word, the maximum value v_a can attain is

$$v_{a\max} = \left(2^{n-1} + 2^{n-2} + \ldots + 2^1 + 2^0\right)\delta v$$
$$= \left(2^n - 1\right)\delta v \tag{5.11.10}$$

It is relatively simple to construct a DAC by taking advantage of the summing amplifier illustrated in Section 5.9. Consider the circuit shown in Figure 5.11.23, where each bit in the word to be converted is represented by means of a 5-V source and a switch. When the switch is closed, the bit takes a value of 1 (5 V); when the switch is not closed, the bit has value 0. Thus, the output of the DAC is proportional to the word $b_{n-1}\ldots b_{n-2}\ldots b_1 b_0$.

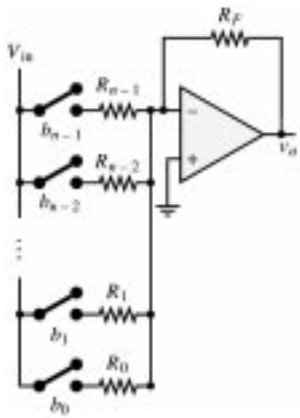

FIGURE 5.11.23 *n*-bit digital-to-analog converter (DAC).

If we select

$$R_i = \frac{R_0}{2^i} \tag{5.11.11}$$

we can obtain weighted gains for each bit so that

$$v_a = -\frac{R_F}{R_0}\left(2^{n-1}b_{n-1} + \ldots + 2^1 b_1 + 2^0 b_0\right)\cdot 5\ \text{V} \tag{5.11.12}$$

and so that the analog output voltage is proportional to the decimal representation of the binary word.

The practical design of a DAC is generally not carried out in terms of discrete components, because of problems such as the accuracy required of the resistor value. Many of the problems associated with this approach can be solved by designing the complete DAC circuit in integrated circuit (IC) form. The specifications stated by the IC manufacturer include the resolution, that is, the minimum nonzero voltage; the full-scale accuracy; the output range; the output settling time; the power supply requirements; and the power dissipation. The following example illustrates the use of a common integrated circuit DAC.

Example 5.11.1

A typical DAC one would use in conjunction with the 8086 microprocessor is the AD558. This is an IC that can be used in a "stand-alone" configuration (without a microprocessor) or with a microprocessor interfaced to it.

1. If one were to set up the AD558 for an output swing of 0 to 10 V, what would be the smallest voltage output increment attainable?

2. On what is the maximum operating frequency (the largest frequency on which the DAC can perform conversion) of the AD558 dependent? Determine the maximum frequency attainable if the converter is to be run at full-scale input.

Solution.

1. Since this DAC is an eight-bit device, the total number of digital increments one could expect is 256. Thus, the finest voltage steps one could expect at the output would be

$$\frac{10}{255} = 39.2 \text{ mV}$$

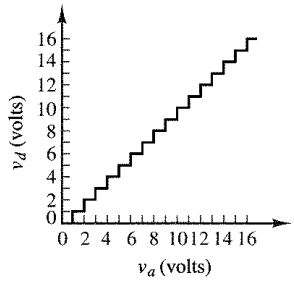
   This means that for every increment of one bit, the output would jump (in a stepwise fashion) by 39.2 mV.
2. The maximum frequency at which a DAC can run is dependent on the settling time. This is defined as the time it takes for the output to settle to within one half of the least significant bit of its final value. Thus, only one transition can be made per settling time. The settling time for the AD558 depends on the voltage range and is defined for a positive-going full-scale step to ±1/2 LSB. The settling time is 1 μsec, and the corresponding maximum conversion frequency is 1 MHz.

Analog-to-Digital Converters

You should by now have developed an appreciation for the reasons why it is convenient to process data in digital form. The device that makes conversion of analog signals to digital form is the **analog-to-digital converter** (ADC), and, just like the DAC, it is also available as a single IC package. In addition to discussing analog-to-digital conversion, we shall also introduce the *sample-and-hold amplifier.*

Quantization. The process of converting an analog voltage (or current) to digital form requires that the analog signal be quantized and encoded in binary form. The process of **quantization** consists of subdividing the range of the signal into a finite number of intervals; usually, one employs $2^n - 1$ intervals, where n is the number of bits available for the corresponding binary word. Following this quantization, a binary word is assigned to each interval (i.e., to each range of voltages or currents); the binary word is then the digital representation of any voltage (current) that falls within that interval. You will note that the smaller the interval, the more accurate the digital representation is. However, some error is necessarily always present in the conversion process; this error is usually referred to as **quantization error**. Let v_a represent the analog voltage and v_d its quantized counterpart, as shown in Figure 5.11.24 for an analog voltage in the range 0 to 0 16 V. In the figure, the analog voltage v_a takes on a value of $v_d = 0$ whenever it is in the range 0 to 1 V; for $1 \le v_a < 2$, the corresponding value is $v_d = 1$; for $2 \le v_a < 3$, $v_d = 2$; and so on, until, for $15 \le v_a < 16$, we have $v_d = 15$. You see that if we now represent the quantized voltage v_d by its binary counterpart, as shown in the table of Figure 5.11.24, each 1-V analog interval corresponds to a unique binary word. In this example, a four-bit word is sufficient to represent the analog voltage, although the representation is not very accurate. As the number of bits increases, the quantized voltage is closer and closer to the original analog signal; however, the number of bits required to represent the quantized value increases.

Tracking ADC. Although not the most efficient in all applications, the **tracking ADC** is an easy starting point to illustrate the operation of an ADC, in that it is based on the DAC presented in the previous section. The tracking ADC, shown in Figure 5.11.25, compares the analog input signal with the output of a DAC; the comparator output determines whether the DAC output is larger or smaller than the analog input to be converted to binary form. If the DAC output is smaller, then the comparator output will cause an up-down counter to count up, until it reaches a level close to the analog signal; if the DAC output is larger than the analog signal, then the counter is forced to count down. Note that the rate at which the up-down counter is incremented is determined by the external clock, and that the binary counter output



Quantized voltage / Binary representation

v_d	b_3	b_2	b_1	b_0
0	0	0	0	0
1	0	0	0	1
2	0	0	1	0
3	0	0	1	1
4	0	1	0	0
⋮			⋮	
14	1	1	1	0
15	1	1	1	1

FIGURE 5.11.24 A digital voltage representation of an analog voltage.

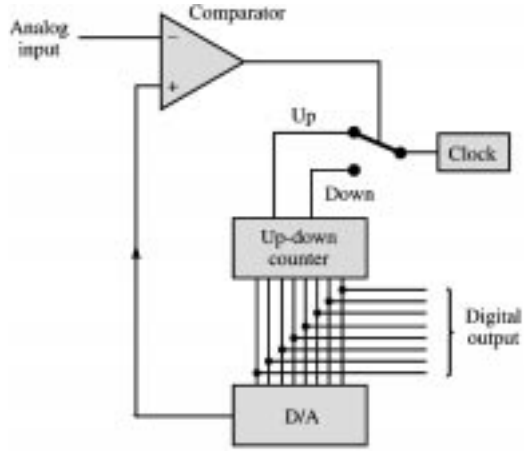


FIGURE 5.11.25 Tracking ADC.

corresponds to the binary representation of the analog signal. A feature of the tracking ADC is that it follows ("tracks") the analog signal by changing one bit at a time.

Integrating ADC. The **integrating ADC** operates by charging and discharging a capacitor, according to the following principle: if one can ensure that the capacitor charges (discharges) linearly, then the time it will take for the capacitor to discharge is linearly related to the amplitude of the voltage that has charged the capacitor. In practice, to limit the time it takes to perform a conversion, the capacitor is not required to charge fully. Rather, a clock is used to allow the input (analog) voltage to charge the capacitor for a short period of time, determined by a fixed number of clock pulses. Then the capacitor is allowed to discharge through a known circuit, and the corresponding clock count is incremented until the capacitor is fully discharged. The latter condition is verified by a comparator, as shown in Figure 5.11.26. The clock count accumulated during the discharge time is proportional to the analog voltage.

In the figure, the switch causes the counter to reset when it is connected to the reference voltage, V_{ref}. The reference voltage is used to provide a known, linear discharge characteristic through the capacitor (see the material on the op-amp integrator in Section 5.9. When the comparator detects that the output of the integrator is equal to zero, it switches state and disables the NAND gate, thus stopping the count. The binary counter output is now the digital counterpart of the voltage v_a.

Other common types of ADC are the so-called successive-approximation ADC and the flash ADC.

Flash ADC. The **flash ADC** is fully parallel and is used for high-speed conversion. A resistive divider network of $2''$ resistors divides the known voltage range into that many equal increments. A network of

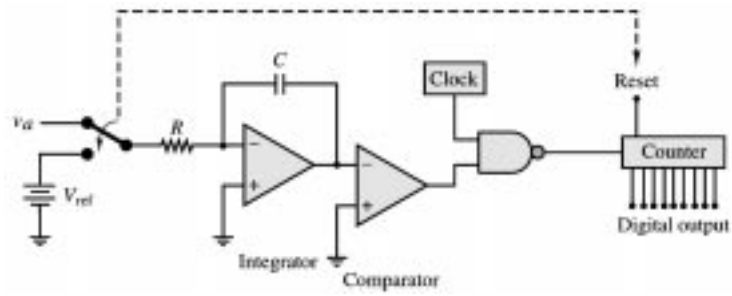

FIGURE 5.11.26 Integrating ADC.

$2'' - 1$ comparators then compares the unknown voltage with that array of test voltages. All comparators with inputs exceeding the unknown are "on"; all others are "off". This comparator code can be converted to conventional binary by a digital priority encoder circuit. For example, assume that the three-bit flash ADC of Figure 5.11.27 is set up with V_{ref} = 8 V. An input of 6.2 V is provided. If we number the comparators from the top of Figure 5.11.27, the state of each of the seven comparators is as given in Table 5.11.4.

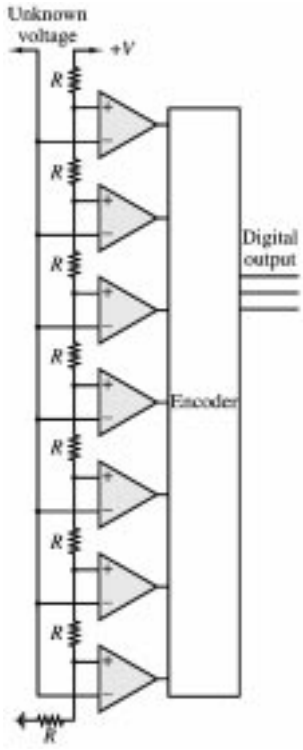

FIGURE 5.11.27 A three-bit flash ADC.

To resolve the uncertainty generated by the finite ADC conversion time of any practical converter, it is necessary to use a sample-and-hold amplifier. The objective of such an amplifier is to "freeze" the value of the analog waveform for a time sufficient for the ADC to complete its task.

A typical sample-and-hold amplifier is shown in Figure 5.11.28. It operates as follows. A MOSFET analog switch is used to "sample" the analog waveform. Recall that when a voltage pulse is provided to the sample input of the MOSFET switch (the gate), the MOSFET enters the ohmic region and in effect becomes nearly a short circuit for the duration of the sampling pulse. While the MOSFET conducts,

TABLE 5.11.4 State of Comparators in a 3-Bit Flash ADC

Comparator	Input on + Line	Input on – Line	Output
1	7 V	6.2 V	H
2	6 V	6.2 V	L
3	5 V	6.2 V	L
4	4 V	6.2 V	L
5	3 V	6.2 V	L
6	2 V	6.2 V	L
7	1 V	6.2 V	L

the analog voltage, v_a, charges the "hold" capacitor, C, at a fast rate through the small "on" resistance of the MOSFET. The duration of the sampling pulse is sufficient to charge C to the voltage v_a. Because the MOSFET is virtually a short circuit for the duration of the sampling pulse, the charging (RC) time constant is very small, and the capacitor charges very quickly. When the sampling pulse is over, the MOSFET returns to its nonconducting state, and the capacitor holds the sampled voltage without discharging, thanks to the extremely high input impedance of the voltage-follower (buffer) stage. Thus, v_{SH} is the sampled-and-held value of v_a at any given sampling time.

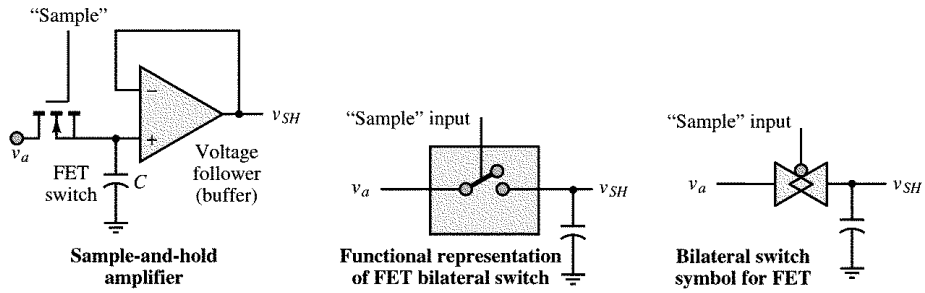

FIGURE 5.11.28 Description of the sample-and-hold process.

The appearance of the output of a typical sample-and-hold circuit is shown in Figure 5.11.29, together with the analog signal to be sampled. The time interval between samples, or **sampling interval**, $t_n - t_{n-1}$, allows the ADC to perform the conversion and make the digital version of the sampled signal available, say, to a computer or to another data acquisition and storage system. The sampling interval needs to be at least as long as the A/D conversion time, of course, but it is reasonable to ask how frequently one needs to sample a signal to preserve its fundamental properties (e.g., peaks and valleys, "ringing", fast transition). One might instinctively be tempted to respond that it is best to sample as frequently as possible, within the limitations of the ADC, so as to capture all the features of the analog signal. In fact, this is not necessarily the best strategy. How should we select the appropriate sampling frequency for a given application? Fortunately, an entire body of knowledge exists with regard to sampling theory, which enables the practicing engineer to select the best sampling rate for any given application. Given the scope of this chapter, we have chosen not to delve into the details of sampling theory, but, rather, to provide the student with a statement of the fundamental result: the **Nyquist sampling criterion**. The Nyquist criterion states that to prevent aliasing** when sampling a signal, *the sample rate should be selected to be at least twice the highest-frequency component present in the signal*. Thus, if we were sampling an audio signal (say, music), we would have to sample at a frequency of at least 40 kHz (twice the highest audible frequency, 20 kHz). In practice, it is advisable to select sampling frequencies substantially greater than the Nyquist rate; a good rule of thumb is five to ten times greater. The following

** Aliasing is a form of signal distortion that occurs when an analog signal is sampled at an insufficient rate.

example illustrates how the designer might take the Nyquist criterion into account in designing a practical A/D conversion circuit.

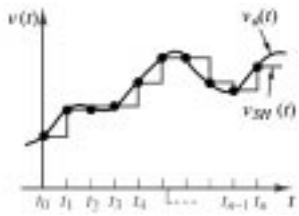

FIGURE 5.11.29 Sampled data.

Example 5.11.2

A typical ADC one would use in conjunction with the 8086 microprocessor is the AD574. This is a successive-approximation converter.

1. What is the accuracy (in volts) the AD574 can provide if $V_{CC} =$ 15.0 V and $0 \le \text{Vin} \le 15.0$ V?
2. On the basis of the data sheet, what is the highest-frequency signal you could convert using the AD574? (Assume that $V_{CC} =$ 15.0 V.)
3. If the maximum conversion time available were 40 msec, what would be the highest-frequency signal you could expect to sample on the basis of the Nyquist criterion?

Solution.

1. According to the data sheet, the least significant bit (LSB) of this converter limits its accuracy, meaning that the output is accurate within ± 1 bit. For the 0- to 15-V swing, this gives a voltage accuracy of

$$\frac{V_{\max} - V_{\min}}{2^n - 1} \quad \text{or} \quad \frac{15}{2^{12} - 1} \times (\pm 1 \text{ bit}) = \pm 3.66 \text{ mV}$$

2. On the basis of the data sheet, the maximum conversion time is 35 μsec. Therefore, the highest frequency of data conversion using the AD574 is

$$f_{\max} = \frac{1}{35\ \mu\text{s}} = 28.57 \text{ kHz}$$

   Thus, the highest signal frequency that could be represented, according to the Nyquist principle, is

$$\frac{1}{2} f_{\max} = \frac{28.57 \times 10^3}{2} = 14.285 \text{ kHz}$$

   This is the maximum theoretical signal frequency that can be represented without distortion, according to the Nyquist principle.
3. Following the same procedure discussed in part 2,

$$\frac{1}{2} f_{\max} = \left(\frac{1}{40 \times 10^{-6}}\right)\left(\frac{1}{2}\right) = 12.5 \text{ kHz}$$

Data Acquisition Systems

A typical data acquisition system, shown in Figure 5.11.30, often employs an *analog multiplexer*, to process several different input signals. A bank of bilateral analog MOSFET switches provides a simple

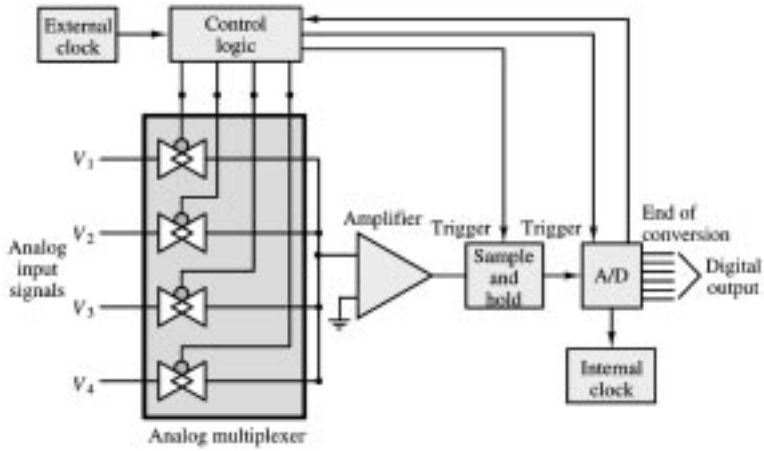

FIGURE 5.11.30 Data acquisition system.

and effective means of selecting which of the input signals should be sampled and converted to digital form. Control logic, employing standard gates and counters, is used to select the desired *channel* (input-signal) and to trigger the sampling circuit and the ADC. When the A/D conversion is completed, the ADC sends an appropriate *end of conversion* signal to the control logic, thereby enabling the next channel to be sampled.

In the block diagram of Figure 5.11.30, four analog inputs are shown; if these were to be sampled at regular intervals, the sequence of events would appear as depicted in Figure 5.11.31. We notice, from a qualitative analysis of the figure, that the effective sampling rate for each channel is one fourth the actual external clock rate; thus, it is important to ensure that the sampling rate for each individual channel satisfies the Nyquist criterion. Further, although each sample is held for four consecutive cycles of the external clock, we must notice that the ADC can use only one cycle of the external clock to complete the conversion, since its services will be required by the next channel during the next clock cycle. Thus, the internal clock that times the ADC must be sufficiently fast to allow for a complete conversion of any sample within the design range.

Timer ICs: the NE555

This section introduces a multipurpose integrated circuit that can perform basic timing functions. The NE555 is a timer circuit capable of producing accurate time delays (pulses) or oscillation. In the time-delay, or monostable, mode, the time delay or pulse duration is controlled by an external RC network. In the astable, or clock generator, mode, the frequency is controlled by two external resistors and one capacitor. Figure 5.11.32 depicts typical circuits for monostable and astable operation of the NE555. Note that the threshold level and the trigger level can also be externally controlled. For the monostable circuit, the pulse width can be computed from the following equation:

$$T = 1.1R_1C \tag{5.11.13}$$

For the astable circuit, the positive pulse width can be computed from the following equation:

$$T_+ = 0.69\left(R_1 + R_2\right)C \tag{5.11.14}$$

and the negative pulse width can be computed from

$$T_- = 0.69R_2C \tag{5.11.15}$$

Data Transmission in Digital Instruments

One of the necessary aspects of data acquisition and control systems is the ability to transmit and receive data. Often, a microcomputer-based data acquisition system is interfaced to other digital devices, such as digital instruments or other microcomputers. In these cases it is necessary to transfer data directly in digital form. In fact, it is usually preferable to transmit data that are already in digital form, rather than analog voltages or currents. Among the chief reasons for the choice of digital over analog is that digital data are less sensitive to noise and interference than analog signals: in receiving a binary signal transmitted over a data line, the only decision to be made is whether the value of a bit is 0 or 1. Compared with the difficulty in obtaining a precise measurement of an analog voltage or current, either of which could be corrupted by noise or interference in a variety of ways, the probability of making an error in discerning between binary 0s and 1s is very small. Further, as will be shown shortly, digital data are often coded in such a way that many transmission errors may be detected and corrected for. Finally,

storage and processing of digital data are much more readily accomplished than would be the case with analog signals. This section explores a few of the methods that are commonly employed in transmitting digital data; both parallel and serial interfaces are considered.

Digital signals in a microcomputer are carried by a bus, consisting of a set of parallel wires each carrying one bit of information. In addition to the signal-carrying wires, there are also control lines that determine under what conditions transmission may occur. A typical computer data bus consists of eight parallel wires and therefore enables the transmission of one byte; digital data are encoded in binary according to one of a few standard codes, such as the BCD code described in Section 5.10, or the ASCII code, which is summarized in Table 5.11.5. This bus configuration is usually associated with **parallel transmission**, whereby all of the bits are transmitted simultaneously, along with some control bits.

Figure 5.11.33 depicts the general appearance of a parallel connection. Parallel data transmission can take place in one of two modes: **synchronous** or **asynchronous**. In synchronous transmission, a timing clock pulse is transmitted along with the data over a control line. The arrival of the clock pulse indicates that valid data have also arrived. While parallel synchronous transmission can be very fast, it requires the added complexity of a synchronizing clock and is typically employed only for internal computer data transmission. Further, this type of communication can take place only over short distances (approximately 4 m). Asynchronous data transmission, on the other hand, does not take place at a fixed clock rate, but requires a **handshake protocol** between sending and receiving ends. The handshake protocol consists of the transmission of *data ready* and *acknowledge* signals over two separate control wires. Whenever the sending device is ready to transmit data, it sends a pulse over the *data ready* line. When this signal reaches the receiver, and if the receiver is ready to receive the data, an *acknowledge* pulse is sent back, indicating that the transmission may occur; at this point, the parallel data are transmitted.

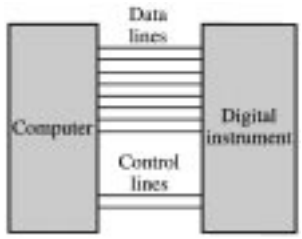

FIGURE 5.11.33 Parallel data transmission.

Perhaps the most common parallel interface is based on the **IEEE 488 standard**, leading to the so-called IEEE 488 bus, also referred to as GPIB (for **general-purpose instrument bus**).

The IEEE 488 Bus

The IEEE 488 bus, shown in Figure 5.11.34, is an eight-bit parallel asynchronous interface that has found common application in digital instrumentation applications. The physical bus consists of 16 lines, of which 8 are used to carry the data, 3 for the handshaking protocol, and the rest to control the data flow. The bus permits connection of up to 15 instruments and data rates of up to 1 Mbyte/sec. There is a limitation, however, in the maximum total length of the bus cable, which is 20 m. The signals transmitted are TTL-compatible and employ negative logic, whereby a logic 0 corresponds to a TTL high state (>2 V) and a logic 1 to a TTL low state (<0.8 V). Often, the eight-bit word transmitted over an IEEE 488 bus is coded in ASCII format (see Table 5.11.5).

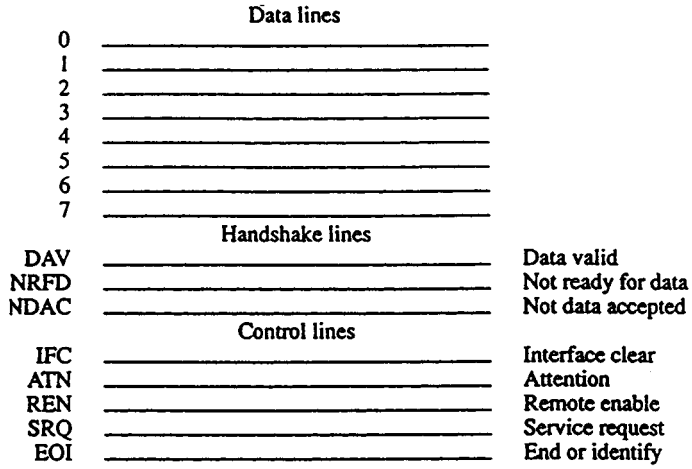

FIGURE 5.11.34 IEEE 488 bus.

In an IEEE 488 bus system, devices may play different roles and are typically classified as *controllers*, which manage the data flow; *talkers* (e.g., a digital voltmeter), which can only send data; *listeners* (e.g., a printer), which can only receive data; and *talkers/listeners* (e.g., a digital oscilloscope), which can receive as well as transmit data. The simplest system configuration might consist of just a talker and a listener. If more than two devices are present on the bus, a controller is necessary to determine when and how data transmission is to occur on the bus. For example, one of the key rules implemented by the controller is that only one talker can transmit at any one time; it is possible, however, for several listeners to be active on the bus simultaneously. If the data rates of the different listeners are different, the talker will have to transmit at the slowest rate, so that all of the listeners are assured of receiving the data correctly.

The set of rules by which the controller determines the order in which talking and listening are to take place is determined by a **protocol**. One aspect of the protocol is the handshake procedure, which enables the transmission of data. Since different devices (with different data rate capabilities) may be listening to the same talker, the handshake protocol must take into account these different capabilities. Let us discuss a typical handshake sequence that leads to transmission of data on an IEEE 488 bus. The three handshake lines used in the IEEE 488 have important characteristics that give the interface system wide flexibility, allowing interconnection of multiple devices that may operate at different speeds. The slowest active device controls the rate of data transfer, and more than one device can accept data simultaneously. The timing diagram of Figure 5.11.35 is used to illustrate the sequence in which the handshake and data transfer are performed:

1. All active listeners use the not ready for data (NRFD) line to indicate their state of readiness to accept a new piece of information. Nonreadiness to accept data is indicated if the NRFD line is held at 0 V. If even one active listener is not ready, the NRFD line of the entire bus is kept at 0 V and the active talker will not transmit the next byte. When all active listeners are ready and they have released the NRFD line, it now goes high.
2. The designated talker drives all eight data input/output lines, causing valid data to be placed on them.
3. Two microseconds after putting valid data on the data lines, the active talker pulls the data valid (DAV) line to 0 V and thereby signals the active listeners to read the information on the data bus. The 2-μsec interval is required to allow the data put on the data lines to reach (settle to) valid logic levels.
4. After the DAV is asserted, the listeners respond by pulling the NRFD line back down to zero. This prevents any additional data transfers from being initiated. The listeners also begin accepting the data byte at their own rates.
5. When each listener has accepted the data, it releases the not data accepted (NDAC) line. Only when the last active listener has released its hold on the NDAC line will that line go to its high-voltage-level state.
6. (a) When the active talker sees that NDAC has come up to its high state, it stops driving the data line. (b) At the same time, the talker releases the DAV line, ending the data transfer. The talker may now put the next byte on the data bus.
7. The listeners pull down the NDAC line back to 0 V and put the byte “away”.

Each of the instruments present on the data bus is distinguished by its own address, which is known to the controller; thus, the controller determines who the active talkers and listeners are on the bus by *addressing* them. To implement this and other functions, the controller uses the five control lines. Of these, ATN (attention) is used as a switch to indicate whether the controller is addressing or instructing the devices on the bus, or whether data transmission is taking place: when ATN is logic 1, the data lines contain either control information or addresses; with ATN = 1, only the controller is enabled to talk. When ATN = 0, only the devices that have been addressed can use the data lines. The IFC (interface clear) line is used to initialize the bus, or to clear it and reset it to a known condition in case of incorrect transmission. The REN (remote enable) line enables a remote instrument to be controlled by the bus;

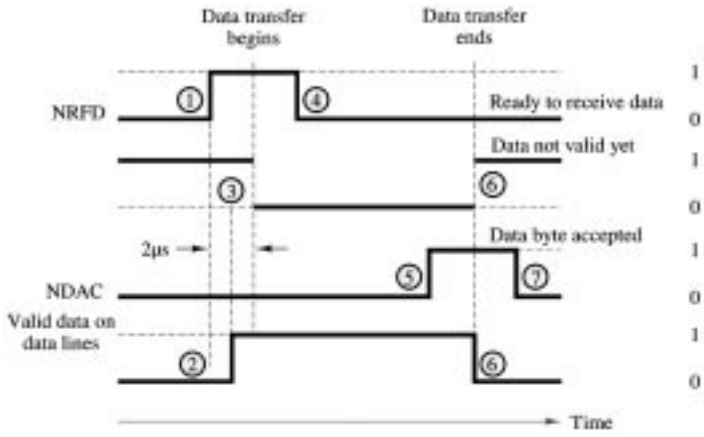

FIGURE 5.11.35 IEEE 488 data transmission protocol.

thus, any function that might normally be performed manually on the instrument (e.g., selecting a range or mode of operation) is now controlled by the bus via the data lines. The SRQ (service request) line is used by instruments on the bus whenever the instrument is ready to send or receive data; however, it is the controller who decides when to service the request. Finally, the EOI (end or identify) line can be used in two modes; when it is used by a talker, it signifies the end of a message; when it is used by the controller, it serves as a *polling* line, that is, a line used to interrogate the instrument about its data output.

Although it was mentioned earlier that the IEEE 488 bus can be used only over distances of up to 20 m, it is possible to extend its range of operation by connecting remote IEEE 488 bus systems over telephone communication lines. This can be accomplished by means of *bus extenders*, or by converting the parallel data to serial form (typically, in RS-232 format) and by transmitting the serial data over the phone lines by means of a modem. Serial communications and the RS-232 standard are discussed in the next section.

The RS-232 Standard

The primary reason why parallel transmission of data is not used exclusively is the limited distance range over which it is possible to transmit data on a parallel bus. Although there are techniques which permit extending the range for parallel transmission, these are complex and costly. Therefore, **serial transmission** is frequently used whenever data is to be transmitted over a significant distance. Since serial data travel along one single path and are transmitted one bit at a time, the cabling costs for long distances are relatively low; further, the transmitting and receiving units are also limited to processing just one signal and are also much simpler and less expensive. Two modes of operation exist for serial transmission: **simplex**, which corresponds to transmission in one direction only; and **duplex**, which permits transmission in either direction. Simplex transmission requires only one receiver and one transmitter, at each end of the link; on the other hand, duplex transmission can occur in one of two manners: **half-duplex** and **full-duplex**. In the former, although transmission can take place in both directions, it cannot occur simultaneously in both directions; in the latter case, both ends can simultaneously transmit and receive. Full-duplex transmission is usually implemented by means of four wires.

The data rate of a serial transmission line is measured in bits per second, since the data are transmitted one bit at a time. The unit of 1 bit/sec is called a **baud**; thus, reference is often made to the baud rate of a serial transmission. The baud rate can be translated into a parallel transmission rate in words per second if the structure of the word is known; for example, if a word consists of 10 bits (start and stop bits plus an 8-bit data word) and the transmission takes place at 1200 baud, 120 words are being transmitted every second. Typical data rates for serial transmission are standardized; the most common rates (familiar to the users of personal computer modem connections) are 300, 600, 1200, and 2400 baud. Baud rates can be as low as 50 baud or as high as 19,200 baud.

Like parallel transmission, serial transmission can also occur either synchronously or asynchronously. In the serial case, it is also true that asynchronous transmission is less costly but not as fast. A handshake protocol is also required for asynchronous serial transmission, as explained in the following. The most popular data-coding scheme for serial transmission is, once again, the ASCII code, consisting of a 7-bit word plus a **parity bit**, for a total of 8 bits per character. The role of the parity bit is to permit error detection in the event of erroneous reception (or transmission) of a bit. To see this, let us discuss the sequence of handshake events for asynchronous serial transmission and the use of parity bits to correct for errors. In serial asynchronous systems, handshaking is performed by using start and stop bits at the beginning and end of each character that is transmitted. The beginning of the transmission of a serial asynchronous word is announced by the "start" bit, which is always a 0-state bit. For the next five to eight successive bit times (depending on the code and the number of bits that specify the word length in the code), the line is switched to the 1 and 0 states required to represent the character being sent. Following the last bit of the data and the parity bit (which will be explained next), there is 1 bit or more in the 1 state, indicating "idle". The time period associated with this transmission is called the "stop" bit interval.

If noise pulses affect the transmission line, it is possible that a bit in the transmission could be misread. Thus, following the 5 to 8 transmitted data bits, there is a party bit that is used for error detection. Here is how the parity bit works. If the transmitter keeps track of the number of 1s in the word being sent, it can send a parity bit, a 1 or a 0, to ensure that the total number of 1s sent is always even (even parity) or odd (odd parity). Similarly, the receiver can keep track of the 1s received to see whether there was an error with the transmission. If an error is detected, retransmission of the word can be repeated.

Serial data transmission occurs most frequently according to the **RS-232 standard**. The RS-232 standard is based on the transmission of voltage pulses at a preselected baud rate; the voltage pulses are in the range –3 to –15 V for a logic 0 and in the range of +3 to +15 V for a logic 1. It is important to note that this amounts to a negative logic convention and that the signals are *not* TTL-compatible. The distance over which such transmission can take place is up to approximately 17 m (50 ft). The RS-232 standard was designed to make the transmission of digital data compatible with existing telephone lines; since phone lines were originally designed to carry analog voice signals, it became necessary to establish some standard procedures to make digital transmission possible over them. The resulting standard describes the mechanical and electrical characteristics of the interface between *data terminal equipment* (DTE) and *data communication equipment* (DCE). DTE consists of computers, terminals, digital instruments, and related peripherals; DCE includes all of those devices that are used to encode digital data in a format that permits their transmission over telephone lines. Thus, the standard specified how data should be presented by the DTE to the DCE so that digital data can be transmitted over voice lines.

A typical example of DCE is the **modem**. A modern converts digital data to audio signals that are suitable for transmission over a telephone line and is also capable of performing the reverse function, by converting the audio signals back to digital form. The term *modem* stands for *mod*ulate-*dem*odulate, because a modem modulates to a sinusoidal carrier using digital pulses (for transmission) and demodulates the modulated sinusoidal signal to recover the digital pulses (at reception). Three methods are commonly used for converting digital pulses to an audio signal: **amplitude-shift keying, frequency-shift keying**, and **phase-shift keying**, depending on whether the amplitude, phase, or frequency of the sinusoid is modulated by the digital pulses. Figure 5.11.36 depicts the essential block of a data transmission system based on the RS-232 standard, as well as examples of digital data encouded for transmission over a voice line.

In addition to the function just described, however, the RS-232 standard also provides a very useful set of specifications for the direct transmission of digital data between computers and instruments. In other words, communication between digital terminal instruments may occur directly in digital form (i.e., without digital communication devices encoding the digital data with analog voice lines). Thus, this standard is also frequently used for direct digital communication.

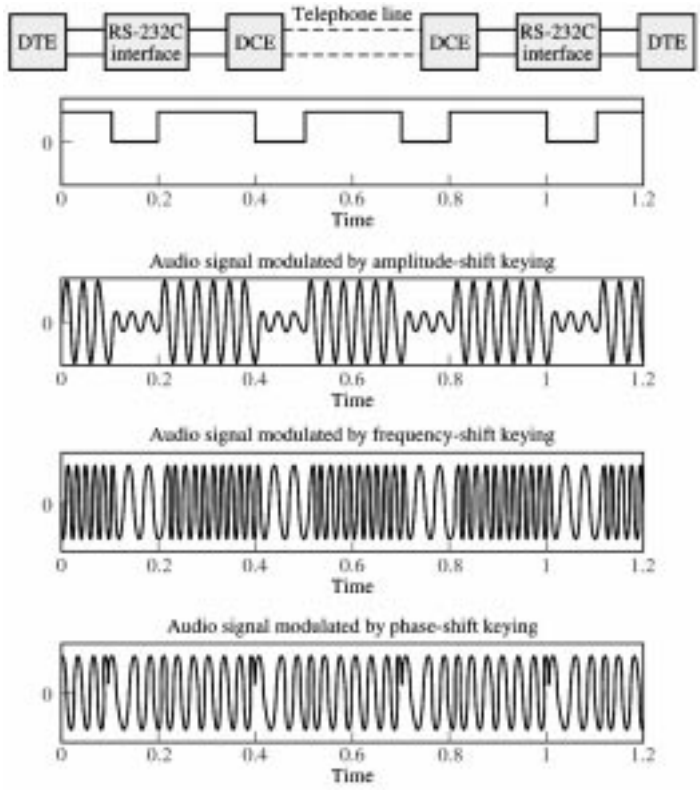

FIGURE 5.11.36 Digital data encoded for analog transmission.

The RS-232 standard can be summarized as follows:

- Data signals are encoded according to a negative logic convention using voltage levels of –3 to –15 V for logic 1 and +3 to +15 V for logic 0.
- Control signals use a positive logic convention (opposite to that of data signals).
- The maximum shunt capacitance of the load cannot exceed 2500 pF; this, in effect, limits the maximum length of the cables used in the connection.
- The load resistance must be between 300 Ω and 3 kΩ.
- Three wires are used for data transmission. One wire each is used for receiving and transmitting data; the third wire is a signal return line (signal ground). In addition, there are 22 wires that can be used for a variety of control purposes between the DTE and DCE.
- The male part of the connector is assigned to the DTE and the female part to the DCE. Figure 5.11.37 labels each of the wires in the 25-pin connector. Since each side of the connector has a *receive* and a *transmit* line, it has been decided by convention that the DCE transmits on the transmit line and receives on the receive line, while the DTE receives on the transmit line and transmits on the receive line.
- The baud rate is limited by the length of the cable; for a 17-m length, any rate from 50 baud to 19.2 kbaud is allowed. If a longer cable connection is desired, the maximum baud rate will decrease according to the length of the cable and **line drivers** can be used to amplify the signals, which are transmitted over twisted-air wires. Line drivers are simply signal amplifiers that are used directly on the digital signal, prior to encoding. For example, the signal generated by a DTE device (say, a computer) may be transmitted over a distance of up to 3300 m (at a rate of 600 baud) prior to being encoded by the DCE.

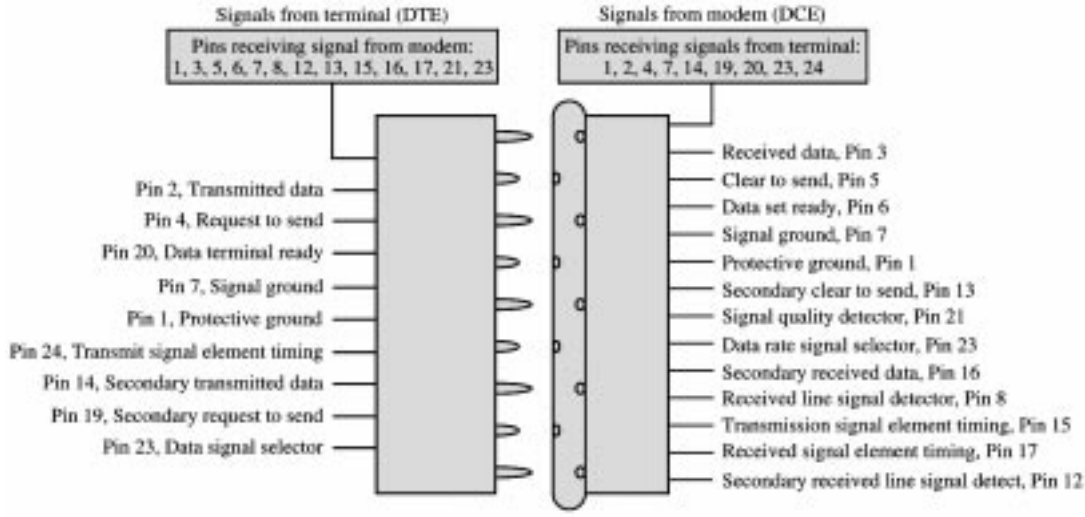

FIGURE 5.11.37 RS-232 connections.

- The serial data can be encoded according to any code, although the ASCII code is by far the most popular.

Other Communication Network Standards

In addition to the popular RS-232 and IEEE bus standards we should mention other communication standards that have become or are rapidly becoming commonplace. Once is the *Ethernet*, which operates at 10 Mb/sec and is based on IEEE Standard 802.3. This is commonly used in office networks. Higher speed networks include FDDI (fiber distributed data interface), which specifies an optical fiber ring with a data rate of 100 Mb/sec, and ATM (asynchronous transfer mode), a packet oriented transfer mode moving data in fixed-size packets called cells. ATM does not operate at a fixed speed. Typical speed is 155 Mb/sec, but there are implementations running as fast as 2 Gb/sec.

5.12 Electromechanical Systems

The objective of this section is to introduce the fundamental notions of electromechanical energy conversion, leading to an understanding of the operation of various electromechanical transducers

The Magnetic Field and Faraday's Law

The quantities used to measure the strength of a magnetic field are the **magnetic flux**, ϕ, in units of **webers** (Wb); and the **magnetic flux density**, B, in units of webers per square(Wb/m^2), or **teslas** (T). The latter quantity, as well as the associated **magnetic field intensity,** H (in units of amperes per meter, or A/m), are vectors. Thus, the density of the magnetic flux and its intensity are in general described in vector form, in terms of the components present in each spatial direction (e.g., on the *x*, *y*, and *z* axes). In discussing magnetic flux density and field intensity in this chapter and the next, we shall almost always assume that the field is a *scalar field*, that is, that it lies in a single spatial direction. This will simplify many explanations.

It is customary to represent the magnetic field by means of the familiar *lines of force* (a concept also due to Faraday); we visualize the strength of a magnetic field by observing the density of these lines in space. You probably know from a previous course in physics that such lines are closed in a magnitude field, that is, that they form continuous loops exiting at a magnetic north pole (by definition) and entering at a magnetic south pole. The relative strengths of the magnetic fields generated by two magnets could be depicted as shown in Figure 5.12.1.

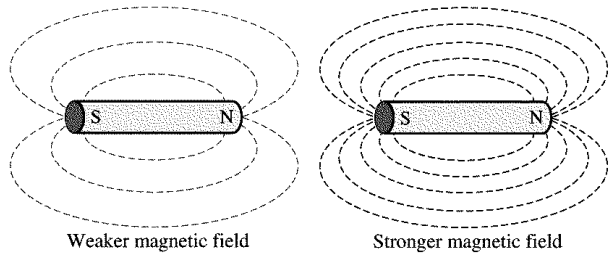

FIGURE 5.12.1 Lines of force in a magnetic field.

Magnetic fields are generated by electric charge in motion, and their effect is measured by the force they exert on a moving charge. As you may recall from previous physics courses, the vector force **f** exerted on a charge of *q* moving at velocity **u** in the presence of a magnetic field with flux density **B** is given by the equation

$$\mathbf{f} = q\mathbf{u} \times \mathbf{B} \tag{5.12.1}$$

where the symbol × denotes the (vector) cross product. If the charge is moving at a velocity **u** in a direction that makes an angle θ with the magnetic field, then the magnitude of the force is given by

$$f = quB\sin\theta \tag{5.12.2}$$

and the direction of this force is at right angles with the plane formed by the vectors **B** and **u**. This relationship is depicted in Figure 5.12.2.

The magnetic flux, ϕ, is then defined as the integral of the flux density over some surface area. For the simplified (but often useful) case of magnetic flux lines perpendicular to a cross-sectional area *A*, we can see that the flux is given by the following integral:

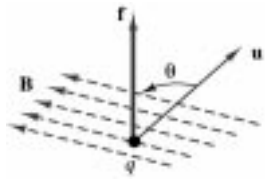

FIGURE 5.12.2 Charge moving in a constant magnetic field.

$$\phi = \int_A B\, dA \tag{5.12.3}$$

in webers (Wb), where the subscript A indicates that the integral is evaluated over the surface A. Furthermore, if the flux were to be uniform over the cross-sectional area A (a simplification that will be useful), the preceding integral could be approximated by the following expression:

$$\phi = B \cdot A \tag{5.12.4}$$

Figure 5.12.3 illustrates this idea by showing hypothetical magnetic flux lines traversing a surface, delimited in the figure by a thin conducting wire.

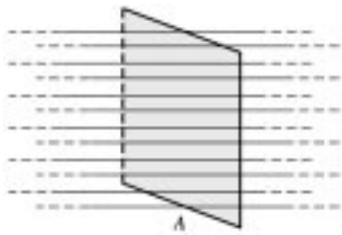

FIGURE 5.12.3 Magnetic flux lines crossing a surface.

Faraday's law states that if the imaginary surface A were bounded by a conductor — for example, the thin wire of Figure 5.12.3 — then a *changing* magnetic field would induce a voltage, and therefore a current, in the conductor. More precisely, Faraday's law states that a time-varying flux causes an induced **electromotive force**, or emf, e, as follows:

$$e = -\frac{d\phi}{dt} \tag{5.12.5}$$

In practical applications, the size of the voltages induced by the changing magnetic field can be significantly increased if the conducting wire is coiled many times around, so as to multiply the area crossed by the magnetic flux lines many times over. For an N-turn coil with cross-sectional area A, for example, we have the emf

$$e = N\frac{d\phi}{dt} \tag{5.12.6}$$

Figure 5.12.4 shows an N-turn coil *linking* a certain amount of magnetic flux; you can see that if N is very large and the coil is tightly wound (as is usually the case in the construction of practical devices), it is not unreasonable to presume that each turn of the coil links the same flux. It is convenient, in practice, to define the **flux linkage**, λ, as

$$\lambda = N\phi \tag{5.12.7}$$

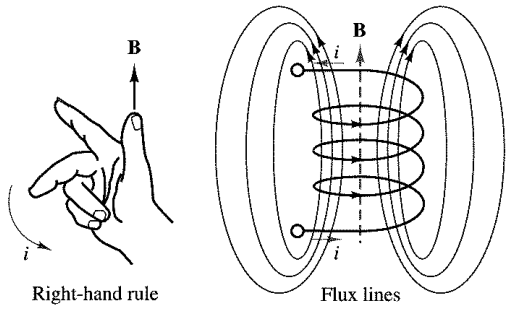

FIGURE 5.12.4 Concept of flux linkage.

so that

$$e = \frac{d\lambda}{dt} \tag{5.12.8}$$

In the analysis of linear circuits, we implicitly assumed that the relationship between flux linkage and current was a linear one:

$$\lambda = Li \tag{5.12.9}$$

so that the effect of a time-varying current was to induce a transformer voltage across an inductor coil, according to the expression

$$v = L\frac{di}{dt} \tag{5.12.10}$$

This is, in fact, the defining equation for the ideal **self-inductance**, *L*. In addition to self-inductance, however, it is also important to consider the **magnetic coupling** that can occur between neighboring circuits. Self-inductance measures the voltage induced in a circuit by the magnetic field generated by a current flowing in the same circuit. It is also possible that a second circuit in the vicinity of the first may experience an induced voltage as a consequence of the magnetic field generated in the first circuit. This principle underlies the operation of all transformers.

Self- and Mutual Inductance

Figure 5.12.5 depicts a pair of coils, one of which, L_1, is excited by a current, i_1, and therefore develops a magnetic field and a resulting induced voltage, v_1, The second coil, L_2, is not energized by a current, but links some of the flux generated by the current i_1 and L_1 because of its close proximity to the first coil. The magnetic coupling between the coils established by virtue of their proximity is described by a quantity called **mutual inductance** and defined by the symbol *M*. The mutual inductance is defined by the equation

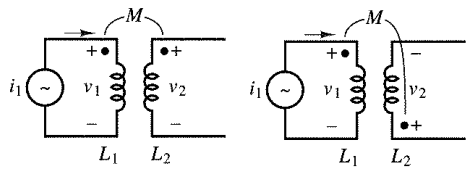

FIGURE 5.12.5 Mutual inductance.

$$v_2 = M\frac{di_1}{dt} \tag{5.12.11}$$

The dots shown in the two figures indicate the polarity of the coupling between the coils. If the dots are at the same end of the coils, the voltage induced in coil 2 by a current in coil 1 has the same polarity as the voltage induced by the same current in coil 1; otherwise, the voltages are in opposition, as shown in the lower part of Figure 5.12.5. Thus, the presence of such dots indicates that magnetic coupling is present between two coils, It should also be pointed out that if a current (and therefore a magnetic field) were present in the second coil, an additional voltage would be induced across coil 1. The voltage induced across a coil is, in general, equal to the sum of the voltages induced by self-inductance and mutual inductance.

Example 5.12.1 Linear Variable Differential Transformer (LVDT)

The linear variable differential transformer (LVDT) is a displacement transducer based on the mutual inductance concept just discussed. Figure 5.12.6 shows a simplified representation of an LVDT, which consists of a primary coil, subject to AC excitation (v_{ex}) and of a pair of identical secondary coils, which are connected so as to result in the output voltage

$$v_{out} = v_1 - v_2$$

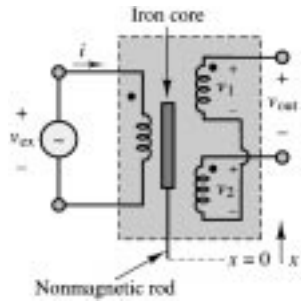

FIGURE 5.12.6 Linear variable differential transformer.

The ferromagnetic core between the primary and secondary coils can be displaced in proportion to some external motion, x, and determines the magnetic coupling between primary and secondary coils. Intuitively, as the core is displaced upward, greater coupling will occur between the primary coil and the top secondary coil, thus inducing a greater voltage in the top secondary coil. Hence, $v_{out} > 0$ for positive displacements. The converse is true for negative displacements. More formally, if the primary coil has resistance R_p and self-inductance L_p, we can write

$$iR_p + L_p\frac{di}{dt} = v_{ex}$$

and the voltages induced in the secondary coils are given by

$$v_1 = M_1\frac{di}{dt}$$

$$v_2 = M_2\frac{di}{dt}$$

so that

$$v_{\text{out}} = \left(M_1 - M_2\right)\frac{di}{dt}$$

where M_1 and M_2 are the mutual inductances between the primary and the respective secondary coils, It should be apparent that each of the mutual inductances is dependent on the position of the iron core. For example, with the core at the *null position*, $M_1 = M_2$ and $v_{\text{out}} = 0$. The LVDT is typically designed so that $M_1 - M_2$ is linearly related to the displacement of the core, x.

Because the excitation is by necessity an AC signal, the output voltage is actually given by the difference of two sinusoidal voltages at the same frequency and is therefore itself a sinusoid, whose amplitude and phase depend on the displacement, x. Thus, v_{out} is an *amplitude-modulated* (AM) signal. To recover a signal proportional to the actual displacement, it is therefore necessary to use a demodulator circuit.

In practical electromagnetic circuits, the self-inductance of a circuit is not necessarily constant; in particular, the inductance parameter, L, is not constant, in general, but depends on the strength of the magnetic field intensity, so that it will not be possible to use such a simple relationship as $v = L\, di/dt$, with L constant. If we revisit the definition of the transformer voltage,

$$e = N\frac{d\phi}{dt} \tag{5.12.12}$$

We see that in an inductor coil, the inductance is given by

$$L = \frac{N\phi}{i} = \frac{\lambda}{i} \tag{5.12.13}$$

This expression implies that the relationship between current and flux in a magnetic structure is linear (the inductance being the slope of the line). In fact, the properties of ferromagnetic materials are such that the flux-current relationship is nonlinear, so that the simple linear inductance parameter used in electric circuit analysis is not adequate to represent the behavior of the magnetic circuits of the present chapter. In any practical situation, the relationship between the flux linkage, λ, and the current is nonlinear, and might be described by a curve similar to that shown in Figure 5.12.7. Wherever the i-λ curve is not a straight line, it is more convenient to analyze the magnetic system in terms of energy calculations, since the corresponding circuit equation would be nonlinear.

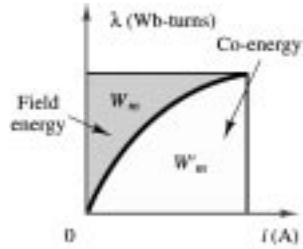

FIGURE 5.12.7

In a magnetic system, the energy stored in the magnetic field is equal to the integral of the instantaneous power, which is the product of voltage and current, just as in a conventional electrical circuit.

$$W_m = \int ei\, dt \tag{5.12.14}$$

However, in this case, the voltage corresponds to the induced emf, according to Faraday's law:

$$e = \frac{d\lambda}{dt} = N\frac{d\phi}{dt} \tag{5.12.15}$$

and is therefore related to the rate of change of the magnetic flux. The energy stored in the magnetic field could therefore be expressed in terms of the current by the integral

$$W_m = \int ei\,dt = \int \frac{d\lambda}{dt} i\,dt = \int i\,d\lambda \tag{5.12.16}$$

It should be straightforward to recognize that this energy is equal to the area above the λ-i curve of Figure 5.12.7. From the same figure, it is also possible to define a fictitious (but sometimes useful) quantity called **co-energy**, equal to the area under and identified by the symbol W'_m. From the figure, it is also possible to see that the co-energy can be expressed in terms of the stored energy by means of the following relationship:

$$W'_m = i\lambda - W_m \tag{5.12.17}$$

Ampère's Law

As explained in the previous section, Faraday's law is one of two fundamental laws relating electricity to magnetism. The second relationship, which forms a counterpart to Faraday's law, is **Ampère's law**. Qualitatively, Ampère's law states that the magnetic field intensity, **H**, in the vicinity of a conductor is related to the current carried by the conductor; thus Ampère's law establishes a dual relationship with Faraday's law.

In the previous section, we described the magnetic field in terms of its flux density, **B**, and flux ϕ, To explain Ampère's law and the behavior of magnetic materials, we need to define a relationship between the magnetic field intensity, **H**, and the flux density, **B**. These quantities are related by:

$$\begin{aligned} \mathbf{B} &= \mu\mathbf{H} \\ &= \mu_r\mu_0\mathbf{H} \quad \text{Wb/m}^2 \text{ or T} \end{aligned} \tag{5.12.18}$$

where the parameter μ is a scalar constant for a particular physical medium (at least, for the applications we consider here) and is called the **permeability** of the medium. The permeability of a material can be factored as the product of the permeability of free space, $\mu_0 = 4\pi \times 107$ H/m, times the relative permeability, μ_r, which varies greatly according to the medium. For example, for air and for most electrical conductors and insulators, μ_r is equal to 1. For ferromagnetic materials, the value of μ_r can take values in the hundreds or thousands. The size of μ_r represents a measure of the magnetic properties of the material. A consequence of Ampère's law is that the larger the value of μ, the smaller the current required to produce a large flux density in an electromagnetic structure. Consequently, many electromechanical devices make use of ferromagnetic materials, called iron cores, to enhance their magnetic properties. Table 5.12.1 gives approximate values of μ_r for some common materials.

Conversely, the reason for introducing the magnetic field intensity is that it is dependent of the properties of the materials employed in the construction of magnetic circuits. Thus, a given magnetic field intensity, **H**, will give rise to different flux densities in different materials. It will therefore be useful to define *sources* of magnetic energy in terms of the magnetic field intensity, so that different magnetic structures and materials can then be evaluated or compared for a given source. In analogy with electromotive force, this "source" will be termed **magnetomotive force** (mmf). As stated earlier, both the

TABLE 5.12.1 Relative Permeabilities for Common Materials

Material	μ_r
Air	1
Permalloy	100,000
Cast steel	1,000
Sheet steel	4,000
Iron	5,195

magnetic flux density and field intensity are vector quantities; however, for ease of analysis, scalar fields will be chosen by appropriately selecting the orientation of the fields, wherever possible.

The field generated by a single conducting wire is not very strong; however, if we arrange the wire into a tightly wound coil with many turns, we can greatly increase the strength of the magnetic field. For such a coil with N turns, one can verify visually that the lines of force associated with the magnetic field link all of the turns of the conducting coil, so that we have effectively increased the current linked by the flux lines N-fold. The product $N \cdot i$ is a useful quantity in electromagnetic circuits and is called the magnetomotive force, $\mathcal{F}$ (often abbreviated mmf), in analogy with the electromotive force defined earlier:

$$\mathcal{F} = Ni \quad \text{ampere-turns } (A \cdot t) \tag{5.12.19}$$

Typical arrangements are the iron-core inductor and the toroid of Figure 5.12.8. The flux densities for these inductors are given by the expressions

$$B = \frac{\mu Ni}{l} \quad \text{Flux density for tightly wound circular coil} \tag{5.12.20}$$

$$B = \frac{\mu Ni}{2\pi r_2} \quad \text{Flux density for toroidal coil} \tag{5.12.21}$$

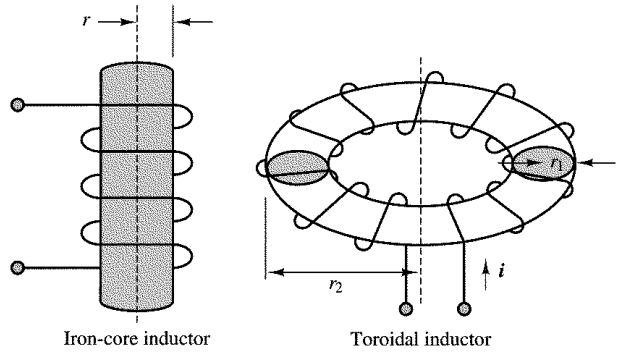

FIGURE 5.12.8 Practical inductors.

Intuitively, the presence of a high-permeability material near a source of magnetic flux causes the flux to preferentially concentrate in the high-μ material, rather than in air, much as a conducting path concentrates the current produced by an electric field in an electric circuit. Figure 5.12.9 depicts an example of a simple electromagnetic structure, which, as we shall see shortly, forms the basis of the practical transformer.

Table 5.12.2 summarizes the variables introduced thus far in the discussion of electricity and magnetism.

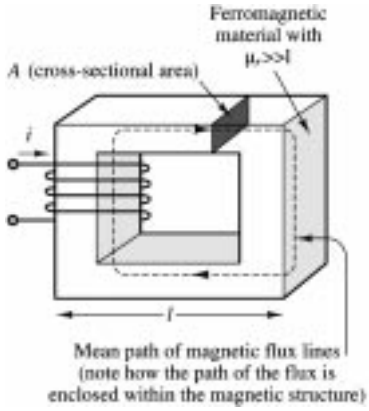

FIGURE 5.12.9 A simple electromagnetic structure.

TABLE 5.12.2 Magnetic Variables and Units

Variable	Symbol	Units
Current	I	A
Magnetic flux density	B	$Wb/m^2 = T$
Magnetic flux	ϕ	Wb
Magnetic field intensity	H	A/m
Electromotive force	e	V
Magnetomotive force	$\mathcal{F}$	A · t
Flux linkage	λ	Wb · t

Magnetic Circuits

It is possible to analyze the operation of electromagnetic devices such as the one depicted in Figure 5.12.9 by means of magnetic equivalent circuits, similar in many respects to the equivalent electrical circuits of the earlier chapters. Before we can present this technique, however, we need to make a few simplifying approximations. The first of these approximations assumes that there exists a **mean path** for the magnetic flux, and that the corresponding mean flux density is approximately constant over the cross-sectional area of the magnetic structure. Thus, a coil wound around a coil with cross-sectional area A will have flux density

$$B = \frac{\phi}{A} \tag{5.12.22}$$

where A is assumed to be perpendicular to the direction of the flux lines. Figure 5.12.9 illustrates such a mean path and the cross-sectional area, A. Knowing the flux density, we obtain the field intensity:

$$H = \frac{B}{\mu} = \frac{\phi}{A\mu} \tag{5.12.23}$$

But then, knowing the field intensity, we can relate the mmf of the coil, $\mathcal{F}$, to the product of the magnetic field intensity, H, and the length of the magnetic (mean) path, l, for one leg of the structure:

$$\mathcal{F} = N \cdot i = H \cdot l \tag{5.12.24}$$

In summary, the mmf is equal to the magnetic flux times the length of the magnetic path, divided by the permeability of the material times the cross-sectional area:

$$\mathcal{F} = \phi \frac{l}{\mu A} \tag{5.12.25}$$

A review of this formula reveals that the magnetomotive force, $\mathcal{F}$, may be viewed as being analogous to the voltage source in a series electrical circuit, and that the flux, ϕ, is then equivalent to the electrical current in a series circuit and the term $l/\mu A$ to the *magnetic resistance* of one leg of the magnetic circuit. You will note that the term $l/\mu A$ is very similar to the term describing the resistance of a cylindrical conductor of length l and cross-sectional A, where the permeability, μ, is analogous to the conductivity, σ. The term $l/\mu A$ occurs frequently enough to be assigned the name of reluctance, and the symbol $\mathcal{R}$.

In summary, when an N-turn coil carrying a current i is wound around a magnetic core such as the one indicated in Figure 5.12.9, the mmf, $\mathcal{F}$, generated by the coil produces a flux, ϕ, that is *mostly* concentrated with the core and is assumed to be uniform across the cross section. Within this simplified picture, then, the analysis of a magnetic circuit is analogous to that of resistive electrical circuits. This analogy is illustrated in Table 5.12.3 and in the examples in this section.

TABLE 5.12.3 Analogy between Electric and Magnetic Circuits

Electrical Quantity	Magnetic Quantity
Electrical field intensity, E, V/m	Magnetic field intensity, H, A · t/m
Voltage, v, V	Magnetomotive force, $\mathcal{F}$, A · t
Current, i, A	Magnetic flux, ϕ, Wb
Current density, J, A/m^2	Magnetic flux density, B, Wb/m^2
Resistance, R, Ω	Reluctance, $\mathcal{R} = l/\mu A$, A · t/Wb
Conductivity, σ, l/Ω · m	Permeability, μ, Wb/A · m

The usefulness of the magnetic circuit analogy can be emphasized by analyzing a magnetic core similar to that of Figure 5.12.9, but with a slightly modified geometry. Figure 5.12.10 depicts the magnetic structure and its equivalent circuit analogy. In the figure, we see that the mmf, $\mathcal{F}$ = Ni, excites the magnetic circuit, which is composed of four legs: two of mean path length l_1 and cross-sectional area $A_1 = d_1 w$, and the other two of mean length l_2 and cross section $A_2 = d_2 w$. Thus, the reluctance encountered by the flux in its path around the magnetic core is given by the quantity $\mathcal{R}_{\text{series}}$, with

$$\mathcal{R}_{\text{series}} = 2\mathcal{R}_1 + 2\mathcal{R}_2$$

and

$$\mathcal{R}_1 = \frac{l_1}{\mu A_1}$$
$$\mathcal{R}_2 = \frac{l_2}{\mu A_2} \tag{5.12.26}$$

It is important at this stage to review the assumptions and simplifications made in analyzing the magnetic structure of Figure 5.12.10:

1. All of the magnetic flux is linked by all of the turns of the coil.
2. The flux is confined exclusively within the magnetic core.
3. The density of the flux is uniform across the cross-sectional area of the core.

You can probably see intuitively that the first of these assumptions might not hold true near the ends of the coil, but that it might be more reasonable if the coil is tightly wound. The second assumption is equivalent to stating that the relative permeability of the core is infinitely higher than that of air

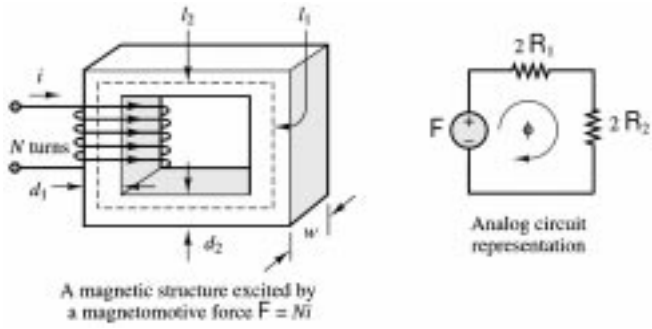

FIGURE 5.12.10 Analogy between magnetic and electric circuits.

(presuming that this is the medium surrounding the core): if this were the case, the flux would indeed be confined within the core. It is worthwhile to note that we made a similar assumption when we treat wires in electric circuits as perfect conductors: the conductivity of copper is substantially greater than that of free space, by a factor of approximately 10^{15}. In the case of magnetic materials, however, even for the best alloys, we have a relative permeability only on the order of 10^3 to 10^4. Thus, an approximation that is quite appropriate for electric circuits is not nearly as good in the case of magnetic circuits. Some of the flux in a structure such as those of Figures 5.12.9 and 5.12.10 would thus not be confined within the core (this is usually referred to as **leakage flux**). Finally, the assumption that the flux is uniform across the core cannot hold for a finite-permeability medium, but it is very helpful in giving an approximate *mean* behavior of the magnetic circuit.

The magnetic circuit analogy is therefore far from being exact. However, short of employing the tools of electromagnetic field theory and of vector calculus, or advanced numerical simulation software, it is the most convenient tool at the engineer's disposal for the analysis of magnetic structures.

Example 5.12.2 Magnetic Reluctance Position Sensor

A simple magnetic structure, very similar to those examined in the previous examples, finds very common application in the so-called variable-reluctance position sensor, which, in turn, finds widespread application in a variety of configurations for the measurement of linear and angular position and velocity. Figure 5.12.11 depicts one particular configuration that is used in many applications. In this structure, a permanent magnet with a coil of wire wound around it forms the sensor; a steel disk (typically connected to a rotating shaft) has a number of tabs that pass between the pole pieces of the sensor. The area of the tab is assumed equal to the area of the cross section of the pole pieces and is equal to a^2. The reason for the name *variable-reluctance sensor* is that the reluctance of the magnetic structure is variable, depending on whether or not a ferromagnetic tab lies between the pole pieces of the magnet.

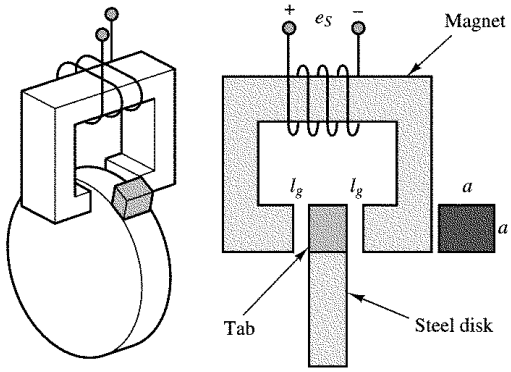

FIGURE 5.12.11 Variable-reluctance position sensor.

The principle of operation of the sensor is that an electromotive force, e_s, is induced across the coil by the change in magnetic flux caused by the passage of the tab between the pole pieces when the disk is in motion. As the tab enters the volume between the pole pieces, the flux will increase because of the lower reluctance of the configuration, until it reaches a maximum when the tab is centered between the poles of the magnet. Figure 5.12.12 depicts the approximate shape of the resulting voltage, which, according to Faraday's law, is given by

$$e_S = -\frac{d\phi}{dt}$$

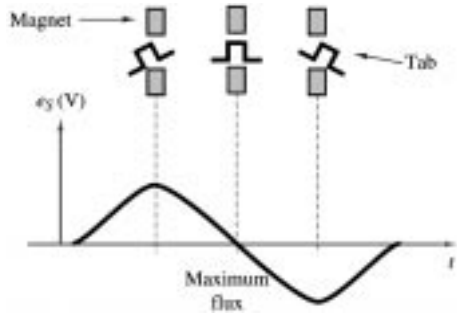

FIGURE 5.12.12 Variable-reluctance position sensor waveform.

The rate of change of flux is dictated by the geometry of the tab and of the pole pieces, and by the speed of rotation of the disk. It is important to note that, since the flux is changing only if the disk is rotating, this sensor cannot detect the static position of the disk.

One common application of this concept is in the measurement of the speed of rotation of rotating machines, including electric motors and internal combustion engines. In these applications, use is made of a *60-tooth wheel*, which permits the conversion of the speed rotation directly to units of revolutions per minute. The output of a variable-reluctance position sensor magnetically coupled to a rotating disk equipped with 60 tabs (teeth) is processed through a comparator or Schmitt trigger circuit. The voltage waveform generated by the sensor is nearly sinusoidal when the teeth are closely spaced, and it is characterized by one sinusoidal cycle for each tooth on the disk. If a negative zero-crossing detector is employed, the trigger circuit will generate a pulse corresponding to the passage of each tooth, as shown in Figure 5.12.13. If the time between any two pulses is measured by means of a high-frequency clock, the speed of the engine can be directly determined in units of rev/min by means of a digital counter.

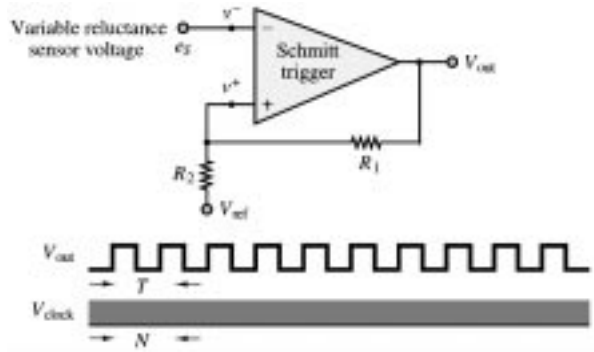

FIGURE 5.12.13 Signal processing for a 60-tooth wheel RPM sensor.

Magnetic Materials and *B-H* Curves

In the analysis of magnetic circuits presented in the previous sections, the relative permeability, μ_r, was treated as a constant. In fact, the relationship between the magnetic flux density, **B**, and the associated field intensity, **H**,

$$\mathbf{B} = \mu\mathbf{H} \tag{5.12.27}$$

is characterized by the fact that the relative permeability of magnetic materials is not a constant, but is a function of the magnetic field intensity. In effect, all magnetic materials exhibit a phenomenon called **saturation**, whereby the flux density increases in proportion to the field intensity until it cannot do so any longer. Figure 5.12.14 illustrates the general behavior of all magnetic materials. You will note that since the *B-H* curve shown in the figure is nonlinear, the value of μ (which is the slope of the curve) depends on the intensity of the magnetic field.

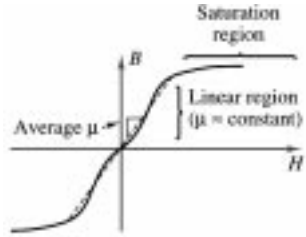

FIGURE 5.12.14 Permeability and magnetic saturation effects.

To understand the reasons for the saturation of a magnetic material, we need to briefly review the mechanism of magnetization. The basic idea behind magnetic materials is that the spin of electrons constitutes motion of charge and therefore leads to magnetic effects, as explained in the introductory section of this chapter. In most materials, the electron spins cancel out, on the whole, and no net effect remains. In ferromagnetic materials, on the other hand, atoms can align so that the electron spins cause a net magnetic effect. In such materials, there exist small regions with strong magnetic properties (called **magnetic domains**), the effects of which are neutralized in unmagnetized material by other, similar regions that are oriented differently, in a random pattern. When the material is magnetized, the magnetic domains tend to align with each other, to a degree that is determined by the intensity of the applied magnetic field.

In effect, the large number of miniature magnets within the material are *polarized* by the external magnetic field. As the field increases, more and more domains become aligned. When all of the domains have become aligned, any further increase in magnetic field intensity does not yield an increase in flux density beyond the increase that would be caused in a nonmagnetic material. Thus, the relative permeability, μ_r, approaches 1 in the saturation region. It should be apparent that an exact value of μ_r cannot be determined; the value of μ_r used in the earlier examples is to be interpreted as an average permeability, for intermediate values of flux density. As a point of reference, commercial magnetic steels saturate at flux densities around a few teslas. Figure 5.12.17, shown later in this section, will provide some actual *B-H* curves for common ferromagnetic materials.

The phenomenon of saturation carries some interesting implications with regard to the operation of magnetic circuits: the results of the previous section would seem to imply that an increase in the mmf (that is, an increase in the current driving the coil) would lead to a proportional increase in the magnetic flux. This is true in the *linear region* of Figure 5.12.14; however, as the material reaches saturation, further increases in the driving current (or, equivalently, in the mmf) do not yield further increases in the magnetic flux.

There are two more features that cause magnetic materials to further deviate from the ideal model of the linear *B-H* relationship: **eddy currents** and **hysteresis**. The first phenomenon consists of currents that are caused by any time-varying flux in the core material. As you know, a time-varying flux will

induce a voltage, and therefore a current. When this happens inside the magnetic core, the induced voltage will cause "eddy" currents (the terminology should be self-explanatory) in the core, which depend on the resistivity of the core. Figure 5.12.15 illustrates the phenomenon of eddy currents. The effect of these currents is to dissipate energy in the form of heat. Eddy currents are reduced by selecting high-resistivity core materials, or by *laminating* the core, introducing tiny, discontinuous air gaps between core layers (see Figure 5.12.15). Lamination of the core reduces eddy currents greatly without affecting the magnetic properties of the core.

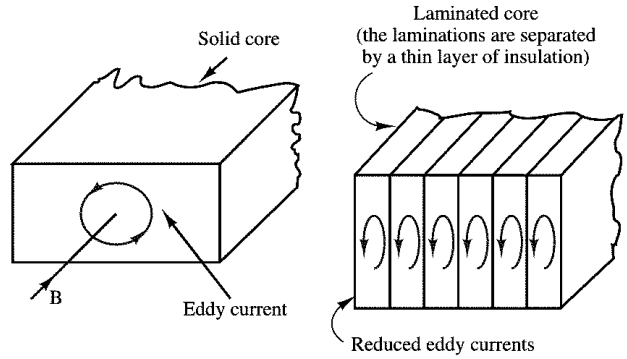

FIGURE 5.12.15 Eddy currents in magnetic structures.

It is beyond the scope of this section to quantify the losses caused by induced eddy currents, but it will be important to be aware of this source of energy loss.

Hysteresis is another loss mechanism in magnetic materials; it displays a rather complex behavior, related to the magnetization properties of a material. The curve of Figure 5.12.16 reveals that the *B*-*H* curve for a magnetic material during magnetization (as H is increased) is displaced with respect to the curve that is measured when the material is demagnetized. To understand the hysteresis process, consider a core that has been energized for some time, with a field intensity of $H_1A \cdot$ t/m. As the current required to sustain the mmf corresponding to H_1 is decreased, we follow the hysteresis curve from the point α to the point β. When the mmf is exactly zero, the material displays the **remanent** (or **residual**) **magnetization** B_r. To bring the flux density to zero, we must further decrease the mmf (i.e., produce a negative current), until the field intensity reaches the value $-H_0$ (point γ on the curve). As the mmf is made more negative, the curve eventually reaches the point α'. If the excitation current go the coil is now increased, the magnetization curve will follow the path $\alpha' = \beta' = \gamma' = \alpha$, eventually returning to the original point in the *B*-*H* plane, but via a different path.

The result of this process, by which an *excess magnetomotive force* is required to magnetize or demagnetize the material, is a net energy loss. It is difficult to evaluate this loss exactly; however, it can be shown that it is related to the area between the curves of Figure 5.2.16. There are experimental techniques that enable the approximate measurement of these losses.

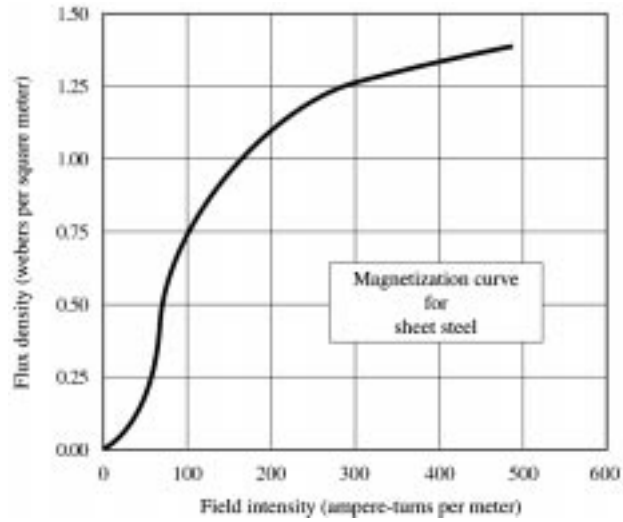
Figures 5.2.17(a) to (c) depict magnetization curves for three very common ferromagnetic materials: cast iron, cast steel, and sheet steel.

Electromechanical Energy Conversion

From the material developed thus far, it should be apparent that electromagnetomechanical devices are capable of converting mechanical forces and displacements to electromagnetic energy, and that the converse is also possible. The objective of this section is to formalize the basic principles of energy conversion in electromagnetomechanical systems, and to illustrate its usefulness and potential for application by presenting several examples of **energy transducers**. A transducer is a device that can convert electrical to mechanical energy (in this case, it is often called an **actuator**), or vice versa (in which case it is called a sensor).

Several physical mechanisms permit conversion of electrical to mechanical energy and back, the principal phenomena being the **piezoelectric effect**, consisting of the generation of a change in electric



(c)

FIGURE 5.12.17 (c) magnetization curve for sheet steel.

field in the presence of strain in certain crystals (e.g., quartz), and **electrostriction** and **magnetostriction**, in which changes in the dimension of certain materials lead to a change in their electrical (or magnetic) properties. Although these effects lead to some interesting applications, this chapter is concerned only with transducers in which electrical energy is converted to mechanical energy through the coupling of a magnetic field. It is important to note that all rotating machines (motors and generators) fit the basic definition of electromechanical transducers we have just given.

Forces in Magnetic Structures

It should be apparent by now that it is possible to convert mechanical forces to electrical signals, and vice versa, by means of the coupling provided by energy stored in the magnetic field. In this subsection, we discuss the computation of mechanical forces and of the corresponding electromagnetic quantities of interest; these calculations are of great practical importance in the design and application of electromechanical actuators. For example, a problem of interest is the computation of the current required to generate a given force in an electromechanical structure. This is the kind of application that is likely to be encountered by the engineer in the selection of an electromechanical device for a given task.

As already seen in this chapter, an electromechanical system includes an electrical system and a mechanical system, in addition to means through which the two can interact. The principal focus of this chapter has been the coupling that occurs through an electromagnetic field common to both the electrical and the mechanical system; to understand electromechanical energy conversion, it will be important to understand the various energy storage and loss mechanisms in the electromagnetic field. Figure 5.12.18 illustrates the coupling between the electrical and mechanical systems. In the mechanical system, energy loss can occur because of the heat developed as a consequence of *friction*, while in the electrical system, analogous losses are incurred because of *resistance*. Loss mechanisms are also present in the magnetic coupling medium, since *eddy current losses* and *hysteresis losses* are unavoidable in ferromagnetic materials. Either system can supply energy, and either system can store energy. Thus, the figure depicts the flow of energy from the electrical to the mechanical system, accounting for these various losses. The same flow could be reversed if mechanical energy were converted to electrical form.

Moving-Iron Transducers

One important class of electromagnetomechanical transducers is that of **moving-iron transducers**. The aim of this section is to derive an expression for the magnetic forces generated by such transducers and to illustrate the application of these calculations to simple, yet common devices such as electromagnets,

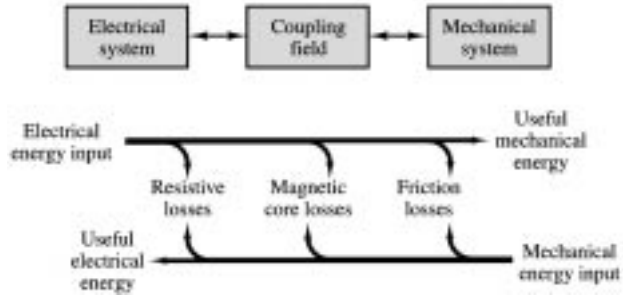


FIGURE 5.12.18 Electromechanical system.

solenoids, and relays. The simplest example of a moving-iron transducer is the electromagnet of Figure 5.12.19, in which the U-shaped element is fixed and the bar is movable. In the following paragraphs, we shall derive a relationship between the current applied to the coil, the displacement of the movable bar, and the magnetic force acting in the air gap.

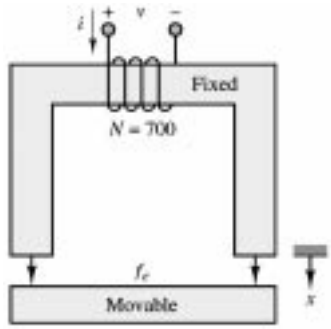

FIGURE 5.12.19 Simple electromagnet.

The principle that will be applied throughout the section is that in order for a mass to be displaced, some work needs to be done; this work corresponds to a change in the energy stored in the electromagnetic field, which causes the mass to be displaced. With reference to Figure 5.12.19, let f_e represent the magnetic force acting on the bar and x the displacement of the bar, in the direction shown. Then the net work into the electromagnetic field, W_m, is equal to the sum of the work done by the electrical circuit plus the work done by the mechanical system. On the basis of a linear approximation, it can be shown that the stored energy in a magnetic structure is given by the expression

$$W_m = \frac{\phi \mathcal{F}}{2} \tag{5.12.28}$$

and since the flux and the mmf are related by the expression

$$\phi = \frac{Ni}{\mathcal{R}} = \frac{\mathcal{F}}{\mathcal{R}} \tag{5.12.29}$$

the stored energy can be related to the reluctance of the structure according to

$$W_m = \frac{\phi^2 \mathcal{R}(x)}{2} \tag{5.12.30}$$

where the reluctance has been explicitly shown to be a function of displacement, as is the case in a moving-iron transducer. Finally, then, we shall use the following approximate expression to compute the magnetic force acting on the moving iron:

$$f = -\frac{dW_m}{dx} = -\frac{\phi^2}{2}\frac{d\mathcal{R}(x)}{dx} \tag{5.12.31}$$

Example 5.12.13 An Electromagnet

An electromagnet is used to support a solid piece of steel as shown in Figure 5.12.19. A force of 8900 N is required to support the weight. The cross-sectional area of the magnet core (the fixed part) is 0.01 m^2. Determine the minimum current that can keep the weight from falling for x = 1.5 mm. Assume negligible reluctance for the steel parts, and negligible fringing in the air gap.

Solution. We have already shown that in magnetic structures with air gaps, the reluctance is mostly due to the air gaps. This explains the assumption that the reluctance of the structure is negligible. For the structure of Figure 5.12.19, the reluctance is therefore given by

$$\mathcal{R}(x) = \frac{l}{\mu_0 A}$$

where A = 0.01 m^2 and $l = 2x$, and therefore

$$\mathcal{R}(x) = \frac{2x}{4\pi \times 10^{-7} \times 0.01} = \frac{x}{1.2566 \times 10^{-8}}$$

The magnitude of the force in the air gap is given by the expression

$$|f| = \frac{\phi^2}{2}\frac{d\mathcal{R}(x)}{dx} = \frac{N^2 i^2}{2\mathcal{R}^2}\frac{d\mathcal{R}(x)}{dx}$$

$$= \frac{i^2}{2}\frac{N^2}{\mathcal{R}^2}\frac{d\mathcal{R}}{dx} = \frac{i^2}{2}(700)^2\frac{6.2832 \times 10^{-9}}{x^2} = 8900 \text{ N}$$

from which the current can be computed:

$$i^2 = 2 \times \frac{8900\left(1.5 \times 10^{-3}\right)^2}{(700)^2\left(6.2832 \times 10^{-9}\right)} 6.504 \text{ A}$$

or

$$i = 2.55 \text{ A}$$

You should recognize the practical importance of these calculations in determining approximate current requirements and force-generation capabilities of electromechanical transducers.

Moving-Coil Transducers

Another important class of electromagnetomechanical transducers is that of **moving-coil transducers**. This class of transducers includes a number of common devices, such as microphones, loudspeakers, and all electric motors and generators. The aim of this section is to explain the relationship between a

fixed magnetic field, the emf across the moving coil, and the forces and motions of the moving element of the transducer.

Motor Action. A moving-coil transducer can act as a motor when an externally supplied current flowing through the electrically conducting part of the transducer is converted into a force that can cause the moving part of the transducer to be displaced. Such a current would flow, for example, if the support of Figure 5.12.20 were made of conducting material, so that the conductor and the right-hand side of the support "rail" were to form a loop (in effect, a 1-turn coil).

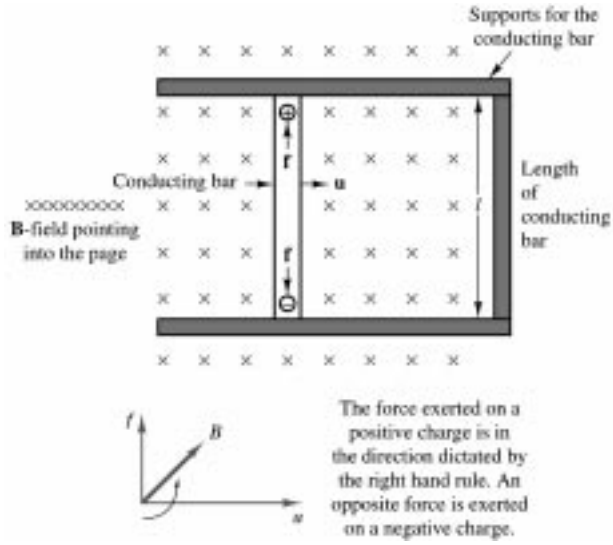

FIGURE 5.12.20 A simple electromechanical motion transducer.

The phenomenon we have just described is sometimes referred to as the "*Bli* law".

Generator Action. The other mode of operation of a moving-coil transducer occurs when an external force causes the coil (i.e., the moving bar, in Figure 5.12.20) to be displaced. This external force is converted to an emf across the coil, as will be explained in the following paragraphs.

It is important to observe that since positive and negative charges are forced in opposite directions in the transducer of Figure 5.12.20, a potential difference will appear across the conducting bar; this potential difference is the electromotive force, or emf. The emf must be equal to the force exerted by the magnetic field. In short, the electric force per unit charge (or electric field) e/l must equal the magnetic force per unit charge $f/q = Bu$. Thus, the relationship

$$e = Blu \tag{5.12.32}$$

which holds whenever **B, l,** and **u** are mutually perpendicular, as in Figure 5.12.20.

It was briefly mentioned that the *Blu* and *Bli* laws indicate that, thanks to the coupling action of the magnetic field, a conversion of mechanical to electrical energy — or the converse — is possible. The simple structure of Figures 5.12.20 can, again, serve as an illustration of this energy-conversion process, although we have not yet indicated how these idealized structures can be converted into a practical device. In this section we shall begin to introduce some physical considerations. Before we proceed any further, we should try to compute the power — electrical and mechanical — that is generated (or is required) by our ideal transducer. The electrical power is given by

$$P_E = ei = Blui \quad \text{(W)} \tag{5.12.33}$$

while the mechanical power required, say, to move the conductor from left to right is given by the product of force and velocity:

$$P_M - f_{\text{ext}} u = Bliu \quad \text{(W)} \tag{5.12.34}$$

Example 5.12.4 The Loudspeaker

A loudspeaker, shown in Figure 5.12.21, uses a permanent magnet and a moving coil to produce the vibrational motion that generates the pressure waves we perceive as sound. Vibration of the loudspeaker is caused by changes in the input current to a coil; the coil is, in turn, coupled to a magnetic structure that can produce time-varying forces on the speaker diaphragm. A simplified model for the mechanics of the speaker is also shown in Figure 5.12.21. The force exerted on the coil is also exerted on the mass of the speaker diaphragm, as shown in Figure 5.12.22, which depicts a free-body diagram of the forces acting on the loudspeaker diaphragm.

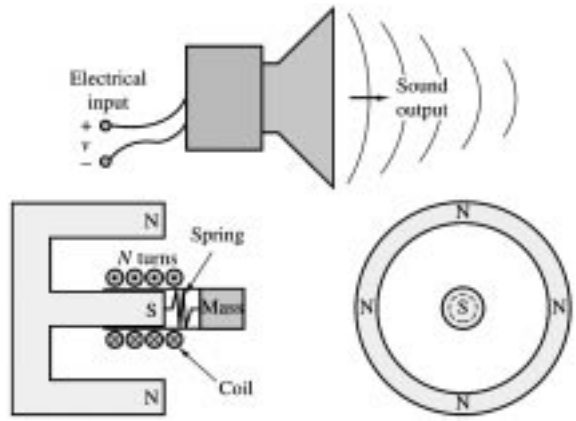

FIGURE 5.12.21 Loudspeaker.

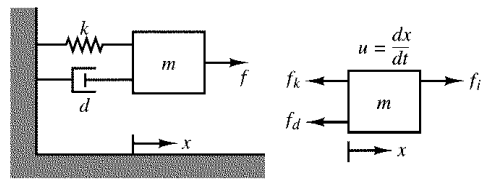

FIGURE 5.12.22 Forces acting on loudspeaker diaphragm.

The force exerted on the mass, f_i, is the magnetic force due to current flow in the coil. The electrical circuit that describes the coil is shown in Figure 5.12.23, where L represents the inductance of the coil, R represents the resistance of the windings, and e is the emf induced by the coil moving through the magnetic field.

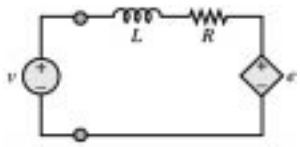

FIGURE 5.12.23 Model of transducer electrical field.

Determine the frequency response, $(\mathbf{U}/\mathbf{V})(j\omega)$, of the speaker using phasor analysis if the model parameters are

$L \approx 0$ H $\quad R = 8\ \Omega \quad m = 0.001$ kg $\quad d = 22.75$

$k \approx 500{,}000$ N/m $\quad N = 47 \quad B = 1T \quad$ Radius of coil = 5 cm

Solution: To determine the frequency response of the loudspeaker, we need to write the fundamental equations that describe the two subsystems that make up the loudspeaker. The electrical subsystem is described by the usual KVL relationship, applied to the circuit of Figure 5.12.23.

$$v = L\frac{di}{dt} + Ri + e$$

where e is the emf generated by the motion of the coil in the magnetic field. Next, according to Newton's law, we can write a force balance equation to describe the dynamics of the mechanical subsystem:

$$m\frac{du}{dt} = f_i - f_d - f_k = f_i - du - kx$$

Now, the coupling between the electrical and mechanical systems is expressed in each of the two preceding equations by the terms e and f_i:

$$e = Blu$$

$$f_i = Bli$$

Since we desire the frequency response, we use phasor techniques to represent the electrical and mechanical subsystem equations:

$$\mathbf{V}(j\omega) = j\omega L\mathbf{I}(j\omega) + R\mathbf{I}(j\omega) + Bl\mathbf{U}(j\omega) \qquad \text{Electrical equation}$$

$$(j\omega m + d)\mathbf{U}(j\omega) + \frac{K}{j\omega}\mathbf{U}(j\omega) = Bl\mathbf{I}(j\omega) \qquad \text{Mechanical equation}$$

Having assumed that the inductance of the coil is negligible, we are able to simplify the electrical equation and to solve for $\mathbf{I}(j\omega)$:

$$\mathbf{I}(j\omega) = \frac{\mathbf{V}(j\omega) - Bl\mathbf{U}(j\omega)}{R}$$

Substituting this equivalence into the mechanical equation and accounting for the length of the coil, $l = 2\pi Nr$, the final expression for the frequency response of the loudspeaker is then given by

$$\frac{\mathbf{U}}{\mathbf{V}}(j\omega) = \frac{2\pi NBr}{Rm} \times \frac{j\omega}{(j\omega)^2 + j\omega\left(\dfrac{d + \dfrac{(2\pi)^2 B^2 N^2 r^2}{R}}{m}\right) + \dfrac{k}{m}}$$

or, numerically,

$$\frac{\mathbf{U}}{\mathbf{V}}(j\omega) = \frac{2\pi \times 47 \times 1 \times 0.05}{8(0.001)} \times \frac{j\omega}{(j\omega)^2 + j\omega\left(\frac{22.75 + \frac{(2\pi)^2(1)^2(47)^2(0.05)^2}{8}}{0.001}\right) + \frac{500{,}000}{0.001}}$$

$$\approx \frac{1{,}845\, j\omega}{\left(j\omega + 13.8 \times 10^3\right)\left(j\omega + 36.2 \times 10^3\right)}$$

$$= \frac{0.051\left(\frac{j\omega}{13.8 \times 10^3}\right)}{\left(1 + \frac{j\omega}{36.2 \times 10^3}\right)\left(1 + \frac{j\omega}{13.8 \times 10^3}\right)}$$

This frequency response shows that the speaker has a lower cutoff frequency $f_{ct} = 13{,}800/2\pi \approx 2200$ Hz and an upper cutoff frequency of $f_{ch} = 36{,}000/2\pi \approx 5800$ Hz. In practice, a loudspeaker with such a frequency response would be useful only as a midrange speaker.

Rotating Electric Machines

The range of sizes and power ratings and the different physical features of rotating machines are such that the task of explaining the operation of rotating machines in a single chapter may appear formidable at first. Some features of rotating machines, however, are common to all such devices. This introductory section is aimed at explaining the common properties of all rotating electric machines. We begin our discussion with reference to Figure 5.12.24, in which a hypothetical rotating machine is depicted in a cross-sectional view. In the figure, a box with a cross inscribed in it indicates current flowing into the page, while a dot represents current out of the plane of the page.

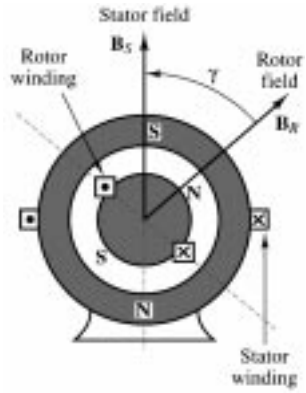

FIGURE 5.12.24 A rotating electric machine.

In Figure 5.12.24, we identify a **stator**, of cylindrical shape, and a **rotor**, which, as the name indicates, rotates inside the stator, separated from the latter by means of an air gap. The rotor stator each consist of a magnetic core, some electrical insulation, and the windings necessary to establish a magnetic flux (unless this is created by a permanent magnet). The rotor is mounted on a bearing-supported shaft, which can be connected to *mechanical loads* (if the machine is a motor) or to a *prime mover* (if the machine is a generator) by means of belts, pulleys, chains, or other mechanical couplings. The windings carry the electric currents that generate the magnetic fields and flow to the electrical loads, and also provide the closed loops in which voltages will be induced (by virtue of Faraday's law, as discussed in the previous section).

Basic Classification of Electric Machines

An immediate distinction can be made between different types of windings characterized by the nature of the current they carry. If the current serves the sole purpose of providing a magnetic field and is independent of the load, it is called a *magnetizing*, or excitation, current, and the winding is termed a **field winding**. Field currents are nearly always DC and are of relatively low power, since their only purpose is to magnetize the core (recall the important role of high-permeability cores in generating large magnetic fluxes from relatively small currents). On the other hand, if the winding carries only the load current, it is called an **armature**. In DC and AC synchronous machines, separate windings exist to carry field and armature currents. In the induction motor, the magnetizing and load currents flow in the same winding, called the *input winding*, or *primary*; the output winding is then called the *secondary*. As we shall see, this terminology, which is reminiscent of transformers, is particularly appropriate for induction motors, which bear a significant analogy to the operation of the transformers. Table 5.12.4 characterizes the principal machines in terms of their field and armature configuration.

TABLE 5.12.4 Configurations of the Three Types of Electric Machines

Machine Type	Winding	Winding Type	Location	Current
DC	Input and output	Armature	Rotor	AC (winding) DC (at brushes)
	Magnetizing	Field	Stator	DC
Synchronous	Input and output	Armature	Stator	AC
	Magnetizing	Field	Rotor	DC
Induction	Input	Primary	Stator	AC
	Output	Secondary	Rotor	AC

It is also useful to classify electric machines in terms of their energy-conversion characteristics. A machine acts as a **generator** if it converts mechanical energy from a prime mover — e.g., an internal combustion engine — to electrical form. Examples of generators are the large machines used in power-generating plants, or the common automotive alternator. A machine is classified as a **motor** if it converts electrical energy to mechanical form. The latter class of machines is probably of more direct interest to you, because of its widespread application in engineering practice. Electric motors are used to provide forces and torques to generate motion in countless industrial applications. Machine tools, robots, punches, presses, mills, and propulsion systems for electric vehicles are but a few examples of the application of electric machines in engineering.

Note that in Figure 5.12.24 we have explicitly shown the direction of two magnetic fields: that of the rotor, $\mathbf{B}_R$, and that of the stator, $\mathbf{B}_S$. Although these fields are generated by different means in differential machines (e.g., permanent magnets, AC currents, DC currents), the presence of these fields is what causes a rotating machine to turn and enables the generation of electric power. In particular, we see that in Figure 5.12.24 the north pole of the rotor field will seek to align itself with the south pole of the stator field. It is this magnetic attraction force that permits the generation of torque in an electric motor; conversely, a generator exploits the laws of electromagnetic induction to convert a changing magnetic field to an electric current.

To simplify the discussion in later sections, we shall presently introduce some basic concepts that apply to all rotating electric machines. Referring to Figure 5.12.25, we note that all machines the force on a wire is given by the expression

$$\mathbf{f} = i_w \mathbf{I} \times \mathbf{B} \tag{5.12.35}$$

where i_w is the current in the wire, $\mathbf{I}$ is a vector along the direction of the wire, and × denotes the cross product of two vectors. Then the torque for a multiturn coil becomes

$$T = KBi_w \sin\alpha \tag{5.12.36}$$

where

B = magnetic flux density caused by the stator field
K = constant depending on coil geometry
α = angle between **B** and the normal to the plane of the coil

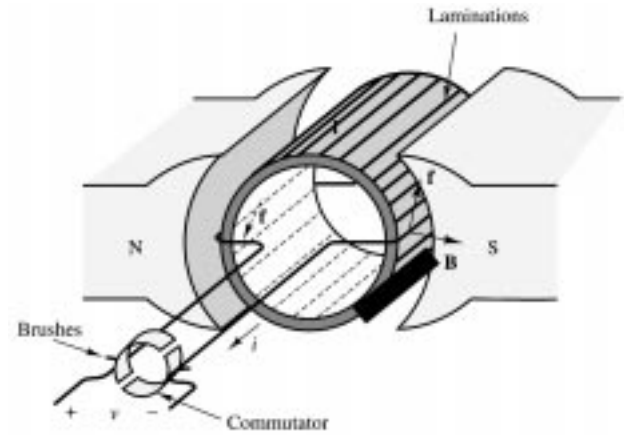

FIGURE 5.12.25 Stator and rotor fields and the force acting on a rotating machine.

Other Characteristics of Electric Machines

As already stated earlier in this chapter, electric machines are **energy-conversion devices**, and we are therefore interested in their energy-conversion **efficiency**. Typical applications of electric machines as motors or generators must take into consideration the energy losses associated with these devices. Figure 5.12.26 represents the various loss mechanisms you must consider in analyzing the efficiency of an electric machine for the case of direct-current machines. It is important for you to keep in mind this conceptual flow of energy when analyzing electric machines. The sources of loss in a rotating machine can be separated into three fundamental groups: electrical (I^2R) losses, core losses, and mechanical losses.

I^2R losses are usually computed on the basis of the DC resistance of the windings at 75°C; in practice, these losses vary with operating conditions. The difference between the nominal and actual I^2R is usually lumped under the category of *stray-load loss*. In direct-current machines, it is also necessary to account for the *brush contact loss* associated with slip rings and commutators.

Mechanical losses are due to *friction* (mostly in the bearings) and *windage,* that is, the air drag force that opposes the motion of the rotor. In addition, if external devices (e.g., blowers) are required to circulate air through the machine for cooling purposes, the energy expended by these devices is also included in the mechanical losses.

Open-circuit core losses consist of hysteresis and eddy current losses, with only the excitation winding energized. Often these losses are summed with friction and windage losses to give rise to the *no-load rotational loss*. The latter quantity is useful if one simply wishes to compute efficiency. Since open-circuit core losses do not account for the changes in flux density caused by the presence of load currents, an additional magnetic loss is incurred that is not accounted for in this term. *Stray-load losses* are used to lump the effects of nonideal current distribution in the windings and of the additional core losses just mentioned. Stray-load losses are difficult to determine exactly and are often assumed to be equal to 1.0% of the output power for DC machines; these losses can be determined by experiment in synchronous and induction machines.

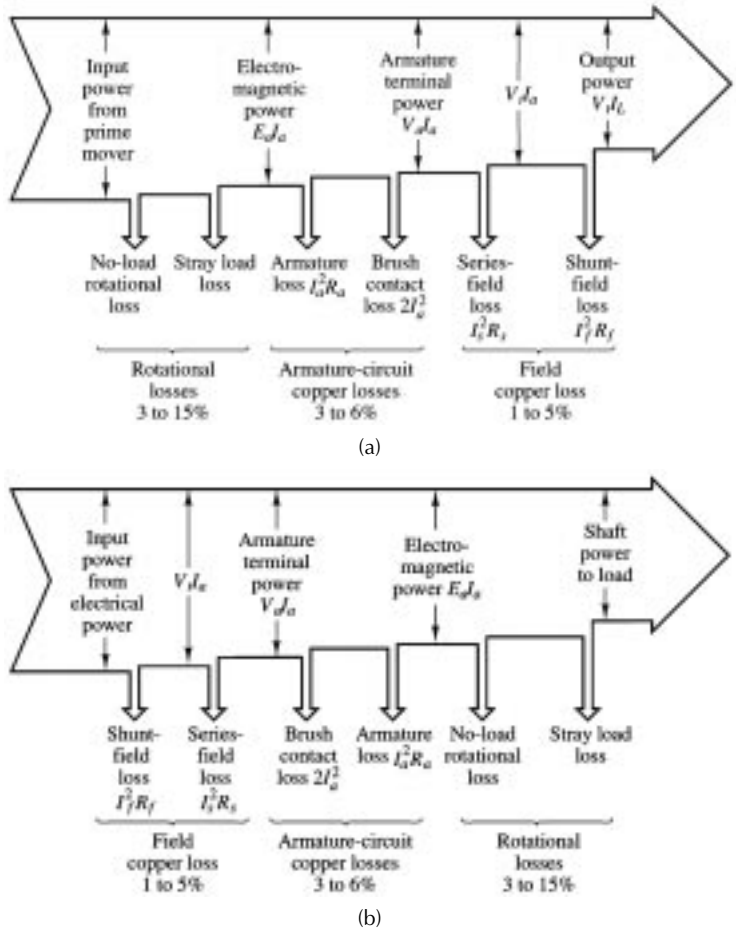

FIGURE 5.12.26 (a) Generator losses, direct current; (b) motor losses, direct current.

The performance of an electric machine can be quantified in a number of ways. In the case of an electric motor, it is usually portrayed in the form of a graphical **torque-speed characteristic.** The torque-speed characteristic of a motor describes how the torque supplied by the machine varies as a function of the speed of rotation of the motor for steady speeds. As we shall see in later sections, the torque-speed curves vary in shape with the type of motor (DC, induction, synchronous) and are very useful in determining the performance of the motor when connected to a mechanical load. Figure 5.12.27 depicts the torque-speed curve of a hypothetical motor. We shall presently describe the essential elements of such a graphical representation of motor performance, and we shall later return to analyze the typical performance curve of each type of motor we encounter in our discussion. It is quite likely that in most engineering applications, the engineer is required to make a decision regarding the performance characteristics of the motor best suited to a specified task. In this context, the torque-speed curve of a machine is a very useful piece of information.

The first feature we note of the torque-speed characteristic is that it bears a strong resemblance to the *i-v* characteristics used in earlier chapters to represent the behavior of electrical sources. It should be clear that, according to this torque-speed curve, the motor is not an ideal source of torque (if it were, the curve would appear as a horizontal line across the speed range). One can readily see, for example, that the hypothetical motor represented by the curves of Figure 5.12.27 would produce maximum torque in the range of speeds between approximately 800 and 1400 rev/min. What determines the actual speed of the motor (and therefore its output torque and power) is the torque-speed characteristic of the load

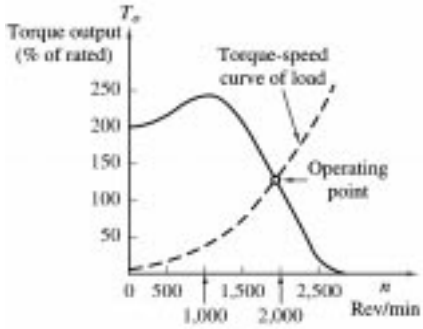

FIGURE 5.12.27 Torque-speed curve for an electric motor.

connected to it, much as a resistive load determines the current drawn from a voltage source. In the figure, we display the torque-speed curve of a load, represented by the dashed line; the operating point of the motor-load pair is determined by the intersection of the two curves.

Another important observation pertains to the fact that the motor of Figure 5.12.27 produces a nonzero torque at zero speed. This fact implies that as soon as electric power is connected to the motor, the latter is capable of supplying a certain amount of torque; this zero-speed torque is called the **starting torque**. If the load the motor is connected to requires less than the starting torque the motor can provide, then the motor can accelerate the load, until the motor speed and torque settle to a stable value, at the operating point. The motor-load pair of Figure 5.12.27 would behave in the manner just described. However, there may well be circumstances in which a motor might not be able to provide a sufficient starting torque to overcome the static load torque that opposes its motion. Thus, we see that a torque-speed characteristic can offer valuable insight into the operation of a motor. As we proceed to discuss each type of machine in greater detail, we shall devote some time to the discussion of its torque-speed curve.

The most common means of conveying information regarding electric machines is the *nameplate*. Typical information conveyed by the nameplate is

1. Type of device (e.g., DC motor, alternator)
2. Manufacturer
3. Rated voltage and frequency
4. Rated current and volt-amperes
5. Rated speed and horsepower

The **rated voltage** is the terminal voltage for which the machine was designed, and which will provide the desired magnetic flux. Operation at higher voltages will increase magnetic core losses, because of excessive core saturation. The **rated current** and **rated volt-amperes** are an indication of the typical current and power levels at the terminal that will not cause undue overheating due to copper losses (I^2R losses) in the windings. These ratings are not absolutely precise, but they give an indication of the range of excitations for which the motor will perform without overheating. Peak power operation in a motor may exceed rated torque (horsepower) or currents by a substantial factor (up to as much as six or seven times the rated value); however, continuous operation of the motor above the rated performance will cause the machine to overheat, and possibly to sustain damage. Thus, it is important to consider both peak and continuous power requirements when selecting a motor for a specific application. An analogous discussion is valid for the speed rating: while an electric machine may operate above rated speed for limited periods of time, the large centrifugal forces generated at high rotational speeds will eventually cause undesirable mechanical stresses, especially in the rotor windings, leading eventually even to self-destruction.

Another important feature of electric machines is the **regulation** of the machine speed or voltage, depending on whether it is used as a motor or as a generator, respectively. Regulation is the ability to maintain speed or voltage constant in the face of load variations. The ability to closely regulate speed in a motor or voltage in a generator is an important feature of electric machines; regulation is often

improved by means of feedback control mechanisms, some of which will be briefly introduced in this chapter. We shall take the following definitions as being adequate for the intended purpose of this chapter.

$$\text{Speed regulation} = \frac{\text{Speed at no load} - \text{Speed at rated load}}{\text{Speed at rated load}} \tag{5.12.37}$$

$$\text{Voltage regulation} = \frac{\text{Voltage at no load} - \text{Voltage at rated load}}{\text{Voltage at rated load}} \tag{5.12.38}$$

Please note that the rated value is usually taken to be the nameplate value, and that the meaning of *load* changes depending on whether the machine is a motor, in which case the load is mechanical, or a generator, in which case the load is electrical.

Basic Operation of All Rotating Machines

We have already seen how the magnetic field in electromechanical devices provides a form of coupling between electrical and mechanical systems. Intuitively, one can identify two aspects of this coupling, both of which play a role in the operation of electric machines: (1) magnetic attraction and repulsion forces generate mechanical torque, and (2) the magnetic field can induce a voltage in the machine windings (coils) by virtue of Faraday's law. Thus, we may think of the operation of an electric machine in terms of either a motor or a generator, depending on whether the input power is electrical and mechanical power is produced (motor action), or the input power is mechanical and the output power is electrical (generator action). Figure 5.12.28 illustrates the two cases graphically.

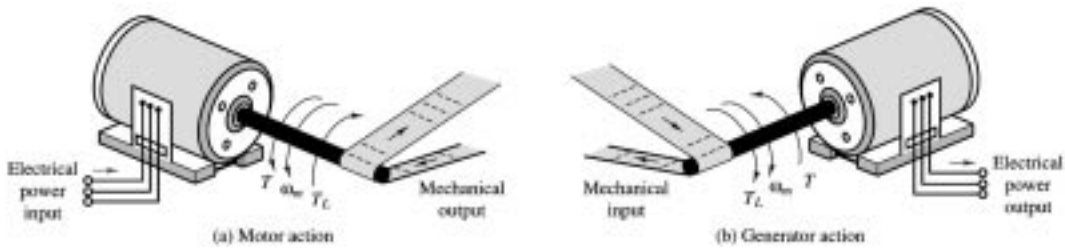

FIGURE 5.12.28 Generator and motor action in an electric machine.

The coupling magnetic field performs a dual role, which may be explained as follows. When a current i flow through conductors placed in a magnetic field, a force is produced on each conductor, according to Equation (5.12.35). If these conductors are attached to a cylindrical structure, a torque is generated, and if the structure is free to rotate, then it will rotate at an angular velocity ω_m. As the conductors rotate, however, they move through a magnetic field and cut through flux lines, thus generating an electromotive force in opposition to the excitation. This emf is also called "counter" emf; it opposes the source of the current i. If, on the other hand, the rotating element of the machine is driven by a prime mover (for example, an internal combustion engine), then an emf is generated across the coil that is rotating in the magnetic field (the armature). If a load is connected to the armature, a current i will flow to the load, and this current flow will in turn cause a reaction torque on the armature that opposes the torque imposed by the prime mover.

You see, then, that for energy conversion to take place, two elements are required: (1) a coupling field, **B**, usually generated in the field winding; and (2) an armature winding that supports the load current, i, and the emf, e.

Magnetic Poles in Electric Machines

Before discussing the actual construction of a rotating machine, we should spend a few paragraphs to illustrate the significance of **magnetic poles** in an electric machine. In an electric machine, torque is

developed as a consequence of magnetic forces of attraction and repulsion between magnetic poles on the stator and on the rotor; these poles produce a torque that accelerates the rotor and a reaction torque on the stator. Naturally, we would like a construction such that the torque generated as a consequence of the magnetic forces is continuous and in a constant direction. This can be accomplished if the number of rotor poles is equal to the number of stator poles. It is also important to observe that the number of poles must be even, since there have to be equal numbers of north and south poles.

Figure 5.12.29 depicts a two-pole machine in which the stator poles are constructed in such a way as to project closer to the rotor than to the stator structure. This type of construction is rather common, and poles constructed in this fashion are called **salient poles**. Note that the rotor could also be constructed to have salient poles.

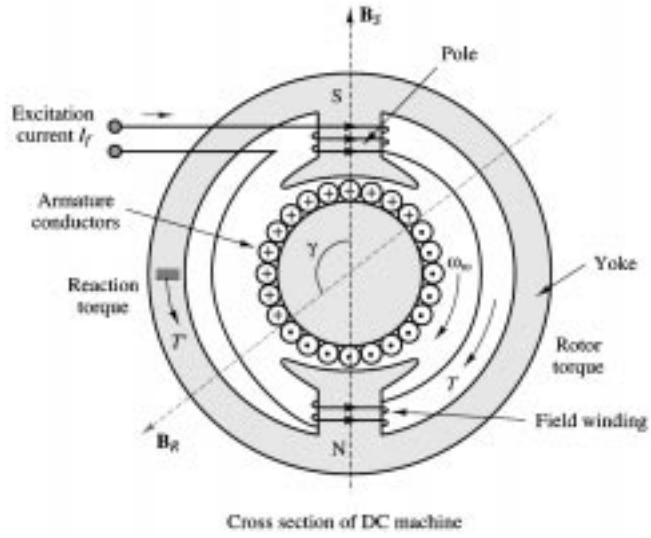

FIGURE 5.12.29 A two-pole machine with salient stator poles.

To understand magnetic polarity, we need to consider the direction of the magnetic field in a coil carrying current. Figure 5.12.30 shows how the *right-hand rule* can be employed to determine the direction of the magnetic flux. If one were to grasp the coil with the right hand, with the fingers curling in the direction of current flow, then the thumb would be pointing in the direction of the magnetic flux. Magnetic flux is by convention viewed as entering the south pole and exiting from the north pole. Thus, to determine whether a magnetic pole is north or south, we must consider the direction of the flux. Figure 5.12.31 shows a cross section of a coil wound around a pair of salient rotor poles. In this case, one can readily identify the direction of the magnetic flux and therefore the magnetic polarity of the poles by applying the right-hand rule, as illustrated in the figure.

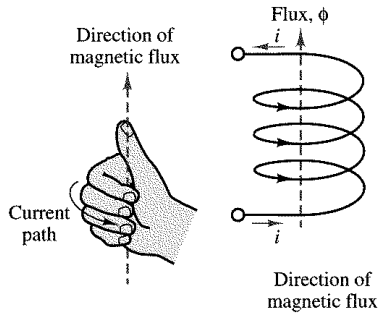

FIGURE 5.12.30 Right-hand rule.

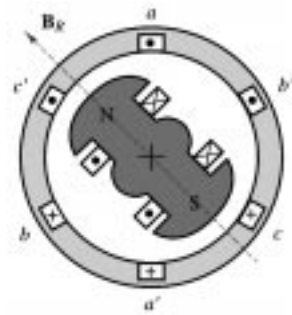

FIGURE 5.12.31 Magnetic field in a salient rotor winding.

Often, however, the coil windings are not arranged as simply as in the case of salient poles. In many machines, the windings are embedded in slots cut into the stator or rotor, so that the situation is similar to that of the stator depicted in Figure 5.12.32. This figure is a cross section in which the wire connections between "crosses" and "dots" have been cut away. In Figure 5.12.32, the dashed line indicates the axis of the stator flux according to the right-hand rule, indicating that the slotted stator in effect behaves like a pole pair. The north and south poles indicated in the figure are a consequence of the fact that the flux exits the bottom part of the structure (thus, the north pole indicated in the figure) and enters the top half of the structure (thus, the south pole). In particular, if you consider that the windings are arranged so that the current entering the right-hand side of the stator (to the right of the dashed line) flows through the back end of the stator and then flows outward from the left-hand side of the stator slots (left of the dashed line), you can visualize the windings in the slots as behaving in a manner similar to the coils of Figure 5.12.31, where the flux axis of Figure 5.12.32 corresponds to the flux axis of each of the coils of Figure 5.12.31. The actual circuit that permits current flow is completed by the front and back ends of the stator, where the wires are connected according to the pattern *a*-*a*′, *b*-*b*′, *c*-*c*′, as depicted in the figure.

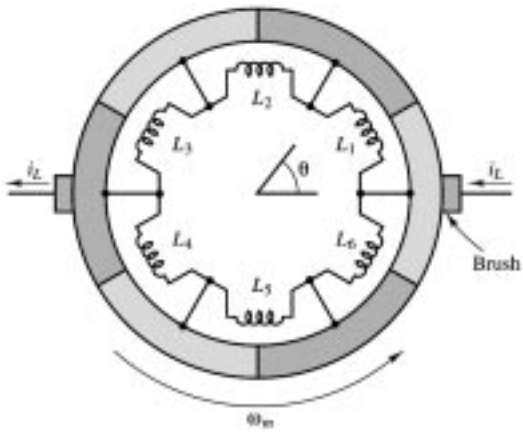

FIGURE 5.12.32 Magnetic field of stator.

Another important consideration that facilitates understanding the operation of electric machines pertains to the use of AC currents. It should be apparent by now that if the current flowing into the slotted stator is alternating, the direction of the flux will also alternate, so that in effect the two poles will reverse polarity every time the current reverses direction, that is, every half-cycle of the sinusoidal current. Further — since the magnetic flux is approximately proportional to the current in the coil — as the amplitude of the current oscillates in a sinusoidal fashion, so will the flux density in the structure. Thus, *the magnetic field developed in the stator changes both spatially and in time.*

This property is typical of AC machines, where a *rotating magnetic field* is established by energizing the coil with an alternating current. As we shall see in the next section, the principles underlying the operation of DC and AC machines are quite different: in a direct-current machine, there is no rotating

field, but a mechanical switching arrangement (the *commutator*) makes it possible for the rotor and stator magnetic fields to always align at right angles to each other.

Direct-Current Machines

As explained in the introductory section, direct-current (DC) machines are easier to analyze than their AC counterparts, although their actual construction is made rather complex by the need to have a commutator, which reverses the direction of currents and fluxes to produce a net torque. The objective of this section is to describe the major construction features and the operation of direct-current machines, as well as to develop simple circuit models that are useful in analyzing the performance of this class of machines.

Physical Structure of DC Machines

A representative DC machine was depicted in Figure 5.12.29, with the magnetic poles clearly identified for both the stator and the rotor. Note the salient pole construction of the stator and the slotted rotor. As previously stated, the torque developed by the machine is a consequence of the magnetic forces between stator and rotor poles. This torque is maximum when the angle γ between the rotor and stator poles is 90°. Also, as you can see from the figure, in a DC machine the armature is usually on the rotor, and the field winding is on the stator.

To keep this torque angle constant as the rotor spins on its shaft, a mechanical switch, called a **commutator**, is configured so the current distribution in the rotor winding remains constant and therefore the rotor poles are consistently at 90° with respect to the fixed stator poles. In a DC machine, the magnetizing current is DC, so that there is no spatial alternation of the stator poles due to time-varying currents. To understand the operation of the commutator, consider the simplified diagram of Figure 5.12.33. In the figure, the brushes are fixed, and the rotor revolves at an angular velocity ω_m; the instantaneous position of the rotor is given by the expression $\theta = \omega_m t - \gamma$.

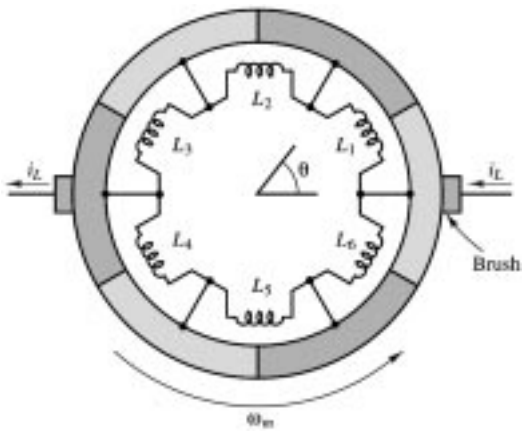

FIGURE 5.12.33 Rotor winding and commutator.

The commutator is fixed to the rotor and is made up in this example of six segments that are made of electrically conducting material but are insulated from each other. Further, the rotor windings are configured so that they form six coils, connected to the commutator segments as shown in Figure 5.12.33.

As the commutator rotates counterclockwise, the rotor magnetic field rotates with it up to $\theta = 30°$. At that point, the direction of the current changes in coils L_3 and L_6 as the brushes make contact with the next segment. Now the direction of the magnetic field is –30°. As the commutator continues to rotate, the direction of the rotor field will again change from –30° to +30°, and it will switch again when the brushes switch to the next pair of segments. In this machine, then, the torque angle, γ, is not always 90°, but can vary by as much as ±30°; the actual torque produced by the machine would fluctuate by as much as ±14%, since the torque is proportional to sin γ. As the number of segments increases, the

torque fluctuation produced by the commutation is greatly reduced. In a practical machine, for example, one might have as many as 60 segments, and the variation of γ from 90° would be only ±3°, with a torque fluctuation of less than 1%. Thus, the DC machine can produce a nearly constant torque (as a motor) or voltage (as a generator).

Configuration of DC Machines

In DC machines, the field excitation that provides the magnetizing current is occasionally provided by an external source, in which case the machine is said to be **separately excited** (Figure 5.12.34(a)). More often, the field excitation is derived from the armature voltage and the machine is said to be **self-excited**. The latter configuration does not require the use of a separate source for the field excitation and is therefore frequently preferred. If a machine is in the separately excited configuration, an additional source, V_f, is required. In the self-excited case, one method used to provide the field excitation is to connect the field in parallel with the armature, since the field winding typically has significantly higher resistance than the armature circuit (remember that it is the armature that carries the load current), this will not draw excessive current from the armature. Further, a series resistor can be added to the field circuit to provide the means for adjusting the field current independent of the armature voltage. This configuration is called a **shunt-connected** machine and is depicted in Figure 5.12.34(b). Another method for self-exciting a DC machine consists of connecting the field in series with the armature, leading to the **series-connected** machine, depicted in Figure 5.12.34(c); in this case, the field winding will support the entire armature current, and thus the field coil must have low resistance (and therefore relatively few turns). This configuration is rarely used for generators, since the generated voltage and the load voltage must always differ by the voltage drop across the field coil, which varies with the load current. Thus, a series generator would have poor (large) regulation. However, series-connected motors are commonly used in certain applications, as will be discussed in a later section.

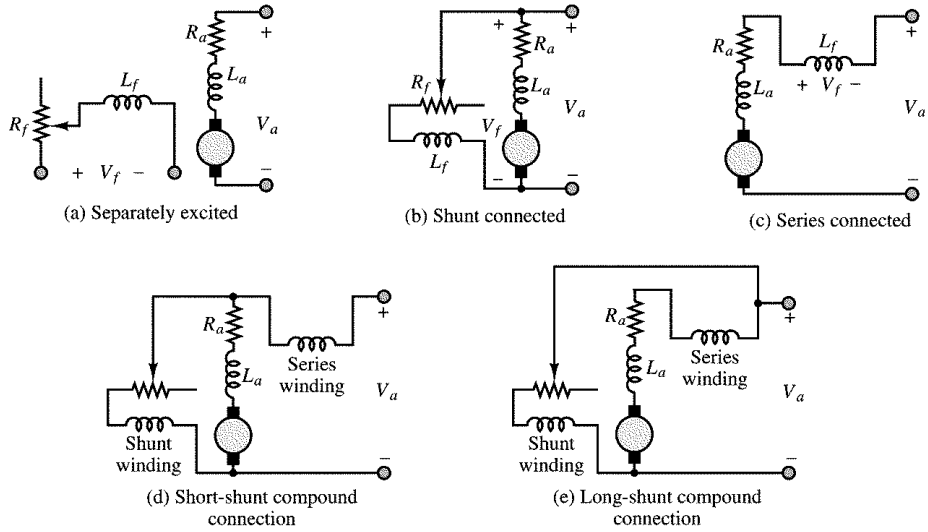

FIGURE 5.12.34

The third type of DC machine is the **compound-connected** machine, which consists of a combination of the shunt and series configurations. Figures 5.12.34(d) and (e) show the two types of connections, called the **short shunt** and the **long shunt**, respectively. Each of these configurations may be connected so that the series part of the field adds to the shunt part (**cumulative compounding**) or so that it subtracts (**differential compounding**).

DC Machine Models

As stated earlier, it is relatively easy to develop a simple model of a DC machine, which is well suited to performance analysis, without the need to resort to the details of the construction of the machine itself. This section will illustrate the development of such models in two steps. First, steady-state models relating field and armature currents and voltages to speed and torque are introduced; second, the differential equations describing the dynamic behavior or DC machines are derived.

When a field excitation is established, a magnetic flux, ϕ, is generated by the field current, I_f. From Equation (5.12.36) we know that the torque acting on the rotor is proportional to the product of the magnetic field and the current in the load-carrying wire; the latter current is the armature current, I_a (i_w, in Equation 5.12.36). Assuming that, by virtue of the cummutator, the torque angle, γ, is kept very close to 90°, and therefore $\sin\gamma = 1$, we obtain the following expression for the torque (in units of N-m) in a DC machine:

$$T = k_T \phi I_a \qquad \text{for } \gamma = 90° \tag{5.12.39}$$

You may recall that this is simply a consequence of the *Bli* law of Chapter 15. The mechanical power generated (or absorbed) is equal to the product of the machine torque and the mechanical speed of rotation, ω_m (in rad/sec), and is therefore given by

$$P_m = \omega_m T = \omega_m k_T \phi I_a \tag{5.12.40}$$

Recall now that the rotation of the armature conductors in the field generated by the field excitation causes a **back emf**, E_b, in a direction that opposes the rotation of the armature. According to the *Blu* law then, this back emf is given by the expression.

$$E_b = k_a \phi \omega_m \tag{5.12.41}$$

where k_a is called the **armature constant** and is related to the geometry and magnetic properties of the structure. The voltage E_b represents a countervoltage (opposing the DC excitation) in the case of a motor, and the generated voltage in the case of a generator. Thus, the electric power dissipated (or generated) by the machine is given by the product of the back emf and the armature current:

$$P_e = E_b I_a \tag{5.12.42}$$

The constants k_T and k_a in Equations (5.12.39) and (5.12.41) are related to geometry factors, such as the dimension of the rotor and the number of turns in the armature winding; and to properties of materials, such as the permeability of the magnetic materials. Note that in the ideal energy-conversion case, $P_m = P_e$, and therefore $k_a = k_T$. We shall, in general, assume such ideal conversion of electrical to mechanical (or vice versa) and will therefore treat the two constants as being identical: $k_a = k_T$. The constant k_a is given by

$$k_a = \frac{pN}{2\pi M} \tag{5.12.43}$$

where

p = number of magnetic poles
N = number of conductors per coil
M = number of parallel paths in armature winding

An important observation concerning the units of angular speed must be made at this point. The equality (under the no-loss assumption) between the constants k_a and k_T in Equations (5.12.39) and

(5.12.41) results from the choice of consistent units, namely, volts and amperes for the electrical quantities, and newton-meters and radians per second for the mechanical quantities. You should be aware that it is fairly common practice to refer to the speed of rotation of an electric machine in units of revolutions per minute (rev/min). In this book, we shall uniformly use the symbol n to denote angular speed in rev/min; the following relationship should be committed to memory:

$$n(\text{rev/min}) = \frac{60}{2\pi}\omega_m \ (\text{rad/sec}) \tag{5.12.44}$$

If the speed is expressed in rev/min, the armature constant changes as follows:

$$E_b = k'_a \phi n \tag{5.12.45}$$

where

$$k'_a = \frac{pN}{60M} \tag{5.12.46}$$

Having introduced the basic equations relating torque, speed, voltages, and currents in electric machines, we may now consider the interaction of these quantities in a DC machine at steady state, that is, operating at constant speed and field excitation. Figure 5.12.35 depicts the electrical circuit model of a separately excited DC machine, illustrating both motor and generator action. It is very important to note the reference direction of armature current flow and of the developed torque, in order to make a distinction between the two modes of operation. The field excitation is shown as a voltage, V_f, generating the field current, I_f, that flows through a variable resistor, R_f, and through the field coil, L_f. The variable resistor permits adjustment of the field excitation. The armature circuit, on the other hand, consists of a voltage source representing the back emf, E_b, the armature resistance, R_a, and the armature voltage, V_a. This model is appropriate both for motor and for generator action. When $V_a < E_b$, the machine acts as a generator (I_a flows out of the machine). When $V_a > E_b$, the machine acts as a motor (I_a flows into the machine). Thus, according to the circuit model of Figure 5.12.35, the operation of a DC machine at steady state (i.e., with the inductors in the circuit replaced by short circuits) is described by the following equations:

$$\begin{aligned} I_f &= \frac{V_f}{R_f} \quad \text{and} \quad V_a = R_a I_a + E_b \qquad (\text{motor action}) \\ I_f &= \frac{V_f}{R_f} \quad \text{and} \quad V_a = -R_a I_a + E_b \qquad (\text{generator action}) \end{aligned} \tag{5.12.47}$$

Equation pair (5.12.47) together with Equations (5.12.39) and (5.12.41) may be used to determine the steady-state operating condition of a DC machine.

The circuit model of Figure 5.12.35 permits the derivation of a simple set of differential equations that describe the *dynamic* analysis of a DC machine. The dynamic equations describing the behavior of a separately excited DC machine are as follows:

$$V_a(t) = I_a(t)R_a + L_a \frac{dI_a(t)}{dt} + E_b(t) \qquad (\text{armature circuit}) \tag{5.12.48a}$$

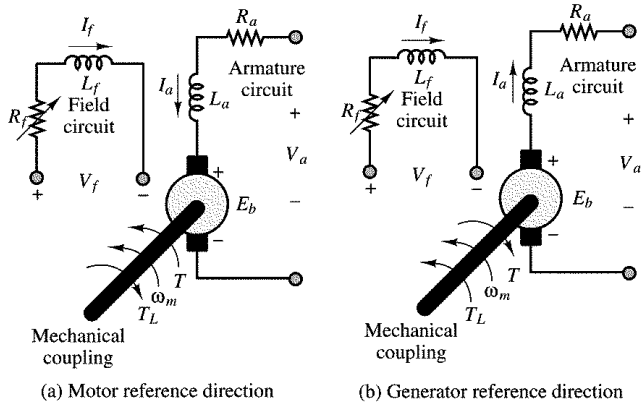

FIGURE 5.12.35 Electrical circuit model of a separately excited DC machine.

$$V_f(t) = I_f(t)R_f + L_f\frac{dI_f(t)}{dt} \qquad \text{(field circuit)} \tag{5.12.48b}$$

These equations can be related to the operation of the machine in the presence of a load. If we assume that the motor is rigidly connected to an inertial load with moment of inertia J and that the friction losses in the load are represented by a viscous friction coefficient, b, then the torque developed by the machine (in the motor mode of operation) can be written as follows:

$$T(t) = T_L + b\omega_m(t) + J\frac{d\omega_m(t)}{dt} \tag{5.12.49}$$

where T_L is the load torque. T_L is typically either constant or some function of speed, ω_m, in a motor. In the case of a generator, the load torque is replaced by the torque supplied by a prime mover, and the machine torque, $T(t)$, opposes the motion of the prime mover, as shown in Figure 5.12.35. Since the machine torque is related to the armature and field currents by Equation (5.12.39), Equations (5.12.48) and (5.12.49) are coupled to each other; this coupling may be expressed as follows:

$$T(t) = k_a\phi I_a(t) \tag{5.12.50}$$

or

$$k_a\phi I_a(t) = T_L + b\omega_m(t) + J\frac{d\omega_m(t)}{dt} \tag{5.12.51}$$

The dynamic equations described in this section apply to any DC machine. In the case of a *separately excited* machine, a further simplification is possible, since the flux is established by virtue of a separate field excitation, and therefore

$$\phi = \frac{N_f}{\mathcal{R}}I_f = k_f I_f \tag{5.12.52}$$

where N_f is the number of turns in the field coil, $\mathcal{R}$ is the reluctance of the structure, and I_f is the field current.

AC Machines

From the previous sections, it should be apparent that it is possible to obtain a wide range of performance characteristics from DC machines, as both motors and generators. A logical question at this point should be, would it not be more convenient in some cases to take advantage of the single- or multiphase AC power that is available virtually everywhere than to expend energy and use additional hardware to rectify and regulate the DC supplies required by direct-current motors? The answer to this very obvious question is certainly a resounding yes. In fact, the AC induction motor is the workhorse of many industrial applications, and synchronous generators are used almost exclusively for the generation of electric power worldwide. Thus, it is appropriate to devote a significant portion of this chapter to the study of AC machines, and of induction motors in particular. The objective if this section is to explain the basic operation of both synchronous and induction machines, and to outline their performance characteristics. In doing so, we shall also point out the relative advantages and disadvantages of these machines in comparison with direct-current machines.

Rotating Magnetic Fields

As mentioned in earlier, the fundamental principle of operation o AC machines is the generation of a rotating magnetic field, which causes the rotor to turn at a speed that depends on the speed of rotation of the magnetic field. We shall now explain how a rotating magnetic field can be generated in the stator and air gap of an AC machine by means of AC currents.

Consider the stator shown in Figure 5.12.36, which supports windings, a-a', b-b', and c-c'. The coils are geometrically spaced 120° apart, and a three-phase voltage is applied to the coils. As you may recall from the discussion of AC power in Section 5.5, the currents generated by a three-phase source are also spaced by 120°, as illustrated in Figure 5.12.37. The phase voltages referencing the neutral terminal would then be given by the expressions

$$v_a = A\cos(\omega_e t)$$

$$v_b = A\cos\left(\omega_e t - \frac{2\pi}{3}\right)$$

$$v_c = A\cos\left(\omega_e t + \frac{2\pi}{3}\right)$$

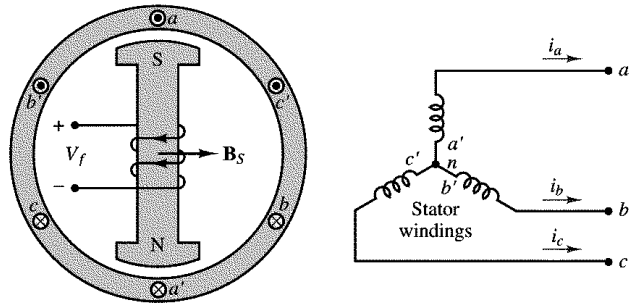

FIGURE 5.12.36 Two-pole three-phase stator.

where ω_e is the frequency of the AC supply, or line frequency. The coils in each winding are arranged in such a way that the flux distribution generated by any one winding is approximately sinusoidal. Such a flux distribution may be obtained by appropriately arranging groups of coils for each winding over the stator surface. Since the coils are spaced 120° apart, the flux distribution resulting from the sum of the contributions of the three windings is the sum of the fluxes due to the separate windings, as shown

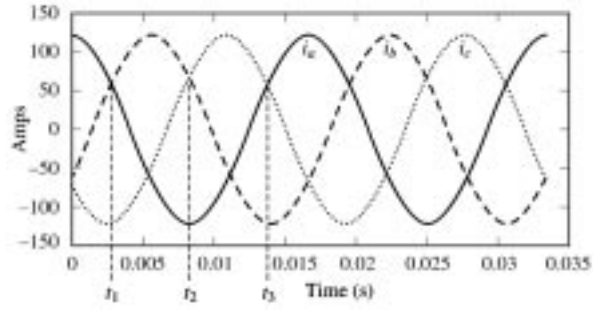

FIGURE 5.12.37 Three-phase stator winding currents.

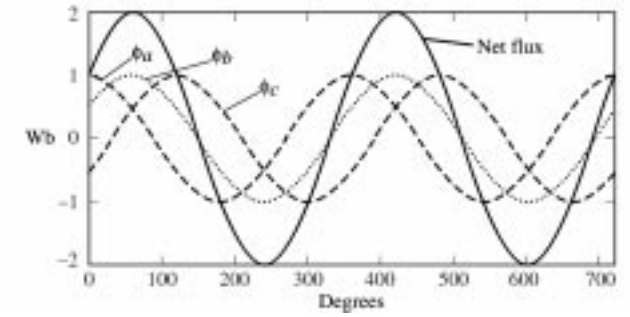

FIGURE 5.12.38 Flux distribution in a three-phase stator winding as a function of angle of rotation.

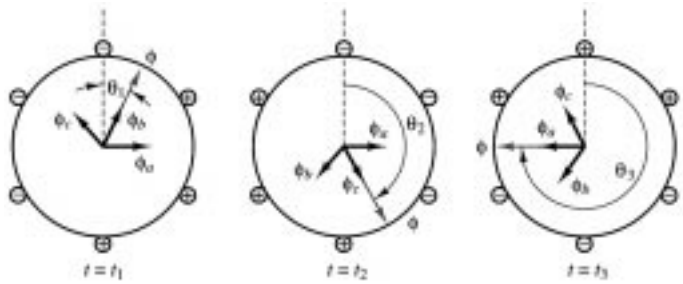

FIGURE 5.12.39 Rotating flux in a three-phase machine.

in Figure 5.12.38. Thus, the flux in a three-phase machine rotates in space according to the vector diagram of Figure 5.12.39, and is constant in amplitude. A stationary observer on the machine's stator would see a sinusoidally varying flux distribution as shown in Figure 5.12.38.

Since the resultant flux of Figure 5.12.38 is generated by the currents of Figure 5.12.37, the speed of rotation of the flux must be related to the frequency of the sinusoidal phase currents. In the case of the stator of Figure 5.12.36, the number of magnetic poles resulting from the winding configuration is two; however, it is also possible to configure the windings so that they have more poles. For example, Figure 5.12.40 depicts a simplified view of a four-pole stator.

In general, the speed of the rotating magnetic field is determined by the frequency of the excitation current, f, and by the number of poles present in the stator, p, according to the equation

$$n_s = \frac{120f}{p} \text{ rev/min}$$

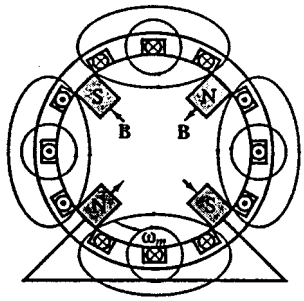

FIGURE 5.12.40 Four-pole stator.

or

$$\omega_s = \frac{2\pi n_s}{60} = \frac{2\pi \times 2f}{p} \tag{5.12.53}$$

where n_s (or ω_s) is usually called the **synchronous speed**.

The Induction Motor

The induction motor is the most widely used electric machine because of its relative simplicity of construction. The stator winding of an induction machine is similar to that of a synchronous machine; thus, the description of the three-phase winding of Figure 5.12.36 also applies to induction machines. The primary advantage of the induction machine, which is almost exclusively used as a motor (its performance as a generator is not very good), is that no separate excitation is required for the rotor. The rotor typically consists of one of two arrangements: **a squirrel cage** or a **wound rotor**. The former contains conducting bars short-circuited at the end and embedded within it; the latter consists of a multiphase winding similar to that used for the stator, but electrically short-circuited.

In either case, the induction motor operates by virtue of currents induced from the stator field in the rotor. In this respect, its operation is similar to that of a transformer, in that currents in the stator (which acts as a primary coil) induce currents in the rotor (acting as a secondary coil). In most induction motors, no external electrical connection is required for the rotor, thus permitting a simple, rugged construction, without the need for slip rings or brushes. Unlike the synchronous motor, the induction motor does not operate at synchronous speed, but at a somewhat lower speed, which is dependent on the load. Figure 5.12.41 illustrates the appearance of a squirrel-cage induction motor. The following discussion will focus mainly on this very common configuration.

You are by now acquainted with the notion of a rotating stator magnetic field. Imagine now that a squirrel-cage rotor is inserted in a stator in which such a rotating magnetic field is present. The stator field will induce voltages in the cage conductors, and if the stator field is generated by a three-phase source, the resulting rotor currents — which circulate in the bars of the squirrel cage, with the conducting path completed by the shorting rings at the end of the cage — are also three-phase, and are determined by the magnitude of the induced voltages and by the impedance of the rotor. Since the rotor currents are induced by the stator field, the number of poles and the speed of rotation of the induced magnetic field are the same as those of the stator field, *if the rotor is at rest*. Thus, when a stator field is initially applied, the rotor field is synchronous with it, and the fields are stationary with respect to each other. Thus, according to the earlier discussion, a *starting torque* is generated.

If the starting torque is sufficient to cause the rotor to start spinning, the rotor will accelerate up to its operating speed. However, an induction motor can never reach synchronous speed; if it did, the rotor would appear to be stationary with respect to the rotating stator field, since it would be rotating at the same speed. But in the absence of relative motion between the stator and rotor fields, no voltage would be induced in the rotor. Thus, an induction motor is limited to speeds somewhere below the synchronous

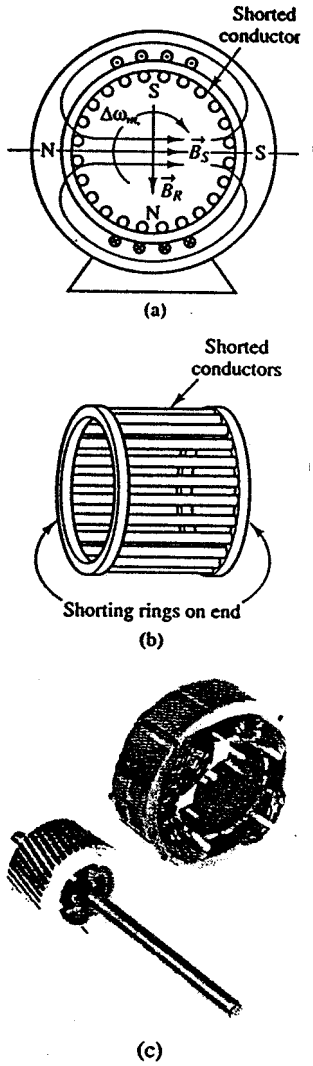

FIGURE 5.12.41 (a) Squirrel-cage induction motor; (b) conductors in rotor; (c) photo of squirrel-cage induction motor.

speed, n_s. Let the speed of rotation of the rotor be n; then, the rotor is losing ground with respect to the rotation of the stator field at a speed $(n_s - n)$. In effect, this is equivalent to backward motion of the rotor at the **slip speed**, defined by $(n_s - n)$. The **slip**, s, is usually defined as a fraction of n_s:

$$s = \frac{n_s - n}{n_s} \tag{5.12.54}$$

which leads to the following expression for the motor speed:

$$n = n_s(1 - s) \tag{5.12.55}$$

The slip, s, is a function of the load, and the amount of slip in a given motor is dependent on its construction and rotor type (squirrel cage or wound rotor). Since there is a relative motion between the stator and rotor fields, voltages will be induced in the rotor at a frequency called the **slip frequency**, related to the relative speed of the two fields. This gives rise to an interesting phenomenon: the rotor

field travels relative to the rotor at the slip speed sn_s, but the rotor is mechanically traveling at the speed $(1 - s)n_s$, so that the net effect is that the rotor field travels at the speed

$$sn_s + (1 - s)n_s = n_s \tag{5.12.56}$$

that is, at synchronous speed. The fact that the rotor field rotates at synchronous speed — although the rotor itself does not — is extremely important, because it means that the stator and rotor fields will continue to be stationary with respect to each other, and therefore a net torque can be produced.

As in the case of DC and synchronous motors, important characteristics of induction motors are the starting torque, the maximum torque, and the torque-speed curve.

Performance of Induction Motors

The performance of induction motors can be described by torque-speed curves similar to those already used for DC motors. Figure 5.12.42 depicts an induction motor torque-speed curve, with five torque ratings marked *a* through *e*. Point *a* is the *starting torque*, also called **breakaway torque**, and is the torque available with the rotor "locked", that is, in a stationary position. At this condition, the frequency of the voltage induced in the rotor is highest, since it is equal to the frequency of rotation of the stator field; consequently, the inductive reactance of the rotor is greatest. As the rotor accelerates, the torque drops off, reaching a maximum value called the **pull-up torque** (point *b*); this typically occurs somewhere between 25 and 40% of synchronous speed. As the rotor speed continues to increase, the rotor reactance decreases further (since the frequency of the induced voltage is determined by the relative speed of rotation of the rotor with respect to the stator field). The torque becomes a maximum when the rotor inductive reactance is equal to the rotor resistance; maximum torque is also called **breakdown torque** (point *c*). Beyond this point, the torque drops off, until it is zero at synchronous speed, as discussed earlier. Also marked on the curve are the *150% torque* (point *d*), and the *rated torque* (point *e*).

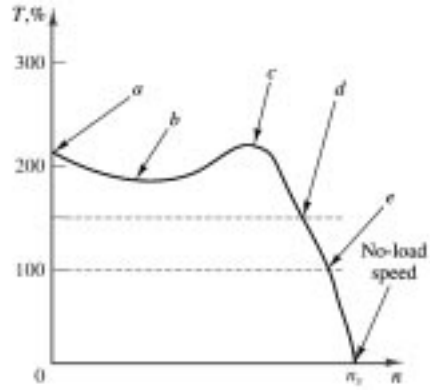

FIGURE 5.12.42 Performance curve for induction motor.

A general formula for the computation of the induction motor steady-state torque-speed characteristic is

$$T = \frac{1}{\omega_e} \frac{mV_S^2 R_R / s}{\left[\left(R_S + \dfrac{R_R}{s}\right)^2 + \left(X_S + X_R\right)^2\right]} \tag{5.12.57}$$

where m is the number of phases.

Different construction arrangements permit the design of induction motors with different torque-speed curves, thus permitting the user to select the motor that best suits a given application. Figure 5.12.43 depicts the four basic classifications, classes A, B, C, and D, as defined by NEMA. The determining features in the classification are the locked-rotor torque and current, the breakdown torque, the pull-down torque, and the percent slip. Class A motors have a higher breakdown torque than class B motors, and a slip of 5% or less. Motors in this class are often designed for a specific application. Class B motors are general-purpose motors; this is the most commonly used type of induction motor, with typical values of slip of 3 to 5%. Class C motors have a high starting torque for a given starting current, and a low slip. These motors are typically used in applications demanding high starting torque but having relatively normal running loads, once running speed has been reached. Class D motors are characterized by high starting torque, high slip, low starting current, and low full-load speed. A typical value of slip is around 13%.

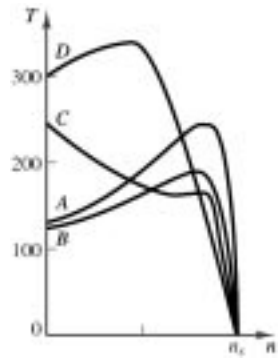

FIGURE 5.12.43 Induction motor classification.

Factors that should be considered in the selection of an AC motor for a given application are the *speed range*, both minimum and maximum, and the speed variation. For example, it is important to determine whether constant speed is required; what variation might be allowed, either in speed or in torque; or whether variable-speed operation is required, in which case a variable-speed drive will be needed. The torque requirements are obviously important as well. The starting and running torque should be considered; they depend on the type of load. Starting torque can vary from a small percentage of full-load to several times full-load torque. Furthermore, the excess torque available at start-up determines the *acceleration characteristics* of the motor. Similarly, *deceleration characteristics* should be considered, to determine whether external braking might be required.

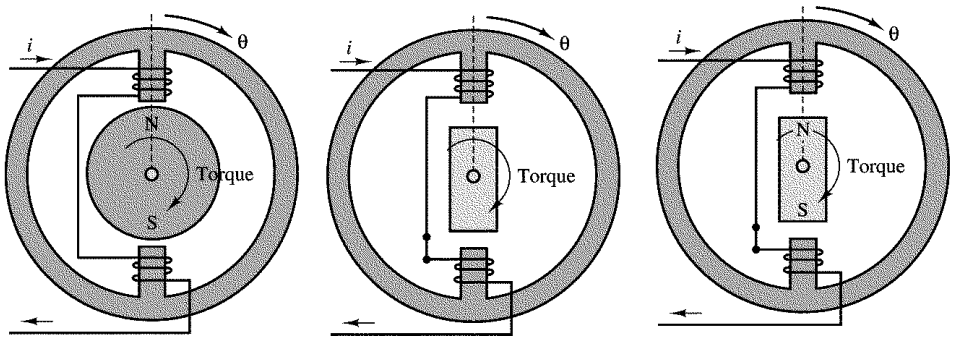
Another factor to be considered is the *duty cycle* of the motor. The duty cycle, which depends on the nature of the application, is an important consideration when the motor is used in repetitive, noncontinuous operation, such as is encountered in some types of machine tools. If the motor operates at zero or reduced load for periods of time, the duty cycle — that is, the percentage of the time the motor is loaded — is an important selection criterion. Last, but by no means least, are the *heating properties* of a motor. Motor temperature is determined by internal losses and by ventilation; motors operating at a reduced speed may not generate sufficient cooling, and forced ventilation may be required.

Stepping Motors

Stepping, or **stepper, motors** are motors that convert digital information to mechanical motion. The principles of operation of stepping motors have been known since the 1920s; however, their application has seen a dramatic rise with the increased use of digital computers. Stepping motors, as the name suggests, rotate in distinct steps, and their position can be controlled by means of logic signals. Typical applications of stepping motors are line printers, positioning of heads in magnetic disks drives, and any other situation where continuous or stepwise displacements are required.

Stepping motors can generally be classified in one of three categories: variable-reluctance, permanent-magnet, and hybrid types. It will soon be shown that the principles of operation of each of these devices bear a definite resemblance to those of devices already encountered in this book. Stepping motors have a number of special features that make them particularly useful in practical applications. Perhaps the most important feature of a stepping motor is that the angle of rotation of the motor is directly proportional to the number of input pulses; further, the angle error per step is very small and does not accumulate. Stepping motors are also capable of rapid response to starting, stopping, and reversing commands, and can be driven directly by digital signals. Another important feature is a self-holding capability that makes it possible for the rotor to be held in the stopped position without the use of brakes. Finally, a wide range of rotating speeds — proportional to the frequency of the pulse signal — may be attained in these motors.

Figure 5.12.44 depicts the general appearance of three types of stepping motors. The **permanent-magnet-rotor stepping motor**, Figure 5.12.44(a), permits a nonzero holding torque when the motor is not energized. Depending on the construction of the motor, it is typically possible to obtain step angles of 7.5, 11.25, 15, 18, 45, or 90°. The angle of rotation is determined by the number of stator poles, as will be illustrated shortly in an example. The **variable-reluctance stepping motor,** Figure 5.12.44(b), has an iron multipole rotor and a laminated wound stator, and rotates when the teeth on the rotor are attracted to the electromagnetically energized stator teeth. The rotor inertia of a variable-reluctance stepping motor is low, and the response is very quick, but the allowable load inertia is small. When the windings are not energized, the static torque of this type of motor is zero. Generally, the step angle of the variable-reluctance stepping motor is 15°.



(a) Permanent-magnet stepping motor (b) Variable-reluctance stepping motor (c) Hybrid stepping motor

FIGURE 5.12.44 Stepping motor configurations.

The **hybrid stepping motor**, Figure 5.12.44(c), is characterized by multitoothed stator and rotor, the rotor having an axially magnetized concentric magnet around its shaft. It can be seen that this configuration is a mixture of the variable-reluctance and permanent-magnet types. This type of motor generally has high accuracy and high torque and can be configured to provide a step angle as small as 1.8°.

For any of these configurations, the principle of operation is essentially the same: when the coils are energized, magnetic poles are generated in the stator, and the rotor will align in accordance with the direction of the magnetic field developed in the stator. By reversing the phase of the currents in the coils or by energizing only some of the coils (this is possible in motors with more than two stator poles), the alignment of the stator magnetic field can take one of a discrete number of positions; if the currents in the coils are pulsed in the appropriate sequence, the rotor will advance in a step-by-step fashion. Thus, this type of motor can be very useful whenever precise incremental motion must be attained. As mentioned earlier, typical applications are printer wheels, computer disk drives, and plotters. Other applications are found in the control of the position of valves (e.g., control of the throttle valve in an

engine or of a hydraulic valve in a fluid power-system), and in drug-dispensing apparatus for clinical applications.

The Universal Motor

If it were possible to operate a DC motor from a single-phase AC supply, a wide range of simple applications would become readily available. Recall that the direction of the torque produced by a DC machine is determined by the direction of current flow in the armature conductors and by the polarity of the field; torque is developed in a DC machine because the commutator arrangement permits the field and armature currents to remain in phase, thus producing torque in a constant direction. A similar result can be obtained by using an AC supply, and by connecting the armature and field windings in series, as shown in Figure 5.12.45. A series DC motor connected in this configuration can therefore operate on a single-phase AC supply, and is referred to as a **universal motor**. An additional consideration is that, because of the AC excitation, it is necessary to reduce AC core losses by laminating the stator; thus, the universal motor differs from the series DC motor in its construction features. Typical torque-speed curves for AC and DC operation of a universal motor are shown in Figure 5.12.46. As shown in Figure 5.12.45, the load current is sinusoidal and therefore reverses direction each half-cycle; however, the torque generated by the motor is always in the same direction, resulting in a pulsating torque, with nonzero averaging value.

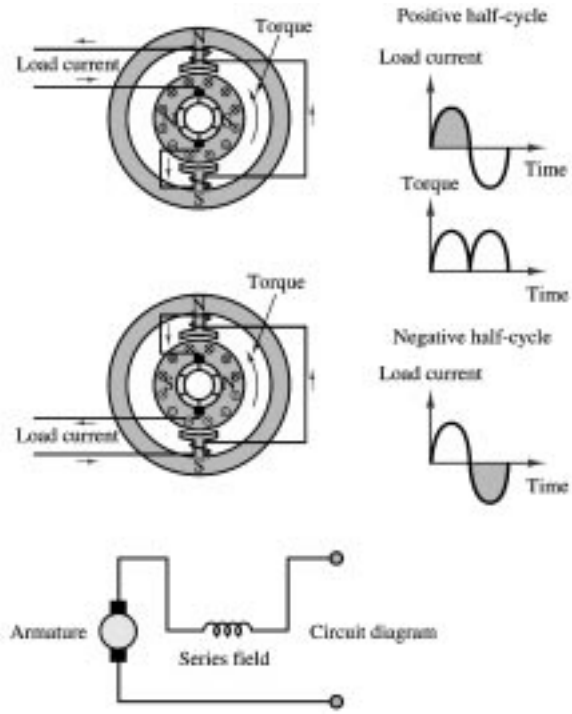


FIGURE 5.12.45 Operation and circuit diagram of a universal motor.

As in the case of a DC series motor, the best method for controlling the speed of a universal motor is to change its (rms) input voltage. The higher the rms input voltage, the greater the resulting speed of the motor. Approximate torque-speed characteristics of a universal motor as a function of voltage are shown in Figure 5.12.47.

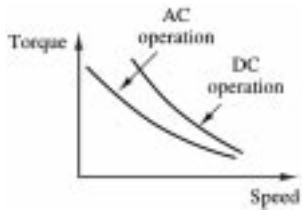

FIGURE 5.12.46 Torque-speed curve of a universal motor.

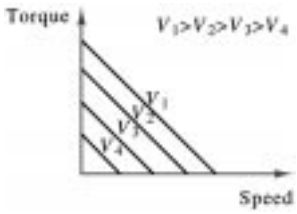

FIGURE 5.12.47 Torque-speed characteristics of a universal motor.

Single-Phase Induction Motors

Thus far, we have not mentioned how the initial starting torque can be provided to a single-phase motor. In practice, single-phase motors are classified by their starting and running characteristics, and several methods exist to provide nonzero starting torque. The aim of this section is to classify single-phase motors by describing their configuration on the basis of the method of starting. For each class of motor, a torque-speed characteristic will also be described.

Split-Phase Motors

Split-phase motors are constructed with two separate stator windings, called **main** and **auxiliary windings**; the axes of the two windings are actually at 90° with respect to each other, as shown in Figure 5.12.48. The auxiliary winding current is designed to be out of phase with the main winding current, as a result of different reactances of the two windings. Different winding reactances can be attained by having a different ratio of resistance to inductance — for example, by increasing the resistance of the auxiliary winding. In particular, the auxiliary winding current, $\mathbf{I}_{aux}$, leads the main winding current, $\mathbf{I}_{main}$. The net effect is that the motor sees a two-phase (unbalanced) current that results in a rotating magnetic field, as in any polyphase stator arrangement. Thus, the motor has a nonzero starting torque, as shown in Figure 5.12.49. Once the motor, a centrifugal switch is used to disconnect the auxiliary winding, since a single winding is sufficient to sustain the motion of the rotor. The switching action permits the use of relatively high-resistance windings, since these are not used during normal operation and therefore one need not be concerned with the losses associated with a higher-resistance winding. Figure 5.12.49 also depicts the combined effect of the two modes of operation of the split-phase motor.

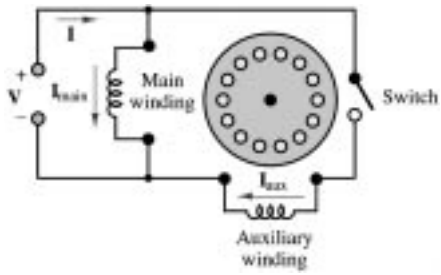

FIGURE 5.12.48 Split-phase motor.

Split-phase motors have appropriate characteristics (at very low cost) for fans, blowers, centrifugal pumps, and other applications in the range of 1/20 to 1/2 hp.

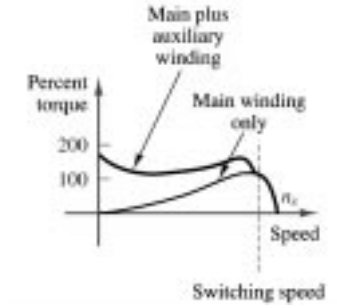

FIGURE 5.12.49 Torque-speed curve of split-phase motor.

Capacitor-Type Motors

Another method for obtaining a phase difference between currents that will give rise to a rotating magnetic field is by the addition of a capacitor. Motors that use this arrangement are termed **capacitor-type motors**. These motors make different use of capacitors to provide starting or running capabilities, or a combination of the two. The **capacitor-start motor** is essentially identical to the split-phase motor, except for the addition of a capacitor in series with the auxiliary winding, as shown in Figure 5.12.50. The addition of the capacitor changes the reactance of the auxiliary circuit in such a way as to cause the auxiliary current to lead the main current. The advantage of using the capacitor as a means for achieving a phase split is that greater starting torque may be obtained than with the split-phase arrangement. A centrifugal switching arrangement is used to disconnect the auxiliary winding above a certain speed, in the neighborhood of 75% of synchronous speed.

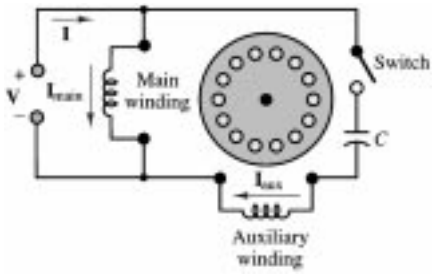

FIGURE 5.12.50 Capacitor-start motor.

Figure 5.12.51 depicts the torque-speed characteristic of a capacitor-start motor. Because of their higher starting torque, these motors are very useful in connection with loads that present a high static torque. Examples of such loads are compressors, pumps, and refrigeration and air-conditioning equipment.

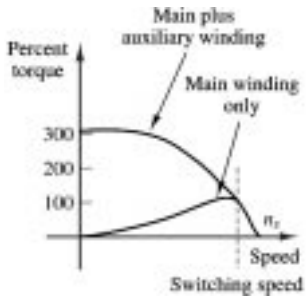

FIGURE 5.12.51 Torque-speed curve for a capacitor-start motor.

It is also possible to use the capacitor-start motor without the centrifugal switch, leading to a simpler design. Motors with this design are called **permanent split-capacitor motors**; they offer a compromise between running and starting characteristics. A typical torque-speed curve is shown in Figure 5.12.52.

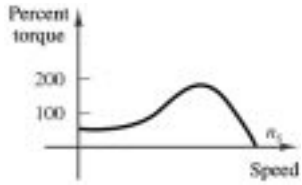

FIGURE 5.12.52 Torque-speed curve for a permanent split-capacitor motor.

A further compromise can be achieved by using two capacitors, one to obtain a permanent phase split and the resulting improvement in running characteristics, the other to improve the starting torque. A small capacitance is sufficient to improve the running performance, while a much larger capacitor provides the temporary improvement in starting torque. A motor with this design is called a **capacitor-start capacitor-run motor**; its schematic diagram is shown in Figure 5.12.53. Its torque-speed characteristic is similar to that of a capacitor-start motor.

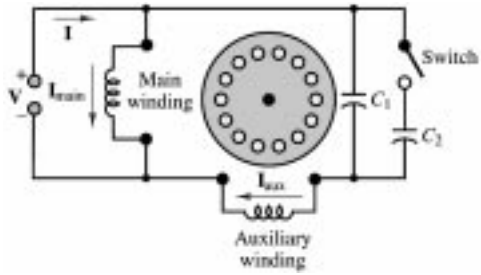

FIGURE 5.12.53 Capacitor-start capacitor-run motor.

Shaded-Pole Motors

The last type of single-phase induction motor discussed in this chapter is the **shaded-pole motor**. This type of motor operates on a different principle from the motors discussed thus far. The stator of a shaded-pole motor has a salient pole construction, as shown in Figure 5.12.54, that includes a shading coil consisting of a copper band wound around part of each pole. The flux in the shaded portion of the pole lags behind the flux in the unshaded part, achieving an effect similar to a rotation of the flux in the direction of the shaded part of the pole. This flux rotation in effect produces a rotating field that enables the motor to have a starting torque. This construction technique is rather inexpensive and is used in motors up to about 1/20 hp.

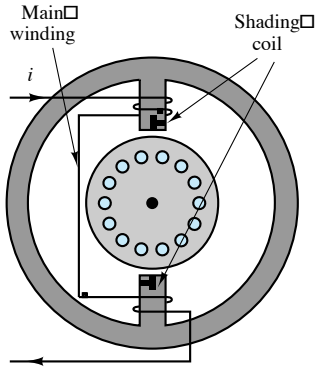

FIGURE 5.12.54 Shaded-pole motor.

A typical torque-speed characteristic for a shaded-pole motor is given in Figure 5.12.55.

Summary of Single-Phase Motor Characteristics

For basic classes of single-phase motors are commonly used:

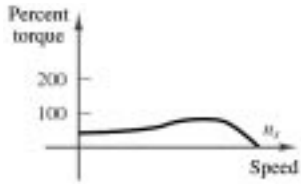

FIGURE 5.12.55 Torque-speed curve of a shaded-pole motor.

1. Single-phase induction motors are used for the larger home and small business tasks, such as furnace oil burner pumps, or hot water or hot air circulators. Refrigerator compressors, lathes, and bench-mounted circular saws are also powered with induction motors.
2. Shaded-pool motors are used in the smaller sizes for quite, low-cost applications. The size range is for 1/30 hp (24.9 W) to 1/2 hp (373 W), particularly for fans and similar drives in which the starting torque is low.
3. Universal motors will operate on any household AC frequency or on DC without modification or adjustment. They can develop very high speed while loaded, and very high power for their size. Vacuum cleaners, sewing machines, kitchen food mixers, portable electric drills, portable circular saws, and home motion-picture projectors are examples of applications of universal motors.
4. The capacitor-type motor finds its widest field of application at low speeds (below 900 rev/min) and in ratings from 3/4 hp (0.5595 kW) to 3 hp (2.238 kW) at all speeds, especially in fan drives.

6.1 Human-Machine Interaction

Thomas B. Sheridan

Over the years machines of all kinds have been improved and made more reliable. However, machines typically operate as components of larger systems, such as transportation systems, communication systems, manufacturing systems, defense systems, health care systems, and so on. While many aspects of such systems can be and have been automated, the human operator is retained in many cases. This may be because of economics, tradition, cost, or (most likely) capabilities of the human to perceive patterns of information and weigh subtle factors in making control decisions which the machine cannot match.

Although the public as well as those responsible for system operation usually demand that there be a human operator, “human error” is a major reason for system failure. And aside from prevention of

error, getting the best performance out of the system means that human and machine must be working together effectively — be properly "impedance matched." Therefore, the performance capabilities of the human relative to those of the machine must be taken into account in system design.

Efforts to "optimize" the human-machine interaction are meaningless in the mathematical sense of optimization, since most important interactions between human and machine cannot be reduced to a mathematical form, and the objective function (defining what is good) is not easily obtained in any given context. For this reason, engineering the human-machine interaction, much as in management or medicine, remains an art more than a science, based on laboratory experiments and practical experience.

In the broadest sense, engineering the human-machine interface includes all of *ergonomics* or *human factors engineering*, and goes well beyond design of displays and control devices. Ergonomics includes not only questions of sensory physiology, whether or not the operator can see the displays or hear the auditory warnings, but also questions of *biomechanics*, how the body moves, and whether or not the operator can reach and apply proper force to the controls. It further includes the fields of operator selection and training, human performance under stress, human factors in maintenance, and many other aspects of the relation of the human to technology. This section focuses primarily on human-machine interaction in control of systems.

The human-machine interactions in control are considered in terms of Figure 6.1.1. In Figure 6.1.1a the human directly controls the machine; i.e., the control loop to the machine is closed through the physical sensors, displays, human senses (visual, auditory, tactile), brain, human muscles, control devices, and machine actuators. Figure 6.1.1b illustrates what has come to be called a *supervisory control system*, wherein the human intermittently instructs a computer as to goals, constraints, and procedures, then turns a task over to the computer to perform automatic control for some period of time.

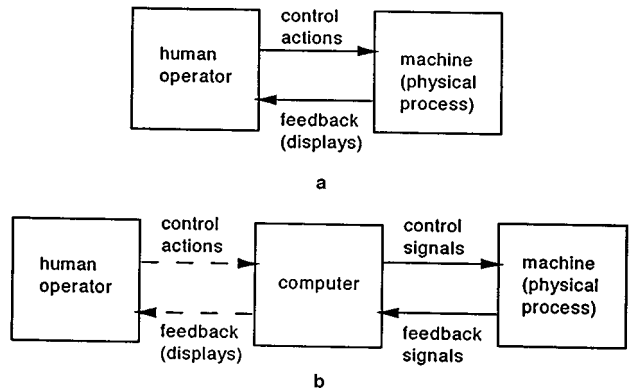

FIGURE 6.1.1 Direct manual control (a) and supervisory control (b).

Displays and control devices can be *analogic* (movement signal directions and extent of control action, isomorphic with the world, such as an automobile steering wheel or computer mouse controls, or a moving needle or pictorial display element). Or they can be *symbolic* (dedicated buttons or general-purpose keyboard controls, icons, or alarm light displays). In normal human discourse we use both speech (symbolic) and gestures (analogic) and on paper we write alphanumeric text (symbolic) and draw pictures (analogic). The system designer must decide which type of displays or controls best suits a particular application, and/or what mix to use. The designer must be aware of important criteria such as whether or not, for a proposed design, changes in the displays and controls caused by the human operator correspond in a natural and common-sense way to "more" or "less" of some variable as expected by that operator and correspond to cultural norms (such as reading from left to right in western countries), and whether or not the movement of the display elements correspond geometrically to movements of the controls.

Direct Manual Control

In the 1940s aircraft designers appreciated the need to characterize the transfer function of the human pilot in terms of a differential equation. Indeed, this is necessary for any vehicle or controlled physical process for which the human is the controller, see Figure 6.1.2. In this case both the human operator *H* and the physical process *P* lie in the closed loop (where *H* and *P* are Laplace transforms of the component transfer functions), and the *HP* combination determines whether the closed-loop is inherently stable (i.e., the closed loop characteristic equation 1 + HP = 0 has only negative real roots).

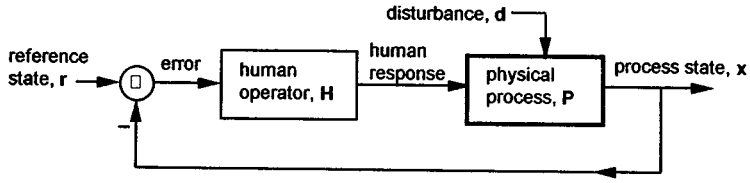

FIGURE 6.1.2 Direct manual control-loop analysis.

In addition to the stability criterion are the criteria of rapid response of process state *x* to a desired or reference state *r* with minimum overshoot, zero "steady-state error" between *r* and output *x*, and reduction to near zero of the effects of any disturbance input *d*. (The latter effects are determined by the closed-loop transfer functions $x = HP/(1 + HP)r + 1/(1 + HP)d$, where if the magnitude of *H* is large enough $HP/(1 + HP)$ approaches unity and $1/(1 + HP)$ approaches 0. Unhappily, there are ingredients of *H* which produce delays in combination with magnitude and thereby can cause instability. Therefore, *H* must be chosen carefully by the human for any given *P*.)

Research to characterize the pilot in these terms resulted in the discovery that the human adapts to a wide variety of physical processes so as to make $HP = K(1/s)(e^{-sT})$. In other words, the human adjusts *H* to make *HP* constant. The term *K* is an overall amplitude or gain, $(1/s)$ is the Laplace transform of an integrator, and (e^{-sT}) is a delay *T* long (the latter time delay being an unavoidable property of the nervous system). Parameters *K* and *T* vary modestly in a predictable way as a function of the physical process and the input to the control system. This model is now widely accepted and used, not only in engineering aircraft control systems, but also in designing automobiles, ships, nuclear and chemical plants, and a host of other dynamic systems.

Supervisory Control

Supervisory control may be defined by the analogy between a supervisor of subordinate staff in an organization of people and the human overseer of a modern computer-mediated semiautomatic control system. The supervisor gives human subordinates general instructions which they in turn may translate into action. The supervisor of a computer-controlled system does the same.

Defined strictly, *supervisory control* means that one or more human operators are setting initial conditions for, intermittently adjusting, and receiving high-level information from a computer that itself closes a control loop in a well-defined process through artificial sensors and effectors. For some time period the computer controls the process automatically.

By a less strict definition, *supervisory control* is used when a computer transforms human operator commands to generate detailed control actions, or makes significant transformations of measured data to produce integrated summary displays. In this latter case the computer need not have the capability to commit actions based upon new information from the environment, whereas in the first it necessarily must. The two situations may appear similar to the human supervisor, since the computer mediates both human outputs and human inputs, and the supervisor is thus removed from detailed events at the low level.

A supervisory control system is represented in Figure 6.1.3. Here the human operator issues commands to a *human-interactive* computer capable of understanding high-level language and providing integrated summary displays of process state information back to the operator. This computer, typically located in a control room or cockpit or office near to the supervisor, in turn communicates with at least one, and probably many (hence the dotted lines), *task-interactive* computers, located with the equipment they are controlling. The task-interactive computers thus receive subgoal and conditional branching information from the human-interactive computer. Using such information as reference inputs, the task-interactive computers serve to close low-level control loops between artificial sensors and mechanical actuators; i.e., they accomplish the low-level automatic control.

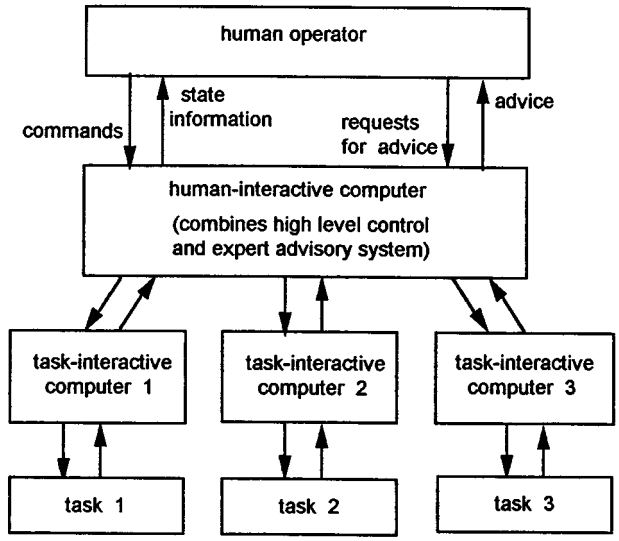

FIGURE 6.1.3 Supervisory control.

The low-level task typically operates at some physical distance from the human operator and his human-friendly display-control computer. Therefore, the communication channels between computers may be constrained by multiplexing, time delay, or limited bandwidth. The task-interactive computer, of course, sends analog control signals to and receives analog feedback signals from the controlled process, and the latter does the same with the environment as it operates (vehicles moving relative to air, sea, or earth, robots manipulating objects, process plants modifying products, etc.).

Supervisory command and feedback channels for process state information are shown in Figure 6.1.3 to pass through the left side of the human-interactive computer. On the right side are represented decision-aiding functions, with requests of the computer for advice and displayed output of advice (from a database, expert system, or simulation) to the operator. There are many new developments in computer-based decision aids for planning, editing, monitoring, and failure detection being used as an auxiliary part of operating dynamic systems. Reflection upon the nervous system of higher animals reveals a similar kind of supervisory control wherein commands are sent from the brain to local ganglia, and peripheral motor control loops are then closed locally through receptors in the muscles, tendons, or skin. The brain, presumably, does higher-level planning based on its own stored data and "mental models," an internalized expert system available to provide advice and permit trial responses before commitment to actual response.

Theorizing about supervisory control began as aircraft and spacecraft became partially automated. It became evident that the human operator was being replaced by the computer for direct control responsibility, and was moving to a new role of monitor and goal-constraint setter. An added incentive was the U.S. space program, which posed the problem of how a human operator on Earth could control a

manipulator arm or vehicle on the moon through a 3-sec communication round-trip time delay. The only solution which avoided instability was to make the operator a supervisory controller communicating intermittently with a computer on the moon, which in turn closed the control loop there. The rapid development of microcomputers has forced a transition from manual control to supervisory control in a variety of industrial and military applications (Sheridan, 1992).

Let us now consider some examples of human-machine interaction, particularly those which illustrate supervisory control in its various forms. First, we consider three forms of vehicle control, namely, control of modern aircraft, "intelligent" highway vehicles, and high-speed trains, all of which have both human operators in the vehicles as well as humans in centralized traffic-control centers. Second, we consider telerobots for space, undersea, and medical applications.

Advanced Control of Commercial Aircraft

Flight Management Systems

Aviation has appreciated the importance of human-machine interaction from its beginning, and today exemplifies the most sophisticated forms of such interaction. While there have been many good examples of display and control design over the years, the current development of the flight management systems (FMS) is the epitome. It also provides an excellent example of supervisory control, where the pilot flies the aircraft by communicating in high-level language through a computer intermediary. The FMS is a centralized computer which interacts with a great variety of sensors, communication from the ground, as well as many displays and controls within the aircraft. It embodies many functions and mediates most of the pilot information requirements shown in Figure 6.1.4. Gone are the days when each sensor had its own display, operating independently of all other sensor-display circuits. The FMS, for example, brings together all of the various autopilot modes, from long-standing low-level control modes, wherein the aircraft is commanded to go to and hold a commanded altitude, heading, and speed, to more-sophisticated modes where the aircraft is instructed to fly a given course, consisting of a sequence of way points (latitudes and longitudes) at various altitudes, and even land automatically at a given airport on a given runway.

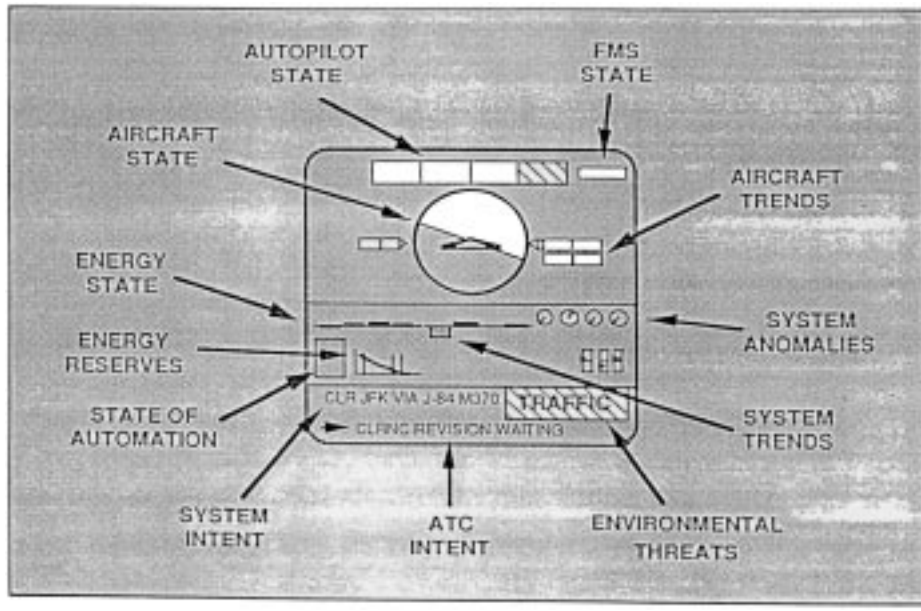

FIGURE 6.1.4 Pilot information requirements. (From Billings, 1991.)

Figure 6.1.5 illustrates one type of display mediated by the FMS, in this case integrating many formerly separate components of information. Mostly it is a multicolor plan-view map showing position and orientation of important objects relative to one's own aircraft (the triangle at the bottom). It shows heading (compass arc at top, present heading 175°), ground speed plus wind speed and wind direction (upper left), actual altitude relative to desired altitude (vertical scale on right side), programmed course connecting various way points (OPH and FLT), salient VOR radar beacons to the right and left of present position/direction with their codes and frequencies (lower left and right corners), the location of key VORs along the course (three-cornered symbols), the location of weather to be avoided (two gray blobs), and a predicted trajectory based on present turn rate, showing that the right turn is appropriately getting back on course.

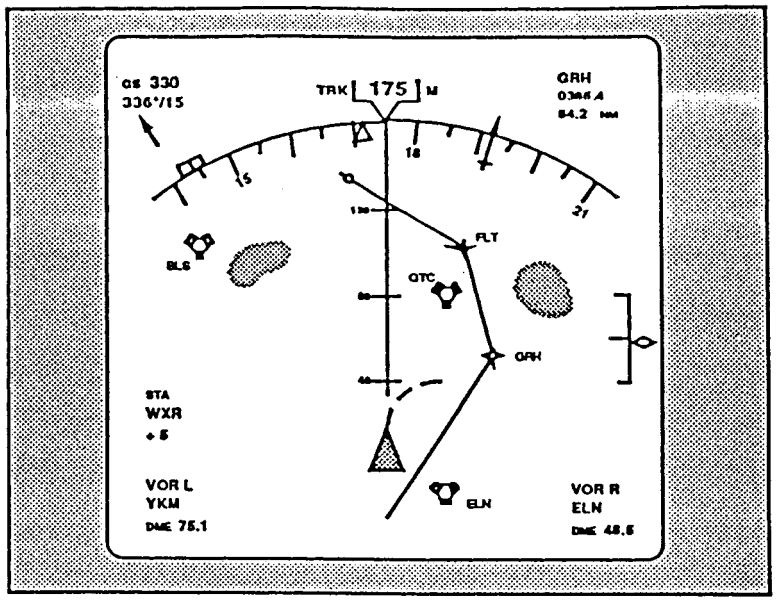

FIGURE 6.1.5 Integrated aircraft map display. (From Billings, 1991.)

Programming the FMS is done through a specialized keyboard and text display unit (Figure 6.1.6) having all the alphanumeric keys plus a number of special function keys. The displays in this case are specialized to the different phases of a flight (taxi, takeoff, departure, enroute approach, land, etc.), each phase having up to three levels of pages.

The FMS makes clear that designing displays and controls is no longer a matter of what can be built — the computer allows essentially any conceivable display/control to be realized. The computer can also provide a great deal of real-time advice, especially in emergencies, based on its many sensors and stored knowledge about how the aircraft operates. But pilots are not sure they need all the information which aircraft designers would like to give them, and have an expression "killing us with kindness" to refer to this plethora of available information. The question is what should be designed based on the needs and capabilities of the pilot.

Boeing, McDonnell Douglas, and Airbus have different philosophies for designing the FMS. Airbus has been the most aggressive in automating, intending to make piloting easier and safer for pilots from countries with less well established pilot training. Unfortunately, it is these most-automated aircraft which have had the most accidents of the modern commercial jets — a fact which has precipitated vigorous debate about how far to automate.

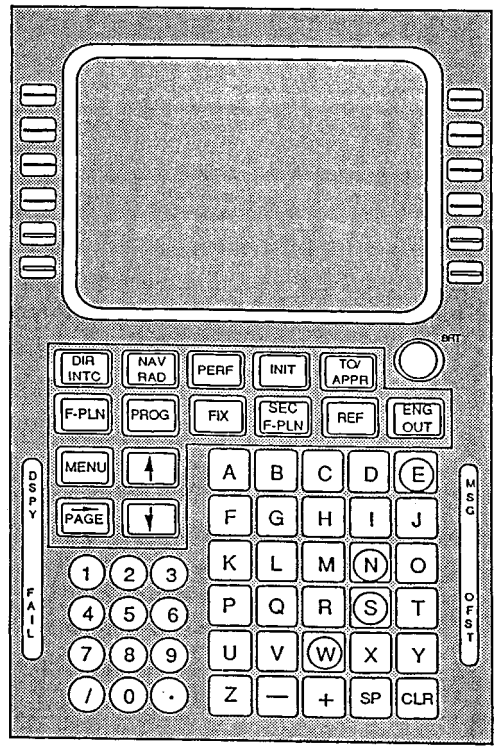

FIGURE 6.1.6 Flight management system control and display unit. (From Billings, 1991.)

Air Traffic Control

As demands for air travel continue to increase, so do demands for air traffic control. Given what are currently regarded as safe separation criteria, air space over major urban areas is already saturated, so that simply adding more airports is not acceptable (in addition to which residents do not want more airports, with their noise and surface traffic). The need is to reduce separations in the air, and to land aircraft closer together or on parallel runways simultaneously. This puts much greater demands on air traffic controllers, particularly at the terminal area radar control centers (TRACONs), where trained operators stare at blips on radar screens and verbally guide pilots entering the terminal airspace from various directions and altitudes into orderly descent and landing patterns with proper separation between aircraft.

Currently, many changes are being introduced into air traffic control which have profound implications for human-machine interaction. Where previously communication between pilots and air traffic controllers was entirely by voice, now digital communication between aircraft and ground (a system called *datalink)* allows both more and more reliable two-way communication, so that weather and runway and wind information, clearances, etc. can be displayed to pilots visually. But pilots are not so sure they want this additional technology. They fear the demise of the “party line” of voice communications with which they are so familiar and which permits all pilots in an area to listen in on each other’s conversations.

New aircraft-borne radars allow pilots to detect air traffic in their own vicinity. Improved ground-based radars detect microbursts or wind shear which can easily put an aircraft out of control. Both types of radars pose challenges as to how best to warn the pilot and provide guidance as to how to respond. But they also pose a cultural change in air traffic control, since heretofore pilots have been dependent upon air traffic controllers to advise them of weather conditions and other air traffic. Furthermore, because of the new weather and collision-avoidance technology, there are current plans for radically altering the rules whereby high-altitude commercial aircraft must stick to well-defined traffic lanes. Instead, pilots

will have great flexibility as to altitude (to find the most favorable winds and therefore save fuel) and be able to take great-circle routes straight to their destinations (also saving fuel). However, air traffic controllers are not sure they want to give up the power they have had, becoming passive observers and monitors, to function only in emergencies.

Intelligent Highway Vehicles

Vehicle Guidance and Navigation Systems

The combination of GPS (global positioning system) satellites, high-density computer storage of map data, electronic compass, synthetic speech synthesis, and computer-graphic displays allows cars and trucks to know where they are located on the Earth to within 100 m or less, and can guide a driver to a programmed destination by a combination of a map display and speech. Some human factor challenges are in deciding how to configure the map (how much detail to present, whether to make the map north-up with a moving dot representing one's own vehicle position or current-heading-up and rapidly changing with every turn). The computer graphics can also be used to show what turns to anticipate and which lane to get in. Synthetic speech can reinforce these turn anticipations, can caution the driver if he is perceived to be headed in the wrong direction or off course, and can even guide him or her how to get back on course. An interesting question is what the computer should say in each situation to get the driver's attention, to be understood quickly and unambiguously but without being an annoyance. Another question is whether or not such systems will distract the driver's attention from the primary tasks, thereby reducing safety. The major vehicle manufacturers have developed such systems, they have been evaluated for reliability and human use, and they are beginning to be marketed in the United States, Europe, and Japan.

Smart Cruise Control

Standard cruise control has a major deficiency in that it knows nothing about vehicles ahead, and one can easily collide with the rear end of another vehicle if not careful. In a smart cruise control system a microwave or optical radar detects the presence of a vehicle ahead and measures that distance. But there is a question of what to do with this information. Just warn the driver with some visual or auditory alarm (auditory is better because the driver does not have to be looking in the right place)? Can a warning be too late to elicit braking, or surprise the driver so that he brakes too suddenly and causes a rear-end accident to his own vehicle. Should the computer automatically apply the brakes by some function of distance to obstacle ahead, speed, and closing deceleration. If the computer did all the braking would the driver become complacent and not pay attention, to the point where a serious accident would occur if the radar failed to detect an obstacle, say, a pedestrian or bicycle, or the computer failed to brake? Should braking be some combination of human and computer braking, and if so by what algorithm? These are human factor questions which are currently being researched.

It is interesting to note that current developmental systems only decelerate and downshift, mostly because if the vehicle manufacturers sell vehicles which claim to perform braking they would be open to a new and worrisome area of litigation.

The same radar technology that can warn the driver or help control the vehicle can also be applied to cars overtaking from one side or the other. Another set of questions then arises as to how and what to communicate to the driver and whether or not to trigger some automatic control maneuver in certain cases.

Advanced Traffic Management Systems

Automobile congestion in major cities has become unacceptable, and advanced traffic management systems are being built in many of these cities to measure traffic flow at intersections (by some combination of magnetic loop detectors, optical sensors, and other means), and regulate stoplights and message signs. These systems can also issue advisories of accidents ahead by means of variable message signs or radio, and give advice of alternative routings. In emergencies they can dispatch fire, police,

ambulances, or tow trucks, and in the case of tunnels can shut down entering traffic completely if necessary. These systems are operated by a combination of computers and humans from centralized control rooms. The operators look at banks of video monitors which let them see the traffic flow at different locations, and computer-graphic displays of maps, alarm windows, and textual messages. The operators get advice from computer-based expert systems, which suggest best responses based on measured inputs, and the operator must decide whether to accept the computer's advice, whether to seek further information, and how to respond.

High-Speed Train Control

With respect to new electronic technology for information sensing, storage, and processing, railroad technology has lagged behind that of aircraft and highway vehicles, but currently is catching up. The role of the human operator in future rail systems is being debated, since for some limited right-of-way trains (e.g., in airports) one can argue that fully automatic control systems now perform safely and efficiently. The train driver's principal job is speed control (though there are many other monitoring duties he must perform), and in a train this task is much more difficult than in an automobile because of the huge inertia of the train — it takes 2 to 3 km to stop a high-speed train. Speed limits are fixed at reduced levels for curves, bridges, grade crossings, and densely populated areas, while wayside signals temporarily command lower speeds if there is maintenance being performed on the track, if there are poor environmental conditions such as rock slides or deep snow, or especially if there is another train ahead. The driver must obey all speed limits and get to the next station on time. Learning to maneuver the train with its long time constants can take months, given that for the speed control task the driver's only input currently is an indication of current speed.

The author's laboratory has proposed a new computer-based display which helps the driver anticipate the future effects of current throttle and brake actions. This approach, based on a dynamic model of the train, gives an instantaneous prediction of future train position and speed based on current acceleration, so that speed can be plotted on the display assuming the operator holds to current brake-throttle settings. It also plots trajectories for maximum emergency braking and maximum service braking. In addition, the computer generates a speed trajectory which adheres at all (known) future speed limits, gets to the next station on time, and minimizes fuel/energy. Figure 6.1.7 shows the laboratory version of this display, which is currently being evaluated.

Telerobots for Space, Undersea, and Medicine

When nuclear power was first adopted in the late 1940s engineers began the development of master-slave remote manipulators, by which a human operator at one location could position and orient a device attached to his hand, and a servomechanism-controlled gripper would move in correspondence and handle objects at another location. At about the same time, remotely controlled wheeled vehicles, submarines, and aircraft began to be developed. Such manipulators and vehicles remotely controlled by humans are called *teleoperators*. Teleoperator technology got a big boost from the industrial robot technology, which came in a decade or so later, and provided improved vision, force, and touch sensors, actuators, and control software. Large teleoperators were developed for rugged mining and undersea tasks, and small teleoperators were developed for delicate tasks such as eye surgery. Eventually, teleoperators have come to be equipped with sensitive force feedback, so that the human operator not only can see the objects in the remote environment, but also can feel them in his grasp.

During the time of the Apollo flights to the moon, and stimulated by the desire to control lunar manipulators and vehicles from Earth and the fact that the unavoidable round-trip time delays of 3 sec (speed of light from Earth to moon and back) would not permit simple closed loop control, supervisory controlled teleoperators were developed. The human could communicate a subgoal to be reached and a procedure for getting there, and the teleoperator would be turned loose for some short period to perform automatically. Such a teleoperator is called a *telerobot.*

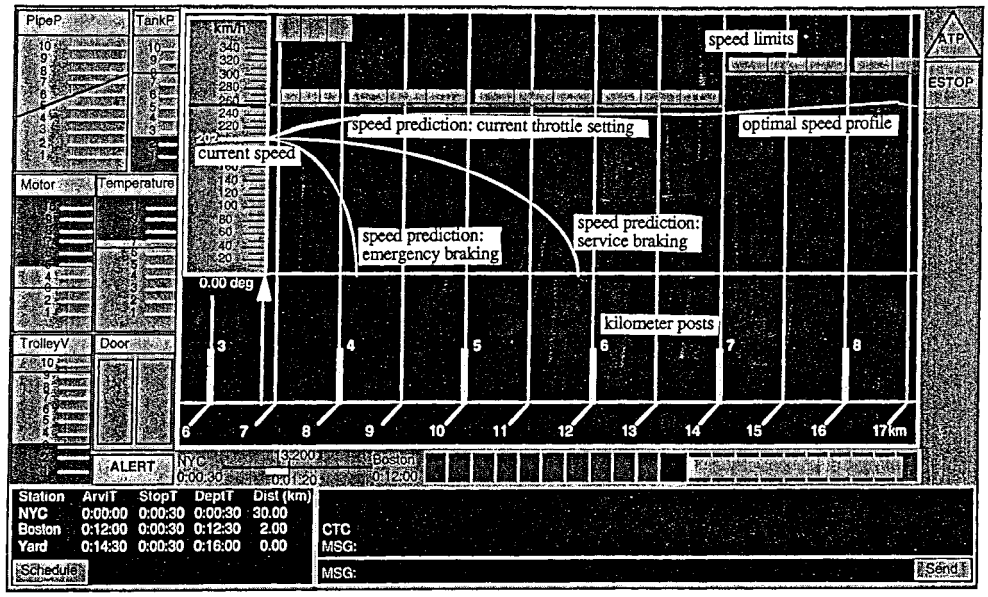

FIGURE 6.1.7 Prototype of computer-generated display for high speed trains. (From Askey, 1995.)

Figure 6.1.8 shows a the Flight Telerobotic Servicer (FTS) developed by Martin Marietta for the U.S. Space Station Freedom. It has two seven-degree of freedom (DOF) arms (including gripper) and one five-DOF "leg" for stabilizing itself while the arms work. It has two video "eyes" to present a stereoimage to its human operator. It can be configured either as a master-slave teleoperator (under direct human control) or as a telerobot (able to execute small programmed tasks using its own eyes and force sensors). Unfortunately, the FTS project was canceled by Congress.

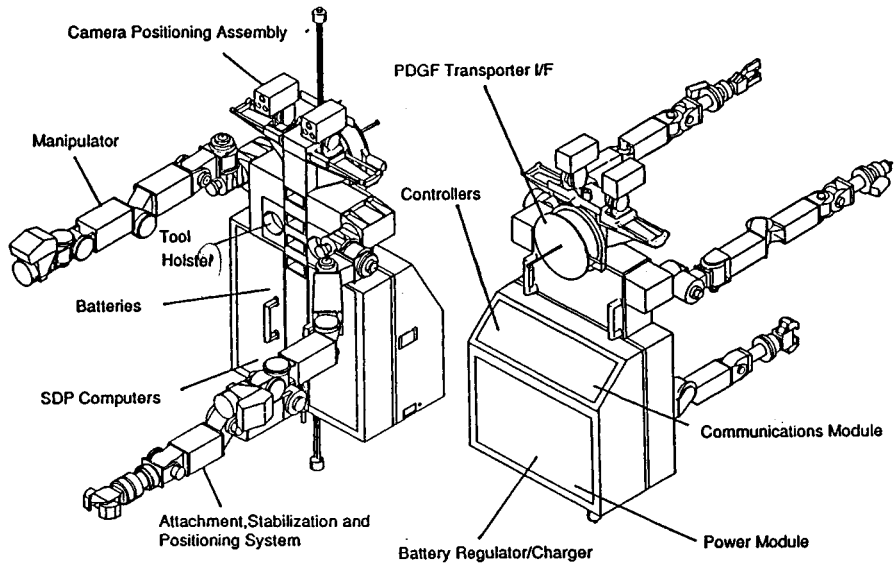

FIGURE 6.1.8 Flight Telerobotic Servicer prototype design. (Courtesy of NASA.)

Figure 6.1.9 shows the remotely operated submersible *Jason* developed by Woods Hole Oceanographic Institution. It is the big brother of *Jason Junior*, which swam into the interior of the ship *Titanic* and made a widely viewed video record when the latter was first discovered. It has a single manipulator arm, sonar and photo sensors, and four thrusters which can be oriented within limited range and which enable it to move in any direction. It is designed for depths up to 6000 m — rather severe pressures! It too, can be operated either in direct teleoperator mode or as a telerobot.

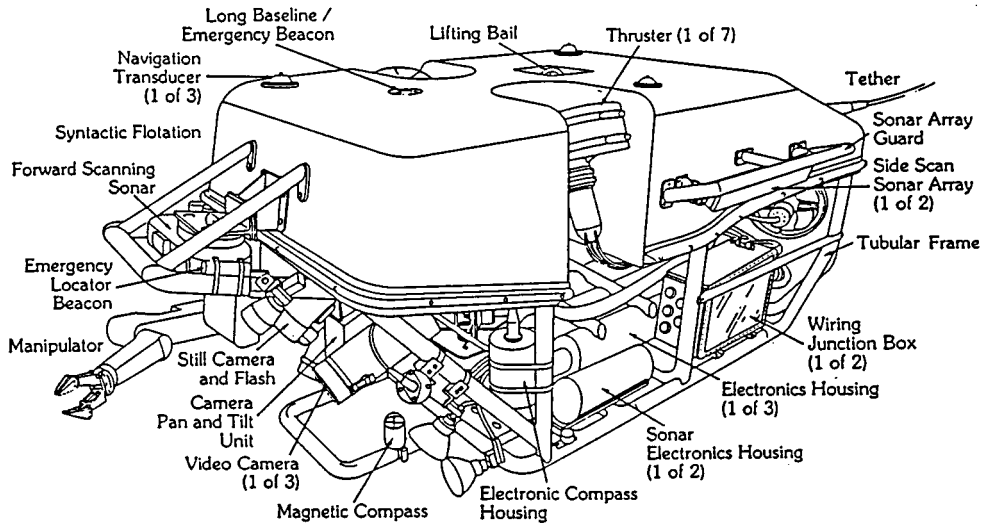

FIGURE 6.1.9 Deep ocean submersible *Jason*. (Courtesy of Woods Hole Oceanographic Institution.)

Common Criteria for Human Interface Design

Design of operator control stations for teleoperators poses the same types of problems as design of controls and displays for aircraft, highway vehicles, and trains. The displays must show the important variables unambiguously to whatever accuracy is required, but more than that must show the variables in relation to one another so as to clearly portray the current "situation" (situation awareness is currently a popular test of the human operator in complex systems). Alarms must get the operator's attention, indicate by text, symbol, or location on a graphic display what is abnormal, where in the system the failure occurred, what is the urgency, if response is urgent, and even suggest what action to take. (For example, the ground-proximity warning in an aircraft gives a loud "Whoop, whoop!" followed by a distinct spoken command "Pull up, pull up!") Controls — whether analogic joysticks, master-arms, or knobs — or symbolic special-purpose buttons or general-purpose keyboards — must be natural and easy to use, and require little memory of special procedures (computer icons and windows do well here). The placement of controls and instruments and their mode and direction of operation must correspond to the desired direction and magnitude of system response.

Human Workload and Human Error

As noted above, new technology allows combination, integration, and simplification of displays compared to the intolerable plethora of separate instruments in older aircraft cockpits and plant control rooms. The computer has taken over more and more functions from the human operator. Potentially these changes make the operator's task easier. However, it also allows for much more information to be presented, more extensive advice to be given, etc.

These advances have elevated the stature of the human operator from providing both physical energy and control, to providing only continuous control, to finally being a supervisor or a robotic vehicle or

system. Expert systems can now answer the operator's questions, much as does a human consultant, or whisper suggestions in his ear even if he doesn't request them. These changes seem to add many cognitive functions that were not present at an earlier time. They make the operator into a monitor of the automation, who is supposed to step in when required to set things straight. Unfortunately, people are not always reliable monitors and interveners.

Mental Workload

Under such complexity it is imperative to know whether or not the mental workload of the operator is too great for safety. Human-machine systems engineers have sought to develop measures of mental workload, the idea being that as mental load increases, the risk of error increases, but presumably measurable mental load comes before actual lapse into error.

Three approaches have been developed for measuring mental workload:

1. The first and most used is the subjective rating scale, typically a ten-level category scale with descriptors for each category from no load to unbearable load.
2. The second approach is use of physiological indexes which correlate with subjective scales, including heart rate and the variability of heart rate, certain changes in the frequency spectrum of the voice, electrical resistance of the skin, diameter of the pupil of the eye, and certain changes in the evoked brain wave response to sudden sound or light stimuli.
3. The third approach is to use what is called a secondary task, an easily measurable additional task which consumes all of the operator's attention remaining after the requirements of the primary task are satisfied. This latter technique has been used successfully in the laboratory, but has shortcomings in practice in that operators may refuse to cooperate.

Such techniques are now routinely applied to critical tasks such as aircraft landing, air traffic control, certain planned tasks for astronauts, and emergency procedures in nuclear power plants. The evidence suggests that supervisory control relieves mental load when things are going normally, but when automation fails the human operator is subjected rapidly to increased mental load.

Human Error

Human error has long been of interest, but only in recent decades has there been serious effort to understand human error in terms of categories, causation, and remedy. There are several ways to classify human errors. One is according to whether it is an error of *omission* (something not done which was supposed to have been done) or *commission* (something done which was not supposed to have been done). Another is *slip* (a correct intention for some reason not fulfilled) vs. a *mistake* (an incorrect intention which was fulfilled). Errors may also be classified according to whether they are in sensing, perceiving, remembering, deciding, or acting. There are some special categories of error worth noting which are associated with following procedures in operation of systems. One, for example, is called a *capture error*, wherein the operator, being very accustomed to a series of steps, say, A, B, C, and D, intends at another time to perform E, B, C, F. But he is "captured" by the familiar sequence B, C and does E, B, C, D.

As to effective therapies for human error, proper design to make operation easy and natural and unambiguous is surely the most important. If possible, the system design should allow for error correction before the consequences become serious. Active warnings and alarms are necessary when the system can detect incipient failures in time to take such corrective action. Training is probably next most important after design, but any amount of training cannot compensate for an error-prone design. Preventing exposure to error by guards, locks, or an additional "execute" step can help make sure that the most critical actions are not taken without sufficient forethought. Least effective are written warnings such as posted decals or warning statements in instruction manuals, although many tort lawyers would like us to believe the opposite.

Trust, Alienation, and How Far to Go with Automation

Trust

If operators do not trust their sensors and displays, expert advisory system, or automatic control system, they will not use it or will avoid using it if possible. On the other hand, if operators come to place too much trust in such systems they will let down their guard, become complacent, and, when it fails, not be prepared. The question of operator trust in the automation is an important current issue in human-machine interface design. It is desirable that operators trust their systems, but it is also desirable that they maintain alertness, situation awareness, and readiness to take over.

Alienation

There is a set of broader social effects that the new human-machine interaction can have, which can be discussed under the rubric of *alienation.*

1. People worry that computers can do some tasks much better than they themselves can, such as memory and calculation. Surely, people should not try to compete in this arena.
2. Supervisory control tends to make people remote from the ultimate operations they are supposed to be overseeing — remote in space, desynchronized in time, and interacting with a computer instead of the end product or service itself.
3. People lose the perceptual-motor skills which in many cases gave them their identity. They become "deskilled", and, if ever called upon to use their previous well-honed skills, they could not.
4. Increasingly, people who use computers in supervisory control or in other ways, whether intentionally or not, are denied access to the knowledge to understand what is going on inside the computer.
5. Partly as a result of factor 4, the computer becomes mysterious, and the untutored user comes to attribute to the computer more capability, wisdom, or blame than is appropriate.
6. Because computer-based systems are growing more complex, and people are being “elevated” to roles of supervising larger and larger aggregates of hardware and software, the stakes naturally become higher. Where a human error before might have gone unnoticed and been easily corrected, now such an error could precipitate a disaster.
7. The last factor in alienation is similar to the first, but all-encompassing, namely, the fear that a “race” of machines is becoming more powerful than the human race.

These seven factors, and the fears they engender, whether justified or not, must be reckoned with. Computers must be made to be not only “human friendly” but also not alienating with respect to these broader factors. Operators and users must become computer literate at whatever level of sophistication they can deal with.

How Far to Go with Automation

There is no question but that the trend toward supervisory control is changing the role of the human operator, posing fewer requirements on continuous sensory-motor skill and more on planning, monitoring, and supervising the computer. As computers take over more and more of the sensory-motor skill functions, new questions are being raised regarding how the interface should be designed to provide the best cooperation between human and machine. Among these questions are: To what degree should the system be automated? How much “help” from the computer is desirable? What are the points of diminishing returns?

Table 6.1.1 lists ten levels of automation, from 0 to 100% computer control. Obviously, there are few tasks which have achieved 100% computer control, but new technology pushes relentlessly in that direction. It is instructive to consider the various intermediate levels of Table 6.1.1 in terms not only of how capable and reliable is the technology but what is desirable in terms of safety and satisfaction of the human operators and the general public.

TABLE 6.1.1 Scale of Degrees of Automation

1.	The computer offers no assistance; the human must do it all.
2.	The computer offers a complete set of action alternatives, and
3.	Narrows the selection down to a few, or
4.	Suggests one alternative, and
5.	Executes that suggestion if the human approves, or
6.	Allows the human a restricted time to veto before automatic execution, or
7.	Executes automatically, then necessarily informs the human, or
8.	Informs the human only if asked, or
9.	Informs the human only if it, the computer, decides to
10.	The computer decides everything and acts autonomously, ignoring the human.
	The current controversy about how much to automate large commercial transport aircraft is often couched in these terms

6.2 The Need for Control of Mechanical Systems

Peter S. Curtiss

Process control typically involves some mechanical system that needs to be operated in such a fashion that the output of the system remains within its design operating range. The objective of a process control loop is to maintain the process at the set point under the following dynamic conditions:

- The set point is changed;
- The load on the process is changed;
- The transfer function of the process is changed or a disturbance is introduced.

The Classical Control System Representation

Feedback-Loop System. A *feedback* (or *closed-loop*) system contains a process, a sensor and a controller. Figure 6.2.1 below shows some of the components and terms used when discussing feedback loop systems.

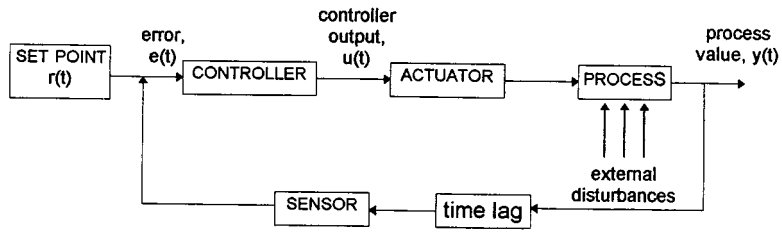

FIGURE 6.2.1 Typical feedback control schematic diagram.

Process. A *process* is a system that produces a motion, a temperature change, a flow, a pressure, or many other actions as a function of the actuator position and external inputs. The output of the process is called the process value. If a positive action in the actuator causes an increase in the process value then the process is called *direct acting*. If positive action in the actuator decreases the process value, it is called *reverse acting*.

Sensor. A *sensor* is a pneumatic, fluidic, or electronic or other device that produces some kind of signal indicative of the process value.

Set Point. The *set point* is the desired value for a process output. The difference between the set point and the process value is called the *process error*.

Controller. A *controller* sends signals to an actuator to effect changes in a process. The controller compares the set point and the process value to determine the process error. It then uses this error to adjust the output and bring the process back to the set point. The controller *gain* dictates the amount that the controller adjusts its output for a given error.

Actuator. An *actuator* is a pneumatic, fluidic, electric, or other device that performs any physical action that will control a process.

External Disturbances. An *external disturbance* is any effect that is unmeasured or unaccounted for by the controller.

Time Constants. The *time constant* of a sensor or process is a quantity that describes the dynamic response of the device or system. Often the time constant is related to the mass of an object or other dynamic effect in the process. For example, a temperature sensor may have a protective sheath around

it that must first be warmed before the sensor registers a change of temperature. Time constant can range from seconds to hours.

Dead Time. The *dead time* or *lag time* of a process is the time between the change of a process and the time this change arrives at the sensor. The delay time is not related to the time constant of the sensor, although the effects of the two are similar. Large dead times must be properly treated by the control system to prevent unstable control.

Hysteresis. *Hysteresis* is a characteristic response of positioning actuators that results in different positions depending on whether the control signal is increasing or decreasing.

Dead Band. The *dead band* of a process is that range of the process value in which no control action is taken. A dead band is usually used in two-position control to prevent "chattering" or in split-range systems to prevent sequential control loops from fighting each other.

Control Point. The *control point* is the actual, measured value of a process (i.e., the set point + steady-state offset + compensation).

Direct/Reverse Action. A *direct-acting* process will increase in value as the signal from the controller increases. A *reverse-acting* process will decrease in value as the signal from the controller increases.

Stability. The *stability* of a feedback control loop is an indication of how well the process is controlled or, alternatively, how controllable the process is. The stability is determined by any number of criteria, including overshoot, settling time, correction of deviations due to external disturbances, etc.

Electric Control. *Electric control* is a method of using low voltages (typically, 24 VAC) or line voltages (110 VAC) to measure values and effect changes in controlled variables.

Electronic Control. *Electronic controls* use solid-state, electronic components used for measurement and amplification of measured signals and the generation of proportional control signals.

Pneumatic Control. *Pneumatic controls* use compressed air as the medium for measuring and controlling processes.

Open-Loop Systems. An *open-loop system* is one in which there is no feedback. A whole-house attic fan in an example. It will continue to run even though the house may have already cooled off. Also, timed on/off devices are open loops.

Examples

Direct-Acting Feedback Control. A classic control example is a reservoir in which the fluid must be maintained at a constant level. Figure 6.2.2 shows this process schematically. The key features of this direct-acting system are labeled. We will refer to the control action of this system shortly after defining some terms.

Cascaded (Master-Slave) Control Loops. If a process consists of several subprocesses, each with a relatively different transfer function, it is often useful to use cascaded control loops. For example, consider a building housing a manufacturing line in which 100% outside air is used but which must also have very strict control of room air temperature. The room temperature is controlled by changing the position of a valve on a coil at the main air-handling unit that supplies the zone. Typically, the time constant of the coil will be much smaller than the time constant of the room. A single feedback loop would probably result in poor control since there is so much dead time involved with both processes. The solution is to use two controllers: the first (the master) compares the room temperature with the thermostat setting and sends a signal to the second (the slave) that uses that signal as its own set point for controlling the coil valve. The slave controller measures the output of the coil, not the temperature of the room. The controller gain on the master can be set lower than that of the slave to prevent excessive cycling.

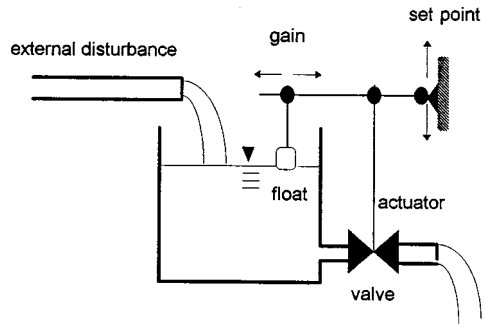

FIGURE 6.2.2 Example of a controlled process.

Sequential Control Loops. Sometimes control action is needed at more than one point in a process. An example of this is an air-handling unit that contains both heating and cooling coils in order to maintain a fixed outlet air temperature no matter the season. Typically, a *sequential* (or *split-range*) system in an air-handling unit will have three temperature ranges of operation, the first for heating mode, the last for cooling mode, and a middle dead-band region where neither the cooling nor heating coils are operating. Most sequential loops are simply two different control loops acting from the same sensor. The term *sequential* refers to the fact that in most of these systems the components are in series in the air or water stream.

Combined Feed-Forward/Feedback Loops. As pointed out earlier, feed-forward loops can be used when the effects of an external disturbance on a system are known. An example of this is outside air temperature reset control used to modify supply air temperatures. The control loop contains both a discharge air temperature sensor (the *primary* sensor) and an outdoor air temperature sensor (the *compensation* sensor). The designer should have some idea about the influence of the outside temperature on the heating load, and can then assign an *authority* to the effect of the outside air temperature on the controller set point. As the outdoor temperature increases, the control point decreases, and vice versa, as shown in Figure 6.2.3.

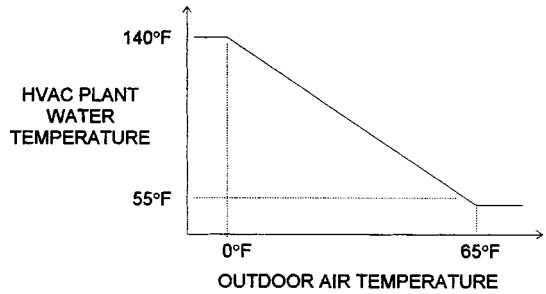

FIGURE 6.2.3 Example of the effect of compensation control.

Predictive Control. *Predictive control* uses a model of the process to predict what the process value will be at some point in the future based upon the current and past conditions. The controller then specifies a control action to be taken at the present that will reduce the future process error.

Adaptive Control. *Adaptive controllers* modify their gains dynamically so to adapt to current process conditions.

Supervisory Controllers. *Supervisory controllers* are used to govern the operation of an entire plant and/or control system. These may be referred to as *distributed control systems* (DCSs) which can be

used to govern the control of individual feedback loops and can also be used to ensure some kind of optimal performance of the entire plant. The controller will vary setpoints and operating modes in an attempt to minimize a cost function. A basic diagram of a supervisory controller in Figure 6.2.4.

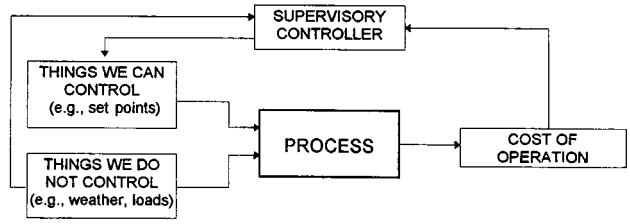

FIGURE 6.2.4 Typical supervisory controller.

6.3 Control System Analysis

Peter S. Curtiss

The Linear Process Approximation

To design controllers it is necessary to have both a dynamic process and control system representation. This section describes the key points of the most common such representation, that of linear processes and their controls. A process is basically a collection of mechanical equipment in which an input is changed or transformed somehow to produce an output. Many processes will be at near-steady-state, while others may be in a more or less constant state of change. We use building control systems as an illustration.

Steady-State Operation

The true response of a seemingly simple process can be, in fact, quite complex. It is very difficult to identify and quantify every single input because of the stochastic nature of life. However, practically any process can be approximated by an equation that takes into account the known input variables and produces a reasonable likeness to the actual process output.

It is convenient to use differential equations to describe the behavior of processes. For this reason, we will denote the "complexity" of the function by the number of terms in the corresponding differential equation (i.e., the *order* or *degree* of the differential equation). In a linear system analysis, we usually consider a step change in the control signal and observe the response. The following descriptions will assume a step input to the function, as shown in Figure 6.3.1. Note that a step change such as this is usually unlikely in most fields of control outside of electronic systems and even then can only be applied to a digital event, such as a power supply being switched on or a relay being energized. Zero-order system output has a one-to-one correspondence to the input,

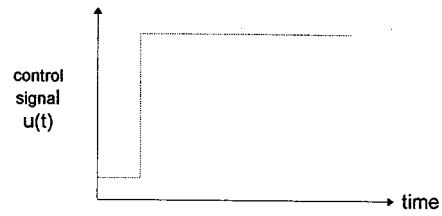

FIGURE 6.3.1 Step change in control signal.

$$y(t) = a_0 \cdot u(t)$$

First-order functions will produce a time-varying output with a step change as input,

$$\frac{dy(t)}{dt} + a_1 \cdot y(t) = b_1 \cdot u(t)$$

and higher-order functions will produce more complex outputs.

The function that relates the process value to the controller input is called the *transfer function* of the process. The time between the application of the step change, t_0, and the time at which the full extent of the change in the process value has been achieved is called the *transfer period*. A related phenomenon is process dead time. If there is a sufficient physical distance between the process output and the sensor assigned to measuring it, then one observes dead time during which the process output is not affected by the control signal (see Figure 6.3.2). The *process gain* (or *static gain*) is the ratio of the percentage

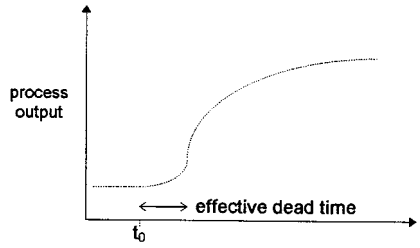

FIGURE 6.3.2 Effective dead time of a process subjected to a step change in controlled signal.

change of the process output to the corresponding percentage change of the control signal for a given response. For example, the gain can be positive (as in a heating coil) or negative (as in a cooling coil).

Dynamic Response

In practice, there are very few processes controlled in a stepwise fashion. Usually, the control signal is constantly modulating much the way that one makes small changes to the steering wheel of a car when driving down the highway. We now consider the dynamic process of level control in buckets filled with water (see Figure 6.3.3). Imagine that the level of water in the bucket on the left of Figure 6.3.3 is the control signal and the level of water in the bucket on the right is the process value. It is obvious that a step change in the control signal will bring about a first-order response of the process value.

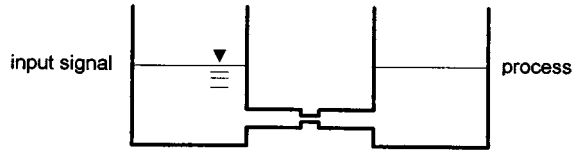

FIGURE 6.3.3 Connected water containers used for example of dynamic response.

Suppose, however, that a periodic signal is applied to the level of the bucket on the left. If the frequency of the signal is small enough, we see a response in the level in the bucket on the right that varies as a function of this driving force, but with a delay and a decrease in the amplitude.

Here the *dynamic process gain* is less than one even though the static process gain is one. There is no dead time in this process; as soon as we begin to increase the control signal the process value will also begin to increase. The dynamic process gain, therefore, can be defined similarly to that of the static gain — it is the ratio of the amplitude of the two signals, comparable with the normalized ranges used in the static gain definition.

The dynamic gain, as its name suggests, is truly dynamic. It will change not only according to the transfer function, but also to the frequency of the control signal. As the frequency increases, the output will lag even farther behind the input and the gain will continue to decrease. At one point, the frequency may be exactly right to cancel any past effects of the input signal (i.e., the phase shift is 180°) and the dynamic gain will approach zero. If the frequency rises further, the process output may decrease as the control signal increases (this can easily be the case with a building cooling or heating coil due to the mass effects) and the dynamic gain will be negative!

At this point it is convenient to define a feedback loop mathematically. A general feedback loop is shown in Figure 6.3.4. The controller, actuator, and process have all been combined into the *forward transfer function* (or *open-loop transfer function*) G and the sensor and dead time have all been combined into the *feedback path* transfer function H. The overall *closed-loop transfer function* is defined as

$$\frac{C}{R} = \frac{C}{1 + G \cdot H}$$

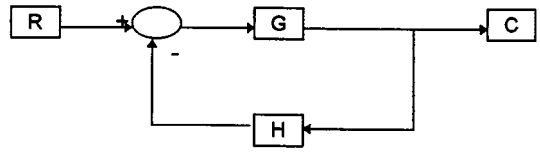

FIGURE 6.3.4 Generalized feedback loop.

The right-hand side of this equation is usually a ratio of two polynomials when using Laplace or *z*-transforms. The roots of the numerator are called the *zeros* of the transfer function and the roots of the denominator are called the *poles* (Shinners, 1978).

The denominator of the closed loop transfer function, $1 + G \cdot H$, is called the *characteristic function.* If we set the characteristic function equal to zero we have the *characteristic equation*

$$1 + G \cdot H = 0$$

The characteristic equation can be used to assess process control stability during system design.

Representation of Processes in *t*, *s*, and *z* Domains

We cannot hope to ever know how a process truly behaves. The world is an inherently stochastic place and any model of a system is going to approximate at best. Nonetheless, we will need to choose some kind of representation in order to perform any useful analysis.

This section will consider three different domains: the continuous-time domain, the frequency domain, and the discrete-time domain. The frequency domain is useful for certain aspects of controller design, whereas the discrete-time domain is used in digital controllers.

Continuous-Time-Domain Representation of a Process

In the time domain we represent a process by a differential equation, such as

$$\frac{d^n y}{dt^n} + a_1 \frac{d^{n-1} y}{dt^{n-1}} + a_2 \frac{d^{n-2} y}{dt^{n-2}} + \cdots + a_{n-1} \frac{dy}{dt} + a_n y = b_0 \frac{d^m u}{dt^m} + b_1 \frac{d^{m-1} u}{dt^{m-1}} + \cdots + b_{m-1} \frac{du}{dt} + b_m u$$

This is just a generalization of the first-order system equation described earlier.

Frequency-Domain Representation of a Process — Laplace Transforms

The solution of higher-order system models, closed-form solution is difficult in the time domain. For this reason, process transfer functions are often written using Laplace transforms. A Laplace transform is a mapping of a continuous-time function to the frequency domain and is defined as

$$F(s) = \int_0^\infty f(t) e^{-st}\, dt$$

Laplace transforms are treated in Section 19. This formulation allows us to greatly simplify problems involving ordinary differential equations that describe the behavior of systems. A transformed differential equation becomes purely algebraic and can be easily manipulated and solved. These solutions are not of great interest in themselves in modern control system design but the transformed system (+) controller differential equation is very useful in assessing control stability. This is the single key aspect of Laplace transforms that is of most interest. Of course, it is possible just to solve the governing differential equation for the system directly and explore stability in that fashion.

The Laplace transform of the previous differential equation is

$$s^n Y(s) + A_1 s^{n-1} Y(s) + \ldots + A_{n-1} s Y(s) + A_n Y(s) = B_0 s^m U(s) + B_1 s^{n-1} U(s) + \ldots + B_{n-1} s U(s) + B_n U(s)$$

This equation can be rewritten as

$$Y(s) \cdot \left(s^n + A_1 s^{n-1} + \ldots + A_{n-1} s + A_n\right) = U(s) \cdot \left(B_0 s^m + B_1 s^{n-1} + \ldots + B_{n-1} s + B_n\right)$$

so that the transfer function is found from

$$\frac{Y(s)}{U(s)} = \frac{s^m + B_1 s^{m-1} + \ldots + B_{m-1} s + A_m}{s^n + A_1 s^{n-1} + \ldots + A_{n-1} s + A_n}$$

This is the expression that is used for stability studies.

Discrete-Time-Domain Representation of a Process. A process in the discrete time domain is described (Radke and Isermann, 1989) by

$$y(k) = a_1 y(k-1) + a_2 y(k-2) + a_3 y(k-3) + \ldots + b_1 u(k-1) + b_2 u(k-2) + b_3 u(k-3) + \ldots$$

This representation is of use when one is designing and analyzing the performance of direct digital control (DDC) systems. Note that the vectors **a** and **b** are *not* the same as for the continuous-time domain equation. The *z*-transform uses the backward shift operator and therefore the *z*-transform of the discrete-time equation is given by

$$y\left(1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \ldots\right) = u\left(b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \ldots\right)$$

The transfer function can now be found:

$$\frac{y}{u} = \frac{b_1 z^{-1} - b_2 z^{-2} - b_3 z^{-3} + \ldots}{1 - a_1 z^{-1} - a_2 z^{-2} - a_3 z^{-3} + \ldots}$$

z-Transform Details. Because *z*-transforms are important in modern control design and are not treated elsewhere in this handbook, some basics of their use are given below. More and more control applications are being turned over to computers and DDC systems. In such systems, the sampling is not continuous, as required for a Laplace transform. The control loop schematic is shown in Figure 6.3.5.

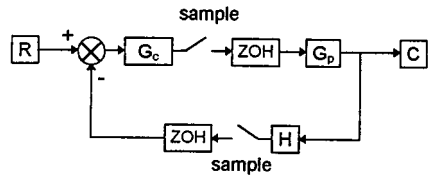

FIGURE 6.3.5 Sampled feedback loop.

It would be prohibitively expensive to include a voltmeter or ohmmeter on each loop; therefore, the controller employs what is called a *zero-order hold*. This basically means that the value read by the controller is "latched" until the next value is read in. This discrete view of the world precludes the use of Laplace transforms for analyses and makes it necessary, therefore, to find some other means of

simplifying the simulation of processes and controllers. The following indicates briefly how *z*-transforms of controlled processes can be derived and how they are used in a controls application. In the design section of this chapter we will use the *z*-transform to assess controller stability.

Recall that the Laplace transform is given as

$$\mathcal{L}\{f(t)\} = \int_0^\infty f(t)e^{-st}\,dt$$

Now suppose we have a process that is sampled at a discrete, constant time interval *T*. The index *k* will be used to count the intervals,

$$\text{at time } t = 0,\ k = 0,$$

$$\text{at time } t = T,\ k = 1,$$

$$\text{at time } t = 2T,\ k = 2,$$

$$\text{at time } t = 3T,\ k = 3,$$

and so forth. The equivalent Laplace transform of a process that is sampled at a constant interval *T* can be represented as

$$\mathcal{L}\{f^*(t)\} = \sum_{k=0}^{\infty} f(kT)e^{-s\cdot kT}$$

By substituting the *backward-shift operator* z for e^{Ts}, we get the definition of the *z*-transform:

$$Z\{f(t)\} = \sum_{k=0}^{\infty} f(kT)z^{-k}$$

Example of Using z-Transfer Functions. Suppose we have a cylindrical copper temperature sensor in a fluid stream with material properties as given. We wish to establish its dynamic characteristics for the purpose of including it in a controlled process model using both Laplace and *z*-transforms. Figure 6.3.6 shows the key characteristics of the sensor. The sensor measures 0.5 cm in diameter and is 2 cm long. For the purposes of this example we will assume that the probe is solid copper. The surface area of the sensor is then

$$A_s = 2\cdot\pi\cdot(0.25\text{ cm})^2 + \pi\cdot(0.5\text{ cm})\cdot(2\text{ cm}) \approx 3.5\text{ cm}^2$$

and the mass is

$$M_s = (9\text{ g/cm}^3)\cdot\left[(2\text{ cm})\cdot\pi\cdot(0.25\text{ cm})^2\right] \approx 3.5\text{ g}$$

The thermal capacitance of the sensor is found from the product of the mass and the heat capacity,

$$C_s = M_s\cdot c_p = 3.5\text{ g}\cdot 0.4\text{ J/g}\cdot\text{K} = 1.4\text{ J/K}$$

and the total surface heat transfer rate is the product of the area and the surface heat transfer coefficient,

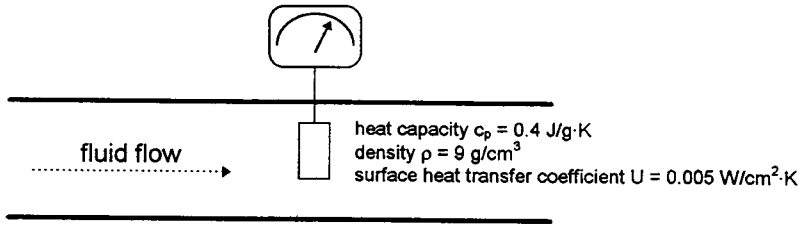

FIGURE 6.3.6 Fluid temperature sensor used in example.

$$UA_s = 0.005\ \mathrm{W/cm^2 \cdot K} \cdot 3.5\ \mathrm{cm^2} = 0.018\ \mathrm{W/K}$$

Now we can perform an energy balance on the sensor by setting the sum of the energy flow into the sensor and the energy stored in the sensor equal to zero:

$$C_s = \frac{dT_s}{dt} + \left(T_s - T_a\right) \cdot UA_s = 0$$

where T_s is the temperature of the sensor and T_a is the ambient fluid temperature. This relationship is a nonhomogeneous first-order differential equation:

$$\frac{dT_s}{dt} + \frac{UA_s}{C_s} T_s = \frac{UA_s}{C_s} T_a$$

The *time constant* of the sensor is defined as

$$\tau = \frac{C_s}{UA_s} = \frac{1.4\ \mathrm{J/K}}{0.018\ \mathrm{W/K}} \approx 80\ \mathrm{sec}$$

The differential equation that describes this sensor is

$$\frac{dT_s}{dt} + \frac{1}{\tau} T_s = \frac{1}{\tau} T_a$$

This example will find the response of the sensor when the fluid temperature rises linearly by 30°C from time t = 0 to time t = 200 seconds and then remains constant. That is, the driving function is

$$T_a(t) = \frac{30°\mathrm{C}}{200\ \mathrm{sec}} t = 0.15°\mathrm{C/sec}\ t \qquad 0 \le t < 200\ \mathrm{sec}$$

$$T_a(t) = 30°\mathrm{C} \qquad t \ge 200\ \mathrm{sec}$$

Assuming an initial condition of T_s = 0 at t = 0, we find that

$$T_s(t) = 0.15t - 12 + 12e^{-0.0125t} \qquad \text{for } t < 200\ \mathrm{sec}$$

and

$$T_s(t) = 30 - 134.2e^{-t/\tau} \qquad \text{for } t > 200\ \mathrm{sec}$$

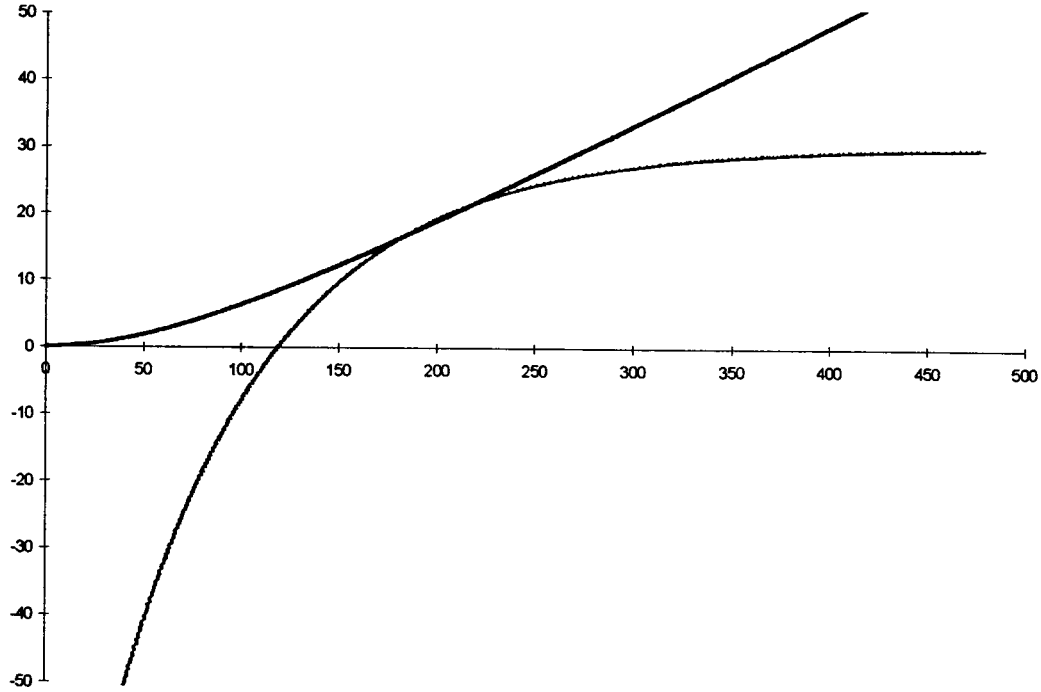

FIGURE 6.3.7 Time domain solution of example.
First line: $T = 0.15t - 12 + 12e^{-0.0125t}$. Second line: $T = 30 - 134.2e^{-t/r}$.

A graph of the entire process (rise time and steady state) is shown in Figure 6.3.7. The two lines intersect at t = 200 seconds.

Solution of example in frequency domain

This same process can be solved using Laplace transforms. First we will solve this problem for the first 200 sec. The Laplace transform of a ramp function can be found from the tables (see Section 19) to get

$$T_s(s) = \frac{1}{\tau(s + 1/\tau)} \frac{0.15}{s^2}$$

This can be expanded by partial fractions to get

$$T_s(s) = 0.15\left[\frac{\tau}{s} + \frac{1}{s^2} + \frac{\tau}{s + 1/\tau}\right]$$

Using the table for the inverse Laplace transforms gives

$$T_s(t) = 0.15\left[-\tau + t + \tau e^{-t/\tau}\right]$$

Substituting τ = 80,

$$T_s(t) = -12 + 0.15t + 12e^{-0.0125t}$$

This is exactly the same as the time-domain solution above. For the steady-state driving force of T_a = 30 for t > 200 sec we also find the same result.

Solution of example in the discrete-time domain

We consider the same problem in the discrete-time domain that a DDC system might use. Recall that the transfer function in the frequency domain was given by

$$\frac{T_s(s)}{T_a(s)} = \frac{\dfrac{1}{\tau}}{s + \dfrac{1}{\tau}}$$

We look to the table in this book's appendix and find that the discrete-time equivalent is

$$\frac{T_s(z)}{T_a(z)} = \frac{1}{\tau} \cdot \frac{z}{z - e^{-T/\tau}}$$

where T is the sampling frequency in seconds. The driving function T_a is a given as

$$T_a(t) = \alpha t$$

where α is the rate of change of the temperature as above (0.15°C/sec). Note that to put this into the discrete-time domain we must correct this rate by the sampling interval,

$$T_a(z) = 0.15 \cdot T \cdot \frac{Tz}{(z-1)^2}$$

using α = (0.15 · T) ºC/sampling interval.

We can now express the response of the process as

$$T_s(z) = \frac{1}{\tau} \cdot \left(\frac{z}{z - e^{-T/\tau}} \right) \cdot (0.15 \cdot T) \cdot \left(\frac{Tz}{(z-1)^2} \right)$$

since the z operator acts on the sensed temperature by performing a backward shift of the time index. In other words, the previous equation can be rewritten as

$$T_{s,k} - \left(2 + e^{-T/\tau}\right) T_{s,k-1} + \left(1 + 2e^{-T/\tau}\right) T_{s,k-2} - e^{-T/\tau} T_{s,k-3} = \frac{0.15}{\tau} \cdot T^2 z^{-1}$$

So the current temperature is determined by the previous three temperature measurements,

$$T_{s,k} = \left(2 + e^{-T/\tau}\right) T_{s,k-1} - \left(1 + 2e^{-T/\tau}\right) T_{s,k-2} + e^{-T/\tau} T_{s,k-3} + \frac{0.15}{\tau} \cdot T^2 z^{-1} \qquad \text{for } kT < 200 \text{ sec}$$

Regarding the last term in the equation, recall that the inverse transform of z^{-k} is given as 1 when $t = k$, and zero otherwise. This term provides the initial "jump-start" of the progression. Table 6.3.1 shows the first few time steps for the z-domain solution using time steps of 0.1 and 1.0 seconds. In general, the accuracy of the z-domain solution increases as the time step grows smaller. The solution for kT > 200 seconds is similar to that for the Laplace transforms.

TABLE 6.3.1 Initial Time Steps for *z*-Domain Solution of Example

Initial 10 Steps for T = 0.1 sec				Initial 10 Steps for T = 1.0 sec			
k	**Time**	$T_{s,\text{exact}}$	$T_{s,z\ \text{transform}}$	**k**	**Time**	$T_{s,\text{exact}}$	$T_{s,z\ \text{transform}}$
0	0.00	0.00000	0.00000	0	0.00	0.0000	0.0000
1	0.10	0.00001	0.00002	1	1.00	0.0009	0.0019
2	0.20	0.00004	0.00006	2	2.00	0.0037	0.0056
3	0.30	0.00008	0.00011	3	3.00	0.0083	0.0112
4	0.40	0.00015	0.00019	4	4.00	0.0148	0.0185

6	0.60	0.00034	0.00039	6	6.00	0.0329	0.0386
7	0.70	0.00046	0.00052	7	7.00	0.0446	0.0512
8	0.80	0.00060	0.00067	8	8.00	0.0580	0.0656
9	0.90	0.00076	0.00084	9	9.00	0.0732	0.0816
10	1.00	0.00093	0.00103	10	10.00	0.0900	0.0994

The next three figures show the effect of using different time intervals in the *z*-domain solution. The values shown here are for the example outlined in this section. If one could use an infinitesimally small time step, the *z*-domain solution would match the exact solution. Of course, this would imply a much larger computational effort to simulate even a small portion of the process. In practice, a time interval will be chosen that reflects a compromise between accuracy and speed of calculation.

Each graph shows two lines, one for the exact solution of the first 200 sec of the example and the other for the *z*-domain solution. Figures 6.3.8 to 6.3.10 give the *z*-domain solution using time intervals of 0.1, 1.0 and 10.0 seconds, respectively. Notice that there is not much difference between the first two graphs even though there is an order of magnitude difference between the time intervals used. The latter two graphs show significant differences.

6.4 Control System Design and Application

Peter S. Curtiss

Controllers

Controllers are akin to processes in that they have gains and transfer functions. Generally, there is no dead time in a controller or it is so small as to be negligible.

Steady-State Effects of Controller Gain

Recall that the process static gain can be viewed as the total change in the process value due to a 100% change in the controller output. A proportional controller acts like a multiplier between an *error signal* and this process gain. Under stable conditions, therefore, there must be some kind of error to yield any controller output. This is called the steady-state or static *offset*.

Dynamic Effects of Controller Gain

Ideally, a controller gain value is chosen that compensates for the dynamic gain of the process under normal operating conditions. The total loop dynamic gain can be considered as the product of the process, feedback, and controller gains. If the total dynamic loop gain is one, the process will oscillate continuously at the natural frequency of the loop with no change in amplitude of the process value. If the loop gain is greater than one, the amplitude will increase with each cycle until the limits of the controller or process are reached or until something fails. If the dynamic loop gain is less than one, the process will eventually settle down to stable control.

Controller Bias

The controller bias is a constant offset applied to the controller output. It is the output of the controller if the error is zero,

$$u = K \cdot e + M$$

where M is the bias. This is useful for processes that become nonlinear at the extremes or for process in which the normal operating conditions are at a nonzero controller output.

PID Controllers

Many mechanical systems are controlled by proportional-integral-derivative (PID) controllers. There are many permutations of such controllers which use only certain portions of the PID controllers or use variations of this kind of controller. In this section we consider this very common type of controller.

Proportional Control

Proportional control results in action that is linear with the error (recall the error definition in Figure 6.2.1) The proportional term, $K_p \cdot e$, has the greatest effect when the process value is far from the desired setpoint. However, very large values of K_p will tend to force the system into oscillatory response. The proportional gain effect of the controller goes to zero as the process approaches set point. Purely proportional control should therefore only be used when

- The time constant of the process is small and hence a large controller gain can be used;
- The process load changes are relatively small so that the steady-state offset is limited;
- The steady-state offset is within an acceptable range.

Integral Control

Integral control makes a process adjustment based on the cumulative error, not its current value. The integral term K_i is the reciprocal of the reset time, T_r, of the system. The reset time is the duration of

each error-summing cycle. Integral control can cancel any steady-state offsets that would occur when using purely proportional control. This is sometimes called *reset* control.

Derivative Control

Derivative control makes a process adjustment based on the current rate of change of the process control error. Derivative control is typically used in cases where there is a large time lag between the controlled device and the sensor used for the feedback. This term has the overall effect of preventing the actuator signal from going too far in one direction or another, and can be used to limit excessive overshoot.

PID Controller in Time Domain

The PID controller can be represented in a variety of ways. In the time domain, the output of the controller is given by

$$u(t) = K_p\left[e(t) + K_i\int_0^t e(t)\,dt + K_d\frac{de(t)}{dt}\right]$$

PID Controller in the *s* Domain

It is relatively straightforward to derive the Laplace transform of the time-domain PID equation. The transfer function of the controller is

$$\frac{U(s)}{E(s)} = \left[K_p + \frac{K_pK_i}{s} + K_pK_ds\right]$$

This controller transfer function can be multiplied by the process transfer function to yield the overall forward transfer function **G** of an *s*-domain process model. The criteria described earlier can then be used to assess overall system stability.

PID Controller in the *z* Domain

Process data are measured discretely at time intervals Δt, and the associated PID controller can be represented by

$$u(k) = K_p\left[e(k) + K_i\,\Delta t\sum_{i=0}^{k} e(i) + K_d\frac{e(k)-e(k-1)}{\Delta t}\right]$$

The change of the output from one time step to the next is given by $u(k) - u(k-1)$, so the PID *difference equation* is

$$u(k)-u(k-1) = K_p\left[\left(1+\frac{K_d}{\Delta t}\right)e(k) + \left(K_i\,\Delta t - 1 - 2\frac{K_d}{\Delta t}\right)e(k-1) + \left(\frac{K_d}{\Delta t}\right)e(k-2)\right]$$

and can be simplified as

$$u(k)-u(k-1) = q_0e(k) + q_1e(k-1) + q_2e(k-2)$$

where

$$q_0 = K_p\left(1+\frac{K_d}{\Delta t}\right);\qquad q_1 = K_p\left(K_i\,\Delta t - 1 - 2\frac{K_d}{\Delta t}\right);\qquad q_2 = K_p\left(\frac{K_d}{\Delta t}\right)$$

Note that we can write this as

$$u\left(1-z^{-1}\right)=e\left(q_0+q_1z^{-1}+q_2z^{-2}\right)$$

The *z*-domain transfer function of the PID controller is then given as

$$\frac{u(z)}{e(z)}=\frac{q_0+q_1z^{-1}+q_2z^{-2}}{1-z^{-1}}=\frac{q_0z^2+q_1z+q_2}{z^2-z}$$

Controller Performance Criteria and Stability

Performance Indexes

Obviously, in feedback loops we wish to reduce the process error quickly and stably. The control systems engineer can use different cost functions in the design of a given controller depending on the criteria for the controlled process. Some of these cost functions (or *performance indexes*) are listed here:

ISE	Integral of the square of the error	$\int^2 e$
ITSE	Integral of the time and the square of the error	$\int e^2$
ISTAE	Integral of the square of the time and the absolute error	$\int^2 \lvert e\rvert$
ISTSE	Integral of the square of the time and the square of the error	$\int^2 e^2$

These indexes are readily calculated with DDC systems and can be used to compare the effects of different controller settings, gains, and even control methods.

Stability

Stability in a feedback loop means that the feedback loop will tend to converge on a value as opposed to exhibiting steady-state oscillations or divergence. Recall that the closed-loop transfer function is given by

$$\frac{C}{R}=\frac{G}{1+GH}$$

and that the denominator, 1 + *GH*, when equated to zero, is called the characteristic equation. Typically, this equation will be a polynomial in *s* or *z* depending on the method of analysis of the feedback loop. Two necessary conditions for stability are that all powers of *s* must be present in the characteristic equation from zero to the highest order and that all coefficients in the characteristic equation must have the same sign. Note that the process may still be unstable even when these conditions are satisfied.

Roots of the Characteristic Equation. The roots of the characteristic equation play an important role in determining the stability of a process. These roots can be real and/or imaginary and can be plotted as shown in Figure 6.4.1. In the *s*-domain, if all the roots are in the left half-plane (i.e., to the left of the imaginary axis), then the feedback loop is guaranteed to be asymptotically stable and will converge to a single output value. If one or more roots are in the right half-plane, then the process is unstable. If one or more roots lie on the imaginary axis and none are in the right half-plane, then the process is considered to be marginally stable. In the *z*-domain, if all the roots lie within the unit circle about the origin then the feedback loop is asymptotically stable and will converge. If one or more roots lie outside

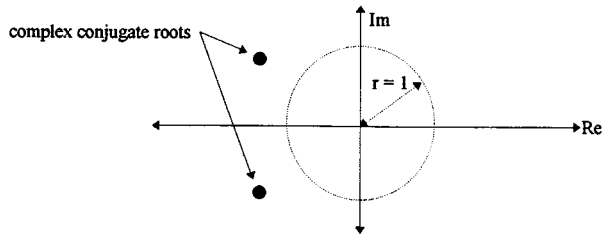

FIGURE 6.4.1 Placement of roots in the imaginary plane (showing unit circle).

the unit circle then the process is unstable. If one or more roots lie on the unit circle and none are outside the unit circle, then the process is marginally stable.

Root locus example

Consider the feedback loop shown in Figure 6.4.2. The characteristic equation is given by $1 + GH = 0$ or

$$1 + K\left(\frac{s}{s+\alpha}\right)\left(\frac{1}{s+\beta}\right) = 0$$

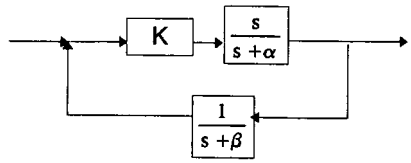

FIGURE 6.4.2 Simple feedback control loop.

For different values of K we can plot the roots of this equation. The graph in Figure 6.4.3 shows an example plot when the characteristic equation is given by $s^2 + (1.25 + K)s + 1.25 = 0$. The plot shows that a system described by this characteristic demonstrates stable response for a process gain of $0.0 \leq K \leq 10.0$. For gains greater than 10, there exists at least one root in the right half-plane and the process is not under stable control.

Note that the root locus plot is always symmetric about the real axis and that the number of separate segments of the locus is equal to the number of roots of the characteristic equation (i.e., the number of poles of the closed-loop transfer function).

Routh-Hurwitz Stability Criteria. The Routh-Hurwitz method is an tabular manipulation of the characteristic equation in the frequency domain and is used to assess stability. If the characteristic equation is given by

$$a_0 s^n + a_1 s^{n-1} + \ldots + a_{n-1} s + a_n = 0$$

then the Routh-Hurwitz method constructs a table from the coefficients as follows:

$$\begin{array}{ccccc} s^n & a_0 & a_2 & a_4 & \ldots \\ s^{n-1} & a_1 & a_3 & a_5 & \ldots \\ s^{n-2} & X_1 & X_2 & X_3 & \ldots \\ s^{n-3} & Y_1 & Y_2 & Y_3 & \ldots \\ \vdots & \vdots & \vdots & \vdots & \ldots \end{array}$$

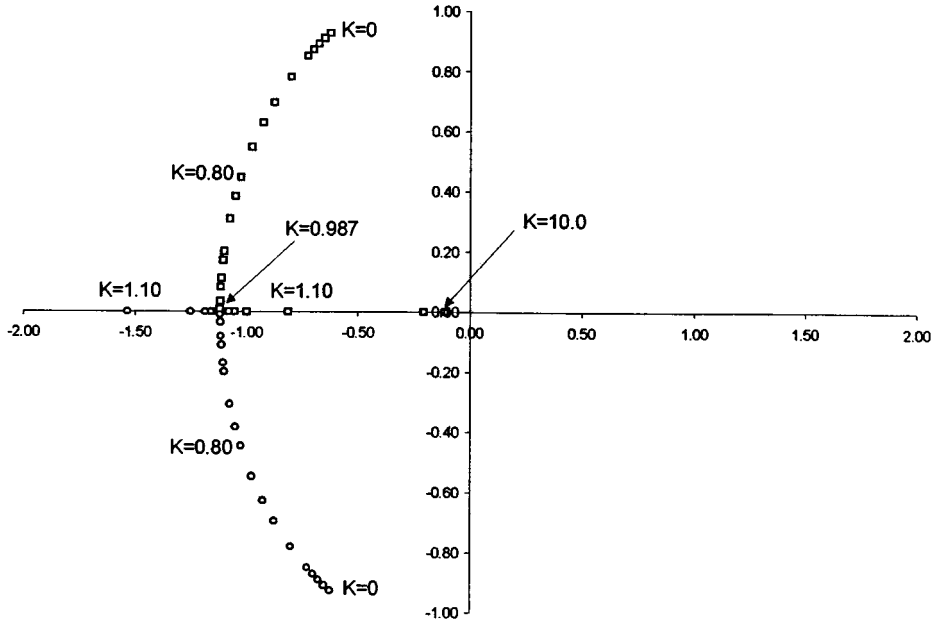

FIGURE 6.4.3 Root locus of $s^2 + (1.25 + K)s + 1.25 = 0$.

where

$$X_1 = \frac{a_1a_2 - a_0a_3}{a_1}; \qquad X_2 = \frac{a_1a_4 - a_0a_5}{a_1}; \qquad X_3 = \frac{a_1a_6 - a_0a_7}{a_1}\cdots$$

$$Y_1 = \frac{X_1a_3 - a_1X_2}{X_1}; \qquad Y_2 = \frac{X_1a_5 - a_1X_3}{X_1}\cdots$$

and so forth. The number of roots in the right-hand plane of the *s*-domain is equal to the number of sign changes in the first column, i.e., the column containing a_0, a_1, X_1, Y_1, etc. In other words, if all the elements in the first column have the same sign, then there are no roots in the right-hand plane and the process is stably controlled. Also, for special cases of the characteristic equation,

- If the first element of any row is zero but the remaining elements are not, then use some small value ε and interpret the final results as $\varepsilon \to 0$.
- If one of the rows before the final row is entirely zeros, then (1) there is at least one pair of real roots of equal magnitude but opposite signs, or (2) there is at least one pair of imaginary roots that lie on the imaginary axis, or (3) there are complex roots symmetric about the origin.

Field Commissioning — Installation, Calibration, Maintenance

Tuning of Feedback Loops

The *tuning* of a controller involves finding controller gains that will ensure at least a critically damped response of the process to a change in set point or process disturbance. A good starting point for PID constants is that derived during the design phase by the stability assessment approaches described above. However, real processes do not necessarily behave as their models would suggest and actual field tuning of controls is needed during the system-commissioning process.

Pole-Zero Cancellation. One method of obtaining the desired critically damped response of a process is to determine the closed-loop transfer function in the form

$$\frac{C}{R} = \frac{(s + A_1)(s + A_2)\ldots(s + A_m)}{(s + B_1)(s + B_2)\ldots(s + B_n)}$$

The coefficients *A* and *B* will depend on both the process characteristics and the controller gains. The objective of pole-zero cancellation is to find values for the controller gains that will set some numerator coefficients equal to those in the denominator, effectively canceling terms. As can be imagined, however, this can be a very difficult exercise, particularly when working with complex roots of the equations. This method can only be used with very simple system models.

Reaction Curve Techniques. Often it is advisable to test a feedback loop *in situ*. Several techniques have been developed that allow for the derivation of "good" PID constants for a given open-loop response. Consider the process response shown in Figure 6.4.4 where Δ_c is the change of process output, Δ_u is the change of controller, *L* is the time between change and intersection, and *T* is the time between lower intersection and upper intersection. We can define the following variables: $A = \Delta_u/\Delta_c$, $B = T/L$, and $R = L/T$. These values can be used with the equations given in Table 6.4.1 to estimate "decent" control constants. The users of these constants should be aware, however, that these constants are based on the typical response of second-order systems and may not provide good values for all processes.

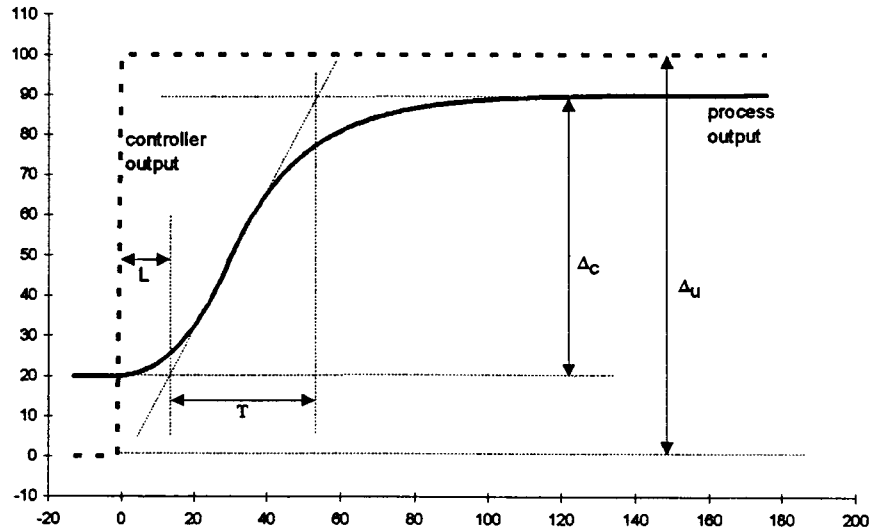

FIGURE 6.4.4 Reaction curve components.

Ultimate Frequency. The ultimate frequency test involves increasing the proportional gain of a process until it begins steady-state oscillations. K_p^* is defined as the proportional gain that results in steady oscillations of the controlled system and T^* is the period of the oscillations. The desired controller gains are given in Table 6.4.2. Note that the use of the ultimate period test is not always easy to do in practice and may be prohibited in certain cases by the a process operations manager.

Neural Network-Based Predictive/Adaptive Controllers

Neural networks are powerful modeling tools used for predicting nonlinear behavior of processes and require a minimum of knowledge about the physical system involved. This approach can be used to predict the behavior of a process and can calculate the future value of the process variables. The effects of current modifications to the future value of the controlled process can be easily quantified and used to obtain the desired process response.

Overview of Neural Networks

The artificial neural network attempts to mimic a few aspects of the behavior of biological neural networks. Inputs to a biological nerve cell are carried along the dendrites of that cell. These inputs come from the positive impulse signals of other cells but may be converted to negative signals by the chemical interactions at the synapse between the cells. All of the inputs are then carried to the soma where they add or subtract from the overall potential difference between the interior of the soma and the surrounding fluid. Once the cell potential rises above a certain level, the cell "fires" and sends signals to other cells along its axon.

The artificial cell behaves in much the same way, except that the output signal is analog instead of digital. Signals from sending cells are passed along to a receiving cell through a series of connections. Each connection has an associated weighting factor that acts as a multiplier on the signal from the sending cell. All the inputs to a cell are summed (along with a cell bias, if included) and the resulting value is used to generate the output of the receiving cell. The output of the cell is referred to as the cell *activation* and the function that uses the net input to generate the cell activation is called the *activation function*. The activation function can theoretically be of any form, although linear and sigmoidal functions are frequently used. Figure 6.5.1 shows a comparison between a biological cell and an artificial cell.

When many different cells are combined together into a richly connected network (Figure 6.5.2), the result can behave mathematically like a nonlinear regression engine capable of mapping inputs to outputs for complex relationships. The trick is to find a series of weights *W* that allow the network to provide the desired outputs using specific inputs.

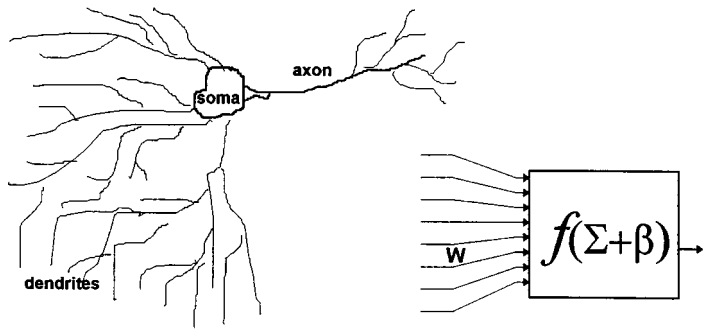

FIGURE 6.5.1 Biological cell vs. artificial cell.

Training Neural Networks

The net input to a cell is given by

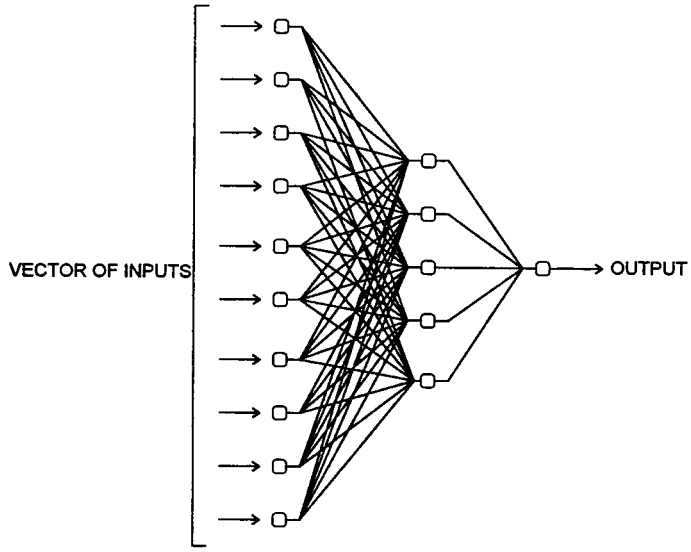

FIGURE 6.5.2 Artificial neural network consisting of several layers of mathematical models of biological neurons.

$$I_{\mathrm{NET},i} = \sum_{j=f}^{1} A_j w_{j\to i}$$

where $I_{\mathrm{NET,i}}$ is the net input of node i due to input from nodes f through I (as in *first* through *last*), A_j is the output of cell j, and $w_{j\to i}$ is the weighting factor associated with the connection between the sending node j and the receiving node i. The output (*activation*) of cell i is then going to be a function of the net input to the cell. Typically, the sigmoid function is used to relate activation to cell inputs

$$A_i = \frac{1}{1 + e^{-I_{\mathrm{NET},i}}}$$

Practically any function can be used as the activation function of each node; the sigmoid function is usually chosen because the derivative, used during the training process, is easy to calculate. Traditional training of neural networks seeks to minimize the error function

$$E = \sum_{p=1}^{N_p} \sum_{i=1}^{N_o} \left(t_{p,i} - A_{p,i}\right)^2$$

where N_P is the number of input/output pairs of data, N_o is the number of outputs of the network, and $t_{p,i}$ is the desired (*target*) output value for a given set of inputs. This error function is minimized by adjusting the values of the weights proportionally to the negative of the derivative of the error with respect to each weight,

$$\Delta w_{j\to i} = -\varepsilon \frac{\partial E}{\partial w_{j\to i}}$$

where ε is the *learning rate* of the network. In a multilayered network the training is initiated by stimulating the network with a specific vector of inputs. The outputs of all the cells are then calculated

in order, starting with the input layer and ending with the output layer. The output is then compared with the known target output value, and any errors are compensated for by adjusting the weights from the output layer back toward the input layer. This method of training is, therefore. called *back-propagation*. With such a method, the previous equation for Δw can be rewritten as

$$\Delta w_{j\to i} = -\varepsilon\delta_i A_j$$

where δ_i represents the effect of a change in the net input to cell j on the output of cell i. For cells in the output layer,

$$\delta_i = \left(t_i - A_i\right) f'\left(I_{\text{NET},i}\right)$$

where f' is the derivative of the sigmoid activation function. For nodes in the hidden layers,

$$\delta_i = f'\left(I_{\text{NET},i}\right)\sum_{j=f}^{1}\left(\delta_i w_{j\to i}\right)$$

The product d_iA_j is something called the *weight-error derivative* (WED). To prevent excessive oscillation of the weights during training, the change of weights can be restricted according to

$$\Delta w(k) = \varepsilon \cdot \text{WED} + \mu \cdot \Delta w(k-1)$$

where μ is the *momentum* of the network. Finally, to gradually reduce the rate at which the weights change, the learning rate ε can be made subject to exponential decay during the training process. This is sometimes called *simulated annealing*.

Bias nodes are like stand-alone cells that connect to each "normal" cell of the network. The output activation of each bias node is always unity and the "weight" connecting the bias node to the normal cell acts as a threshold function that suppresses or augments the output of the cell.

Using Networks for Controlling Feedback Loop Processes

Neural networks offer the potential for and have demonstrated improved control of processes through predictive techniques. The concept is fairly simple: train a network to predict the dynamic behavior of a process and then use these predictions to modify the controller output to place the process at a desired set point $R(t)$ at some time in the future. Initial results from computer simulations of such a controller are presented in Curtiss et al. (1993 a,b,c). Anderson (1989) described a computer simulation in which a network was trained to recognize the dynamic properties of an inverted pendulum (e.g., a broom balanced on an open palm). A control system was developed in which the angle and position of the pendulum were used to move the supporting base in order to maintain the pendulum upright. A neural network-based predictive controller is outlined in the classic discussion by Nguyen and Widrow (1989) on the "truck backer-upper" problem in which a tractor-trailer is backed into position at a loading dock.

Properly tuned fixed-gain controllers will usually work over a relatively wide range of process operation provided that the external perturbations and influences are small or time invariant. With nonlinear processes, however, a conventional control algorithm can lead to unstable control if the gains were chosen for a range different from the current operating conditions.

Architecture of the Network

With the neural network approach it is possible to overcome these problems by using as many additional salient inputs (the *auxiliary* inputs) as necessary and by incorporating an inherently nonlinear model to accomplish the control objectives. The network is trained using examples of the time-dependent relationship between a value of the feedback and previous values of the feedback, the controller output and

the auxiliary inputs. An example of the network architecture required for this is shown in Figure 6.5.3. In practice there does not need to be a limit on the number of previous measurements of any of the inputs, although the final size of the network and the corresponding training time and memory requirements need to be taken into consideration.

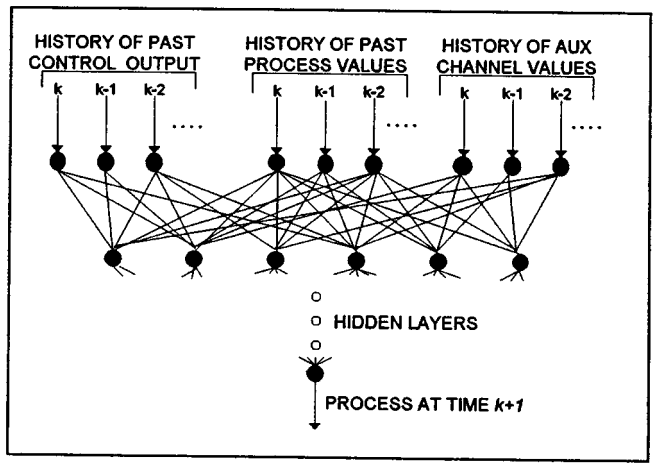

FIGURE 6.5.3 Network used for process prediction.

The network, once trained, can predict the future feedback value for any controller output. The trick is to find the controller output that causes the future process value to match the set point. This is accomplished by finding the derivative of the future error with respect to the current controller signal. Starting with the current process conditions, the feedback value is predicted at each time step into the future over a preset time window (). During each step of the prediction the values for the controller output and auxiliary inputs are held constant. This simulation is performed twice: the first time with a small increase in the controller output and the second time with a small decrease. This allows for the calculation of the change of the future process value (and hence the change of the future error) as a function of the change in the current controller output. The controller output is then modified by

$$\Delta U(t) = -G_{\text{net}} \cdot E_f(t) \frac{\partial E_f(t)}{\partial U(t)}$$

where E_f is the future error and G_{net} is the network controller gain. For a multiple-output controller, the additional outputs are simply added as more outputs of the network and the future predictions repeated several times to find the correct partial derivatives.

Many different variations on this theme are possible, for example, using the sum of the absolute values of all the errors over the prediction window (or the sum of the square of the errors, etc.) instead of simply the future error. Computer-simulated results of such tests are provided by Curtiss et al. (1993).

Estimating the Size of the Prediction Time Window. It is possible to use the network model to determine the size of the time window by estimating the amount of time required for the process to reach some future steady state after a simulated change in the controller output. An example of such an open-loop response it is shown in Figure 6.5.5. Here the network is simulating the response of a reverse-acting process after a decrease in actuator position at time step 0. About 70% (ln 2) of total rise time is achieved after 15 time steps. This kind of calculation can be performed during the control sequence and should indicate the proper time window size.

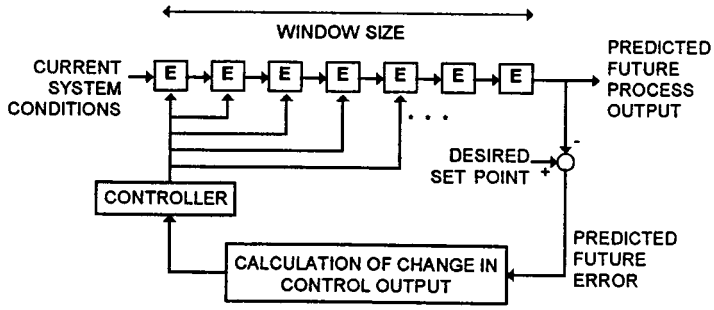

FIGURE 6.5.4 Schematic of procedure for determining future process value and error.

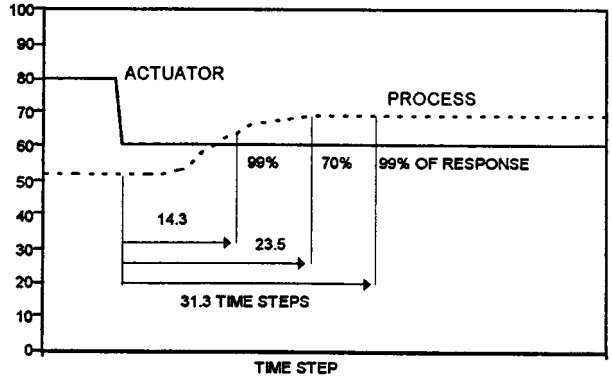

FIGURE 6.5.5 Example of computer-simulated process step change (used to determine size of time window).

Example of PID vs. Network Controller

Figure 6.5.6 shows an example of a process under PID control that demonstrates nonlinearity at different ranges of actuator position. Figure 6.5.7 shows the same process under the influence of a predictive neural network controller that had been trained on the process. Note that the network-based controller does not show the same problems of unstable control in certain actuator ranges. The size of the time window (15 time steps) was determined using the method discussed in the previous section. .

Using Networks as Supervisory Controllers

The previous section discussed the use of neural networks to minimize a predicted error of a feedback-loop process. It is possible to apply a similar methodology for supervisory plant control to optimize the process according to some cost function. A network is first trained to predict the cost function under a wide range of operating conditions. This network is then used to predict what will happen with different control strategies Figure 6.5.8. shows a schematic of this technique. The left side of the figure shows the training mode, where the network is attempting to associate the various plant inputs with the cost function output. There can be multiple inputs, including uncontrollable variables (e.g., ambient conditions, plant loads, etc.) and controlled variables (i.e., the various process set points.)

Once the network is sufficiently trained, it is used to find values for the set points under any set of uncontrolled variables. The technique for doing so is similar to the back-propagation training technique of the network. The inputs corresponding to the controlled variables are replaced with *virtual nodes* whose outputs are always unity. These nodes are connected to the predictor network through adjustable weights. The optimization occurs by finding values for these weights that allow the model to predict a desired output. These weights can be found through any number of search methods, including the gradient descent technique used in back-propagation training. In this case, the predictor network is "trained"

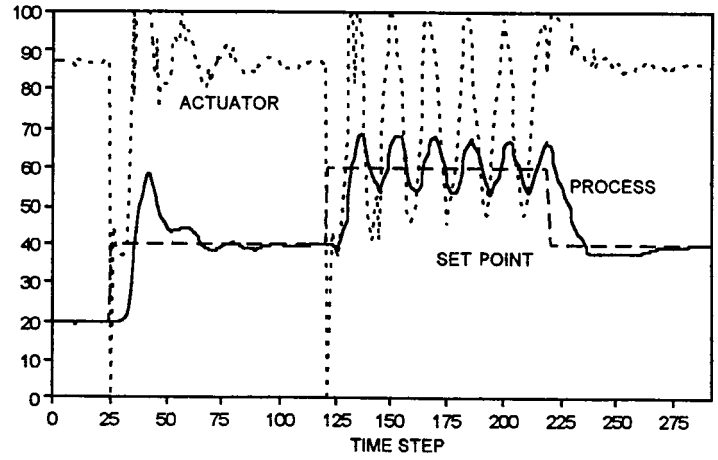

FIGURE 6.5.6 Example of computer simulation using a PID controller.

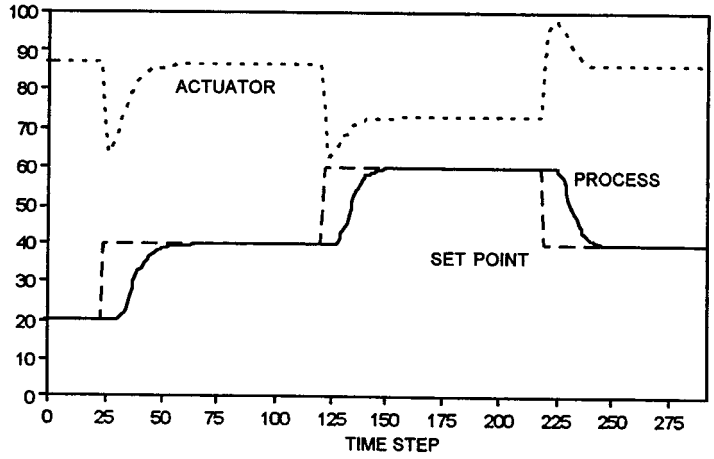

FIGURE 6.5.7 Example of computer simulation using a neural network controller.

normally, except that all weights in the network are static except those connected to the virtual nodes. Once weights have been found that produce the desired output, the set points can be found from direct interpretation of these weights. Constraints can be imposed on the weights either through physical limitations (e.g., freezing points) or from predictions from local-loop neural network controllers.

Fuzzy Logic Controllers

Fuzzy logic controllers (FLC) use conditional relationships to analyze one or more inputs. That is, the inputs are subject to a series of *if…then* queries to produce some intermediate values. An example would be something like a simple cruise control on an automobile:

- *If* vehicle speed = much lower than set point, *then* need to increase speed = large
- *If* vehicle speed = slightly lower than set point, *then* need to increase speed = small

These intermediate values are then used to determine the actual change of speed in the car:

- *If* need to increase speed = large, *then* increase of throttle position = 10%
- *If* need to increase speed = small, *then* increase of throttle position = 3%

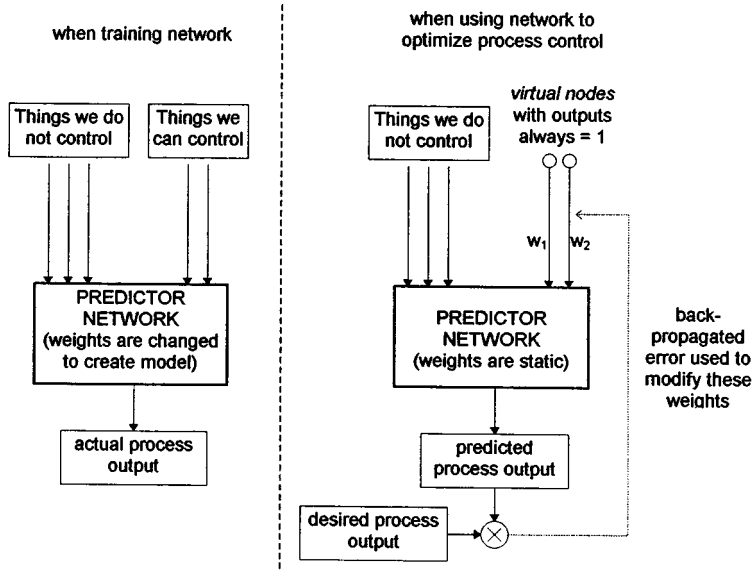

FIGURE 6.5.8 Using network model to optimize process control.

In fuzzy control, the satisfaction of a particular *if* statement may not lead to or be restricted by a true or false response. A range of weighting coefficients is assigned to a particular conditional, with the coefficients generally decreasing as the certainty of a specific condition decreases. In the example above, "need to increase speed = large" may be assigned a certainty of 1 when the speed of the vehicle is less than 50% of the desired speed of the car. This certainty will decrease as the speed of the car increases, so that "need to increase speed = large" may be 0 when the speed of the car is greater than 90% of the desired speed, but the certainty of "need to increase speed = small" will be large. It is possible that for a given speed of the car, two or more conditions may be satisfied with different magnitudes of certainty. These conditions can then be applied to the output rules along with their respective certainties to determine the actual increase (or decrease) in the controller output. When the speed of the car is below the desired speed, the initial rules may yield, for example,

- Need to increase speed = large with certainty = 0.3
- Need to increase speed = small with certainty = 0.7

the actual output would then be

- Increase of throttle position = $(0.3 \times 10\% + 0.7 \times 3\%)/(0.3 + 0.7) = 5.1\%$

The following section formalizes some of these ideas and includes a detailed example.

Section 19 Mathematics contains the formalism underlying fuzzy set theory and fuzzy logic. The reader is referred to that section and the one that follows for the technical basis for FLCs.

Fuzzy Logic Controllers for Mechanical Systems

Introduction

In the last decade, FLCs have been receiving more attention (Leigh and Wetton 1983; Daley and Gill, 1985; Yasunobu and Miyamoto, 1985; Xu, 1989), not only in test cases, but also in real industrial process control applications, including building mechanical systems (Sakai and Ohkusa, 1985; Ono et al., 1989; Togai and Maski, 1991; Huang and Nelson, 1991; Meijer, 1992). The basic idea of this approach is to incorporate the experience of human operators in the design of controllers. From a set of linguistic rules describing operators' control strategies, a control algorithm can be constructed (Ralston and Ward, 1985).

Computer simulations and experiments have shown that FLCs may have better performance than those obtained by conventional controllers. In particular, FLCs appear very useful when the processes are too complex for analysis using conventional control algorithms or when the available information is qualitative, inexact, or uncertain. Thus, fuzzy logic control may be viewed as a compromise between conventional precise mathematical control and humanlike decision making, as indicated by Gupta (Gupta and Tsukamoto, 1980).

However, fuzzy logic controllers sometimes fail to obtain satisfactory results with the initial rule set drawn from the operators' experience. This is because there still are some differences between the way a plant is operated by an experienced operator and by an FLC using the rules based directly on his or her experience. It is often difficult to express human experience exactly using linguistic rules in a simple form. Sometimes there is no experience that could be used to construct control rules for FLCs. In these cases it is necessary to design, develop, and modify control rules for FLCs to obtain optimal performance. There have been few discussions about rule development and adjustment strategies for FLCs (Sheridah, 1984; Scharf and Mandic, 1985; Wakileh and Gill, 1988; Ollero and Williams, 1989).

The Basic Aspects of an FLC

An FLC includes three parts: fuzzifier, fuzzy reasoning unit, and defuzzifier. The fuzzifier converts ordinary inputs into their fuzzy counterparts, the fuzzy reasoning unit creates fuzzy control signals based on these fuzzy variables, and the defuzzifier converts the fuzzy control signals into the real control outputs. The block diagram of a fuzzy control system is shown in Figure 6.5.9, where e, d, and u are tracking error, derivative error, and output control action; $\tilde{e}$, $\tilde{d}$, and $\tilde{u}$ are their fuzzy counterparts, respectively; y is the controlled parameter; and r is the set point for y. K_p is the scale factor for e, K_d is the scale factor for d, and K_o is the output gain.

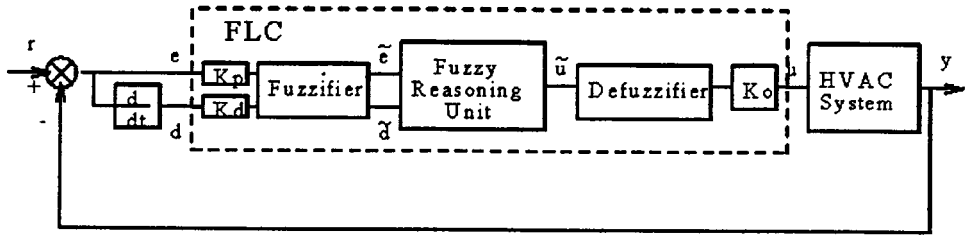

FIGURE 6.5.9 The block diagram of a fuzzy control system.

The control rules expressed in natural language are expressed in the following form:

IF (e is A) AND (d is B) THEN (u is C)

where A, B, and C are fuzzy subsets defined on the universes of discourse of e, d, and u, respectively. Every rule is interpreted into a fuzzy reasoning matrix:

$$R_k = \left[A_k(e) \otimes B_k(d)\right]^{\Theta} \otimes C_k(k) \qquad k = (1, N)$$

where N is the number of rules, the symbol $\otimes$ denotes aggregation operator, and the symbol Θ denotes an align-turning operator (see Section 19). The general fuzzy relation matrix R can be constructed as the union of the individual rules:

$$R = \bigcup_{k=1}^{N} R_k$$

This matrix represents the relationship between the fuzzy inputs and the fuzzy control output. The fuzzy control output can then be calculated from the known fuzzy input $\tilde{e}$ and $\tilde{d}$ by

$$\tilde{u} = \left[\tilde{e} \otimes \tilde{d}\right]^{\Theta} \circ R$$

where the symbol ° denotes the max-min composition operator (see Section 19).

The input universe of discourse for tracking error *e* or derivative error *d* is divided into several degrees connected with a number of fuzzy subsets by membership functions. In this study, *e* and *d* can each range from –6 to +6, and 13 degrees are used:

$$-6, -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, 6$$

Also, seven fuzzy subsets are defined as:

$$\text{NL, NM, NS, ZZ, PS, PM, PL.}$$

where the first letters N and P mean negative and positive, the second letters L, M, and S mean large, middle, and small, and ZZ means zero. These degrees and fuzzy subsets are shown in Table 6.5.1 which uses a 1.0–0.8–0.5–0.1 distribution. For example, if *e* = 3, then its membership in PL is 0.1, its membership in PM is 0.8, etc.

TABLE 6.5.1 The Membership Function of Input of an FLC

The fuzzifier converts ordinary inputs into their fuzzy counterparts. In this study, a fuzzy singleton is used as a fuzzification strategy, which interprets an input, *e* (or *d*), into a fuzzy value, $\tilde{e}$ (or $\tilde{d}$), with membership function (μ) equal to zero except at the element nearest to the real input, where μ = 1.0. For example, if *e* = 3.2, the nearest element is 3, then the fuzzy singleton will be

$$\tilde{d} = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 1,\ 0,\ 0,\ 0)$$

This fuzzy singleton has membership function $\mu = 1.0$ at the point of element $e = 3$. The defuzzifier converts the fuzzy control output created by the rule-based fuzzy reasoning unit into a real control action. In this study, weighted combination method is used as defuzzification strategy, which can be explained by the following example, if

$$\tilde{u} = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.4,\ 0.8,\ 0.7,\ 0.5,\ 0.1)$$

then

$$u = \left[0.2(1) + 0.4(2) + 0.8(3) + 0.7(4) + 0.5(5) + 0.1(6)\right] / \left[0.2 + 0.4 + 0.8 + 0.7 + 0.5 + 0.1\right] = 3.4$$

Rule Refinement. An FLC is characterized by a set of linguistic statements which are usually in the form of *if-then* rules. The initial set of rules is usually constructed based on the operators' experience, or sometimes by analyzing the dynamic process of the controlled plant. Both approaches require modifying the initial set of rules to obtain an optimal rule set. This is called *rule refinement.*

Figure 6.5.10 shows an initial rule set analyzed on a "linguistic plane". The horizontal axis expresses the fuzzy subsets defined on the universe of discourse for the tracking error (e), and the vertical axis expresses the fuzzy subsets defined on the universe of discourse for the derivative error (d). Both have seven fuzzy "values": NL, NM, NS, ZZ, PS, PM, PL. On the cross points of these fuzzy values there are output control action levels, which are also fuzzy subsets having seven "values" from Level 1 (TIny) to Level 7 (Very Strong). For example, the cross point of e = NM and d = PM indicates u = Level 3. This corresponds to the rule:

IF (e is NM) AND (d is PM) THEN (u is Level 3)

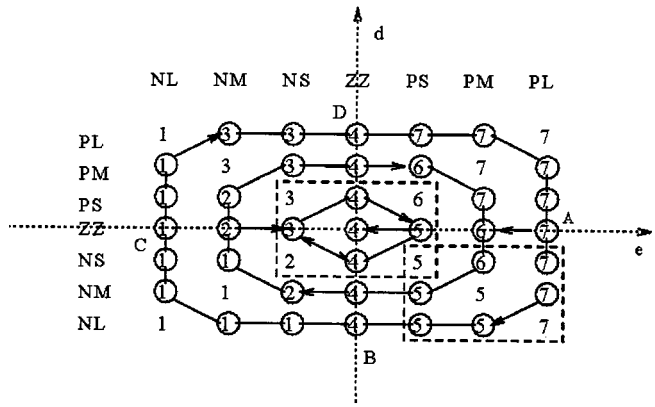

FIGURE 6.5.10 The initial rule set and performance trajectory on the linguistic plane.

For example, the initial rule set could be based on the following control strategies. First, it tries to keep a proportional relationship between the control action (u) and the tracking error (e). Note that if the derivative error (d) is ZZ, then the output control action (u) increases from Level 1 to Level 7 when the tracking error (e) changes from NL to PL. Second, the influence of derivative error (d) is considered such that, if it is positive, then increase the control action (u) a little bit, and if it is negative, then decrease the control action (u). For example, if the tracking error (e) keeps PM, the control action (u)

increases from Level 6 to Level 7 when the derivative error (*d*) is positive, and it decreases from Level 6 to Level 5 when the derivative error (*d*) is negative.

Consider a second-order plant with a transfer function:

$$H(s) = \frac{1.0}{s^2 + 0.1s + 1.0}$$

that is controlled using the initial rule set to respond to a step input for computer simulation. The performance trajectory of the FLC is shown by the arrows in Figure 6.5.10 and the dynamic process of the normalized controlled parameter (CP) is shown in Figure 6.5.11 where the horizontal axis indicates the number of sample period (SP). The dynamic process can be divided into two stages. At the first stage, there is a strong oscillation with a higher frequency, and, at the second stage, there is a moderate swing with a smaller frequency. Looking at the performance trajectory in the linguistic plane, we can see that the stronger oscillation occurs at the out-cycle (points further from the center). As time increases, the state moves to the in-cycle near the center of the plane and becomes moderate. This shows that FLCs have the desirable property of a structure-variable controller. The rules at the out-cycle belong to one kind of structure for the first stage, and the rules at the in-cycle belong to another structure for the second stage.

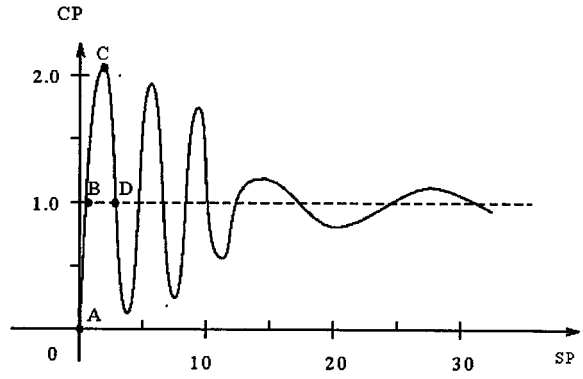

FIGURE 6.5.11 The dynamic process corresponding to Figure 6.5.10.

If the initial rule set does not satisfy a good design for a controller, then It can be modified by intuitive reasoning. A rule set is often symmetrically positioned about the central point, which is the desired stable operating point, where the tracking error (*e*) and the derivative error (*d*) both equal zero and the control action (*u*) is medium. When a positive step increase is imposed to the set point, the tracking error (*e*) has the biggest value and the derivative error (*d*) is zero at the beginning time (point A in the linguistic plane). With the regulating action, the tracking error (*e*) will decrease, the derivative error (*d*) will be negative, and the performance trajectory will enter into the right-bottom block in the linguistic plane. So, the rules in this area have the most important effect on the behavior of the first stage of the dynamic process. The most important area responsible for the behavior of the second stage is the central block.

To avoid strong oscillations, it is apparent that the control actions in the right-bottom block should be decreased. The modified rule set and its simulation of response to a step input are shown in Figure 6.5.12. The performance trajectory expressed in the linguistic plane is a spiral (Figure 6.5.12). We can see that the performance of the control system has been improved, but a small oscillation still exists and there is a little overshoot indicated by point C in Figures 6.5.12 to 6.5.13. Once again, the rule set is modified and the final rule set and its simulation of response to a step input are shown in Figure 6.5.14

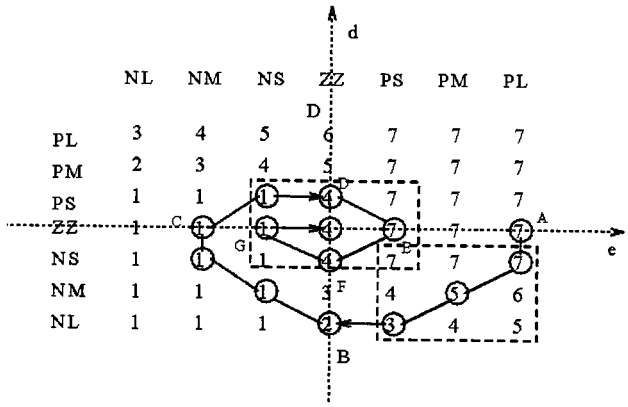

FIGURE 6.5.12 The second rule set on the linguistic plane.

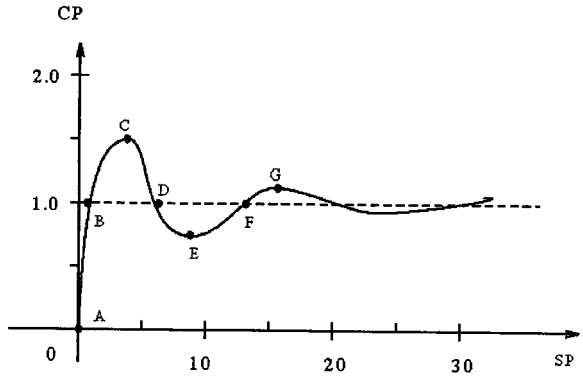

FIGURE 6.5.13 The dynamic process corresponding to Figure 6.5.12.

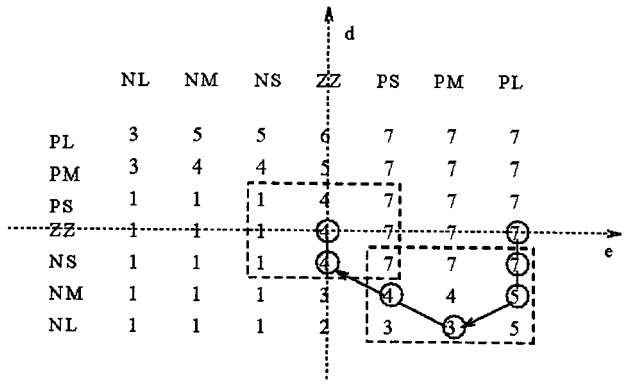

FIGURE 6.5.14 The third rule set on the linguistic plane.

and Figure 6.5.15. The final rule set gives good performance with a short rise time and a very small overshoot and it is considered satisfactory.

By analyzing the performance trajectory on the linguistic plane, a rule set is refined. It relies heavily on intuitive reasoning when comparing the dynamic process of the controlled parameter for the present rule set with the desired one.

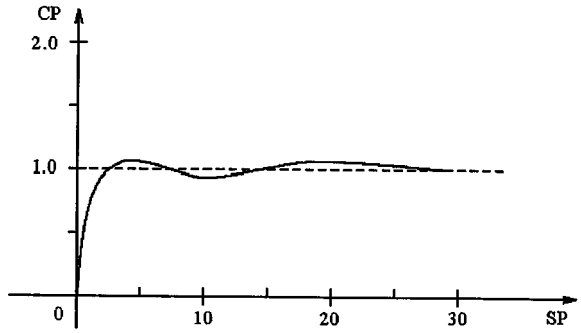

FIGURE 6.5.15 The dynamic process corresponding to Figure 6.5.14.

Completeness and Interaction of Rules and Selection of Membership Functions. The second significant influence on the behavior of an FLC is the membership functions. They should be chosen carefully in the adjustment process. As mentioned in Section 6.3, the fuzzy subsets, language variables NL, NM, NS, ZZ, PS, PM, and PL, are defined on the universe discourse of tracking error (e) or derivative error (d). Some possible membership functions are shown in Figures 6.5.16 to 6.5.18. The membership functions should be chosen to make these language variables have suitable coverage on the universe of discourse. For the case of Figure 6.5.16, the whole range is not covered by these language variables. There are some values of e or d, on which the membership functions of all language variables are zero. In this case, an empty output control action could be created. This means that the control actions are lost for those points which are not covered by any input fuzzy subset. This is referred as the non-completeness of control rules. FLCs should satisfy the condition of completeness for their membership functions. The membership function shown in Figure 6.5.17 cannot be used for an effective FLC. In other words, the union of all fuzzy subsets, X_i, i = [1,7], should be greater than zero for all $e \in E$, i.e.,

$$\forall e \in E \qquad \bigcup_{i=1}^{7} X_i(e) > 0$$

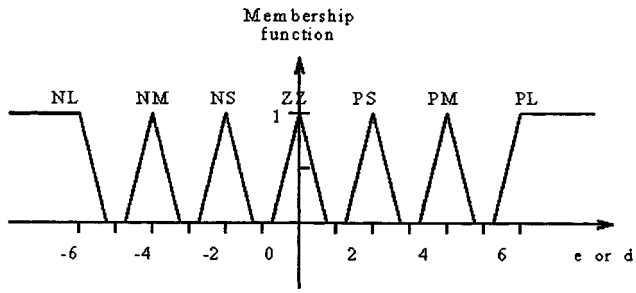

FIGURE 6.5.16 Non-complete membership function.

On the other hand, there can be interaction among the rules if the overlap of fuzzy subsets occurs on the range of the universe of discourse. In this case, the membership functions have the forms shown in Figures 6.5.17 and 6.5.18. The interaction tends to smooth out the set of control rules. Consider the single-input-single-output case for simplicity; the rule set is

IF (e is A_i) THEN (u is C_i) $\qquad i$ = [1,N]

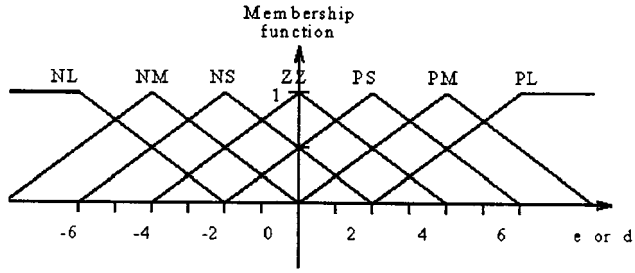

FIGURE 6.5.17 Heavy overlap membership function.

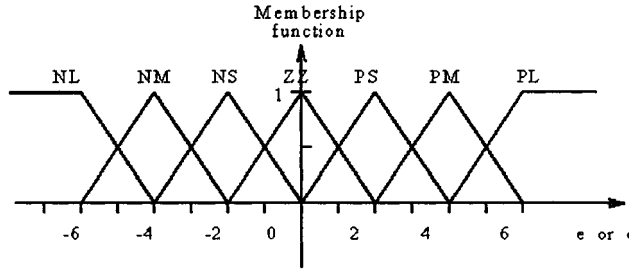

FIGURE 6.5.18 Moderate overlap membership function

where N is the number of rules in the set. These rules are incorporated into a fuzzy relation matrix as follows:

$$R = \bigcup_{i=1}^{N} R_i = \bigcup_{i=1}^{N} \left(A_i \otimes C_i\right)$$

If the fuzzy value of input e is known as $\tilde{e}$, the fuzzy output $\tilde{u}$ then can be calculated as follows:

$$\tilde{u} = \tilde{e} \circ R$$

If $\tilde{e}$ is A_i, $\tilde{u}$ is expected to be C_i. But now the interaction of rules due to overlap results in:

$$C_i \subseteq A_i \circ R$$

The equality is established only when no overlap occurs. This analysis is based on the fuzzy logic scheme including max-min composition operator. A more-detailed example of the numeric calculation is given in the appendices to this section.

If the overlap is heavy as shown in Figure 6.5.17, there will be large deformation and the control rules will lose their original shape. In the limit, as the membership functions become unity for all values, the output of the FLC will always be the same fuzzy quantity. This means that the fuzzy reasoning system conveys no valuable information and the FLC has lost its efficacy.

A moderate overlap, shown in Figure 6.5.18, is desirable to allow for reasoning with uncertainty and the need for completeness of the control rules. How does one determine the "size" of overlap? At present, we use intuitive judgment to choose membership functions when adjusting an FLC. There appears to be some latitude in choosing the amount of overlap, on which the performance of an FLC does not change significantly. The quantitative analysis will be given after further research.

When we modify the control rules in the linguistic plane, the overlapping membership functions let the rules near the performance trajectory have an effect on the output control actions. This is because interactions occur among the neighboring rules.

Scale Factors and Output Gain

The scale factors, K_p and K_d, and the output gain, K_o, shown in Figure 6.5.19, also have significant influence on the behavior of an FLC. Their influence is not as complicated as those of rules and membership functions. The adjustment for the scale factors and output gain is comparatively simple. The scale factor K_p relates the actual range of tracking error (e) to the universe of discourse (E) defined in the fuzzy logic system. In this work, E consists of 13 degrees as indicated in earlier sections. Then K_p is determined as the ratio of the range of E to the range of the real variable:

$$K_p = \frac{E_{\max} - E_{\min}}{e_{\max} - e_{\min}}$$

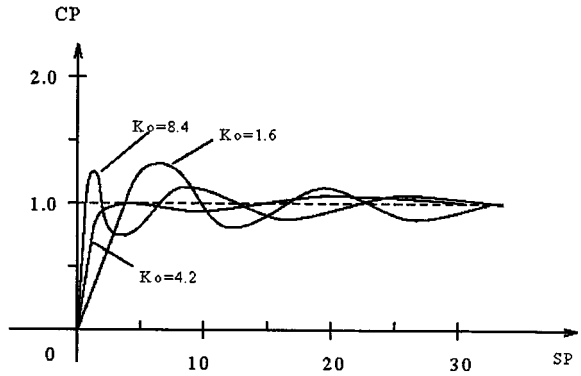

FIGURE 6.5.19 The influence of K_o on the behavior of FLCs.

For scale factor K_d, there is the similar analysis leading to

$$K_d = \frac{D_{\max} - D_{\min}}{d_{\max} - d_{\min}}$$

where D is the universe of discourse for derivative error (d) defined in the fuzzy logic system. Small K_p or K_d will narrow the control band, while large K_p or K_d will lead to loss of control for large inputs.

The output gain K_o is defined as follows:

$$K_o = \frac{u_{\max} - u_{\min}}{U_{\max} - U_{\min}}$$

It is the ratio of range of real output control action (u) to the range of its universe of discourse (U) defined in the fuzzy logic system. K_o acts as an amplification factor of the whole FLC. Figure 6.5.19 shows the influence of K_o on the step response simulation of an FLC with the final rule set used in Figure 6.5.14. Increasing K_o results in a shorter rise time. The performance trajectory in the linguistic plane will become steeper for the first stage and oscillation occurs. Decreasing K_o results in a longer rise time, and the performance trajectory in the linguistic plane will become moderate during the first stage. But, in our simulation, oscillation still occurred. This is because different K_o, larger or smaller, results in a new route of the performance trajectory which will activate the different rules which might

cause oscillation. So the influence of output gain, K_o, should be considered together with the change of the activated rules.

Conclusion

An FLC can perform much better than a conventional controller, such as a PID controller, if the FLC has been well constructed. The main disadvantage of using FLCs today seems to be the lack of a systematic procedure for the design of FLCs. The general method for designing an FLC is to use trial and observation. No useful mathematical tool has yet been developed for the design of an FLC because of its fuzziness, complexity, and nonparameterization.

There are three significant elements that have notable influence on the behavior of an FLC:

1. The control rules expressed in linguistic language,
2. The membership functions defined for fuzzy subsets, and
3. The scale factors attached to the input and the output gains.

The control rules play the main role in forming the dynamics of FLCs. The rule set can be analyzed and modified using the performance trajectory technique and evaluated using the dynamic process curve of the controlled parameter. The membership functions define the "shape" of fuzzy subsets. They should have appropriate width to avoid noncompleteness and suitable interaction among the fuzzy control rules. The scale factors (K_p and K_d) and output gain (K_o) serve as amplification factors.

At present, each application must be individually designed. The initial sets of rules are specifically set up for different applications. Work is now underway to develop a self-adaptive FLC which will choose the initial set of rules automatically according to the process dynamics and refine it on the basis of the global performance evaluation.

Appendices

Table of Transforms

The following table lists some of the more common transforms used in the analysis of building systems. More-extensive tables can be found in most mathematics and numerical analysis reference books.

List of Some *s*- and *z*-Transforms

Continous-Time Domain	Frequency Domain	Discrete-Time Domain
$1\ t=0 \quad 0\ t\neq 0$	—	1
$1\ t=k \quad 0\ t\neq k$	—	z^{-k}
1	$\frac{1}{s}$	$\frac{z}{z-1}$
t	$\frac{1}{s^2}$	$\frac{Tz}{(z-1)^2}$
e^{-at}	$\frac{1}{s+a}$	$\frac{z}{z-e^{-aT}}$
te^{-at}	$\frac{1}{(s+a)^2}$	$\frac{Tze^{-aT}}{\left(z-e^{-aT}\right)^2}$
$1-e^{-at}$	$\frac{a}{s(s+a)}$	$\frac{z\left(1-e^{-aT}\right)}{(z-1)\left(z-e^{-aT}\right)}$
$e^{-at}-e^{-bt}$	$\frac{b-a}{(s+a)(s+b)}$	$\frac{z\left(e^{-aT}-e^{-bT}\right)}{\left(z-e^{-aT}\right)\left(z-e^{-bT}\right)}$

Special FLC Mathematical Operations

- $\otimes$ aggregation operator
- Θ align-turning operator
- $\circ$ max-min composition operator
- $\bigcup$ union operator
- $\exists$ exists
- $\in$ in
- $\forall$ for all
- $\subseteq$ is the subset of

The aggregation operator ($\otimes$) is used to define a two-dimensional fuzzy variable F from fuzzy subsets A and B (one-dimensional fuzzy variables) as follows:

$$F = A(e) \otimes B(d) = \begin{bmatrix} \mu_F(1,1) & \cdots & \cdots & \cdots & \mu_F(1,N) \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \mu_F(i,j) & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \mu_F(M,1) & \cdots & \cdots & \cdots & \mu_F(M,N) \end{bmatrix}$$

where

$$\mu_F(i,j) = \min\left(\mu_A(i), \mu_B(j)\right)$$

$$A(e) = \left(e_i, \mu_A(i)\right)$$

$$B(d) = \left(d_j, \mu_B(j)\right)$$

e_i is the ith element of the subset $A(e)$ and $\mu_A(i)$ is its membership function; d_j is the jth element of the subset $B(d)$ and $\mu_B(j)$ is its membership function.

The align-turning operator (Θ) is an operator acting on a two-dimensional fuzzy variable to create a one-dimensional fuzzy variable, which has a set of membership functions aligned according to a certain order, as follows:

$$\begin{aligned} S &= \left[A \otimes B\right]^{\Theta} \\ &= \left(\mu_S(1,1), \mu_S(1,2), \ldots, \mu_S(i,j), \ldots, \mu_S(M,N)\right) \end{aligned}$$

where j varies from 1 to N first and i varies from 1 to M.

An Example of Numeric Calculation for Influence of Membership Function

Suppose that there are two rules:

R1: IF (e is PM) THEN (u is VS) and

R2: IF (e is PS) THEN (u is ST).

For the first rule,

$$\tilde{e}_1 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5)$$

$$\tilde{u}_1 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0)$$

Then the rule can be interpreted into a fuzzy reasoning matrix as follows:

$$R_1 = \tilde{e}_1 \otimes \tilde{u}_1$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5
\end{bmatrix}$$

$$\equiv \mu_{R_1}(i, j)$$

where the membership in R_1 for the element (i,j) of the matrix, $\mu_{R_1}(i, j)$ is

$$\mu_{R_1}(i, j) = \min\left(\mu_{\tilde{e}_1}(i), \mu_{\tilde{u}_1}(j)\right)$$

For the second rule,

$$\tilde{e}_2 = (0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5,\ 0.1,\ 0)$$

$$\tilde{u}_2 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0,\ 0.7,\ 0.2)$$

Then the second rule can be interpreted into a fuzzy reasoning matrix as follows:

$$R_2 = \tilde{e}_2 \otimes \tilde{u}_2$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}$$

$$\equiv \mu_{R_2}(i,j)$$

where the membership in R_2 for the element (i,j) of the matrix, $\mu_{R_2}(i,j)$ is

$$\mu_{R_2}(i,j) = \min\left(\mu_{\tilde{e}_2}(i), \mu_{\tilde{u}_2}(j)\right)$$

The general fuzzy relation matrix R is then constructed as the union of these two rules:

$$R_2 = R_1 \cup R_2$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.5 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.7 & 1.0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5
\end{bmatrix}$$

$$\equiv \mu_R(i,j)$$

where

$$\mu_R(i,j) = \max\left(\mu_{R_1}(i), \mu_{R_2}(j)\right)$$

Assume that there is an input (e) and its fuzzy value $\tilde{e}$ = PM, then the output is expected to be VS according to the first rule. But now the output is calculated through the fuzzy matrix R as follows:

$$\begin{aligned}\tilde{u} &= \tilde{e} \circ R \\ &= \text{PM} \circ R \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5) \circ R \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 0.8,\ 0.7,\ 1.0)\end{aligned}$$

where

$$\mu_{\tilde{u}}(j) = \max_i\left(\min\left(\mu_{\tilde{e}}(i), \mu_R(i,j)\right)\right)$$

While

$$\begin{aligned}\tilde{u}_1 &= \text{VS} \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0)\end{aligned}$$

So,

$$\tilde{u}_1 \subseteq \tilde{u}$$

This chapter describes the primary as well as derived energy sources. The objective is to provide information on the extent, availability, measurements and estimation, properties, and limitations of each type of resource. These considerations are important for an engineer to know and understand before attempting selection and design of an energy conversion system. The chapter also includes environmental impacts of energy resources since the environmental aspects are expected to play a major role in the selection of energy resources. In addition, there is a brief discussion of the costs associated with each resource to help in the economic analysis and comparison the resources.

The chapter starts with an introduction and background of a historical perspective on energy use and projections of the future energy needs in the U.S., the industrialized countries, and the world. The primary energy sources described in this chapter include fossil fuels such as coal, natural gas, petroleum (including their synthetic derivatives), biomass (including refuse-derived biomass fuels), nuclear, solar radiation, wind, geothermal, and ocean. In addition there is a brief section on derived energy sources including electricity. So, the terminology and units used for each energy resource and their equivalence are provided.

7.1 Introduction

D. Yogi Goswami

Global energy consumption in the last 50 years has increased at a very rapid rate. Present trends in global population growth, rapid industrialization, and urbanization in major population centers of the world suggest that the world energy demand will continue to increase in the next 50 years (U.S. DOE, 1991). Figure 7.1.1 shows the historical and projected world energy consumption compiled by the Energy Information Agency.

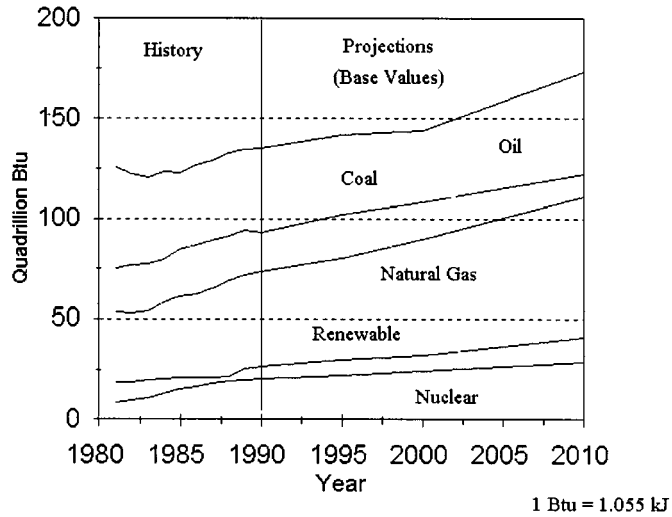

FIGURE 7.1.1 Historical and projected energy consumption. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C.)

The energy resources available to furfill the world demand include

Fossil fuels (oil, coal, natural gas)
Nuclear fuels
Geothermal
Solar radiation
Hydropower

Biomass (crops, wood, municipal solid waste)
Wind
Ocean

Out of all the energy resources, fossil fuels have been used the most (88% of total consumption) because of their extremely high energy densities and simplicity of conversion and use. Figure 7.1.2 shows the world energy production by resource.

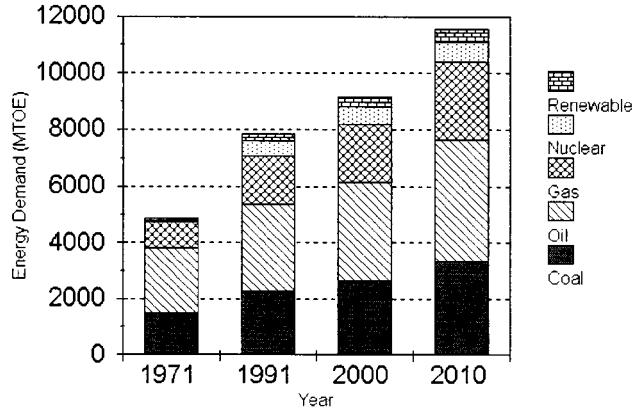

FIGURE 7.1.2 World energy production by resource. (From EIA. *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

Recent concerns about the environment are expected to increase the use of natural gas for power production. Renewable energy resources, such as solar energy, wind, and biomass, are also expected to increase their share of the energy use. There is a strong sentiment in the world in favor of exploiting renewable energy resources, especially because of environmental concerns. How far that sentiment translates into practical use will depend on the development of the renewable energy technologies and prices of the fossil fuels.

Defining Terms

MTOE: Mega tons of oil equivalent; 1 MTOE = 42.63×10^{12} Btu.
Quadrillion Btu: 10^{15} British thermal units (Btu), also known as Quad; 1 Btu = 1055 joules).

7.2 Types of Derived Energy

D. Yogi Goswami

Energy from renewable and nonrenewable fuels can be converted to the derived energy forms — thermal, mechanical, and electrical, which are useful for various end uses such as transportation, buildings (heating, cooling, lighting), agricultural, and industrial end uses. The derived energy forms are easily transformed from one type to the other. Figure 7.2.1 shows the projected U.S. energy use by end-use sector.

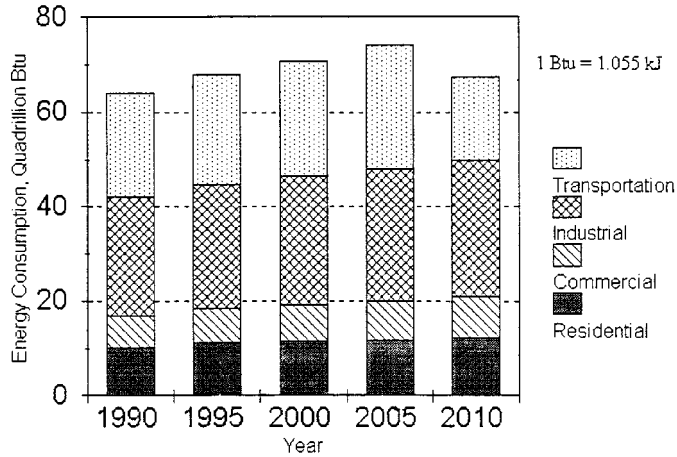

FIGURE 7.2.1 Projected U.S. energy use by end-use sector. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C., 1992.)

Transportation is mainly dependent on oil resources. Efforts to reduce urban air pollution are expected to increase the use of electricity as the preferred energy form for urban transportation. For most of the other end uses electricity will continue to be the preferred energy form. Therefore, it is important to understand the activity in the area of electricity production. Figure 7.2.2 shows the world installed electricity generation capacity by primary energy sources. The United States produces 700 GW (gigawatts or 10^9 W), representing more than 25% of the world electricity capacity. Other major electricity producers are Russia, Europe, Japan, and China. It is expected that China, India, and Southeast Asian countries will add major electricity capacity in the next 20 years.

Integrated resource planning (IRP), or least-cost planning, is the process used to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be attributed to the resource. IRP examines all of the options, including the demand-side options, to minimize the total costs. There is considerable emphasis on IRP in a number of states in United States for future electric capacity and on **demand-side management** (DSM) for the current capacity (Kreith and Burmeister, 1993). The IRP process generally includes some combination of the following steps (Kreith and Burmeister, 1993): development of a load forecast; inventory of existing resources; identification of additional electrical capacity needs; demand-side management programs; screening and identification of options that are feasible; uncertainty analysis in view of uncertainty of future load, fuel prices, capital costs, etc; and selection of a resource or a mix of resources.

Demand Side Management DSM refers to a mix of electrical utility-sponsored custom incentives and disincentives that influence the amount and timing of customer demand in order to better utilize the available resources. Kreith and Burmeister (1993) and SERI (1991) list a number of DSM strategies.

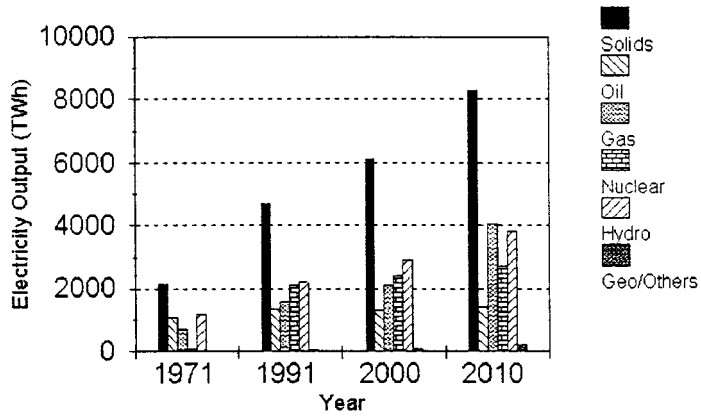

FIGURE 7.2.2 World electricity output. (From EIA, *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

Defining Terms

Demand-side management (DSM): Refers to a mix of incentives and disincentives that influence the amount and timing of energy use in order to better utilize the available resources.

Integrated resource planning (IRP): The process to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be all attributed to the resource.

7.3 Fossil Fuels

Coal

Robert Reuther

Coal Composition and Classification

Coal is a sedimentary rock formed by the accumulation and decay of organic substances derived from plant tissues and exudates that have been buried over periods of geological time along with various mineral inclusions. Coal is classified by **type and rank.** Coal type classifies coal by the plant sources from which it was derived. Coal rank classifies coal by its degree of metamorphosis from the original plant sources and is therefore a measure of the age of the coal. The process of metamorphosis or aging is termed **coalification.**

The study of coal by type is known as coal petrography. Coal type is determined from the examination of polished sections of a coal sample using a reflected-light microscope. The degree of reflectance and color of a sample are identified with specific residues of the original plant tissues. These various residues are referred to as **macerals.** Macerals are collected into three main groups: vitrinite, inertinite, and exinite (sometimes referred to as liptinite). The maceral groups and their associated macerals are listed in Table 7.3.1 along with a description of the plant tissue from which each distinct maceral type is derived.

TABLE 7.3.1 Coal Maceral Groups and Macerals

Maceral Group	Maceral	Derivation
Vitrinite	Collinite	Humic gels
	Telinite	Wood, bark, and cortical tissue
	Pseudovitrinite	? (Some observors place in the inertinite group)
Exinite	Sporinite	Fungal and other spores
	Cutinite	Leaf cuticles
	Resinite	Resin bodies and waxes
	Alginite	Algal remains
Inertinite	Micrinite	Unspecified detrital matter, <10 μm
	Macrinite	Unspecified detrital matter, 10–100 μm
	Semifusinite	“Burned” woody tissue, low reflectance
	Fusinite	“Burned” woody tissue, high reflectance
	Sclerotinite	Fungal sclerotia and mycelia

Modified from Berkowitz, N., *An Introduction to Coal Technology.* Academic Press, New York, 1979.

Coal rank is the most important property of coal, since it is rank which initiates the classification of coal for use. Rank is a measure of the age or degree of coalification of coal. Coalification describes the process which the buried organic matter goes through to become coal. When first buried, the organic matter has a certain elemental composition and organic structure. However, as the material becomes subjected to heat and pressure, the composition and structure slowly change. Certain structures are broken down, and others are formed. Some elements are lost through volatilization while others are concentrated through a number of processes, including being exposed to underground flows which carry away some elements and deposit others. Coalification changes the values of various properties of coal. Thus, coal can be classified by rank through the measurement of one or more of these changing properties.

In the United States and Canada, the rank classification scheme defined by the American Society of Testing and Materials (ASTM) has become the standard. In this scheme, the properties of **gross calorific value** and **fixed carbon** or **volatile matter content** are used to classify a coal by rank. Gross calorific value is a measure of the energy content of the coal and is usually expressed m units of energy per unit mass. Calorific value increases as the coal proceeds through coalification. Fixed carbon content is a measure of the mass remaining after heating a dry coal sample under conditions specified by the ASTM.

Fixed carbon content increases with coalification. The conditions specified for the measurement of fixed carbon content result in being able alternatively to use the volatile matter content of the coal measured under dry, ash-free conditions as a rank parameter. The rank of a coal proceeds from lignite, the "youngest" coal, through subbituminous, bituminous, and semibituminous, to anthracite, the "oldest" coal. There exist subdivisions within these rank categories which are defined in Table 7.3.2. (Some rank schemes include meta-anthracite as a rank above, or "older" than, anthracite. Others prefer to classify such deposits as graphite. Graphite is a minimal resource and is valuable primarily for uses other than as a fuel.) According to the ASTM scheme, coals are ranked by calorific value up to the high volatile A bituminous rank, which includes coals with calorific values (measured on a moist, mineral matter-free basis) greater than 14,000 Btu/lb (32,564 kJ/kg). At this point, fixed carbon content (measured on a dry, mineral matter-free basis) takes over as the rank parameter. Thus, a high volatile A bituminous coal is defined as having a calorific value greater than 14,000 Btu/lb, but a fixed carbon content less than 69 wt%. The requirement for having two different properties with which to define rank arises because calorific value increases significantly through the lower-rank coals, but very little (in a relative sense) in the higher-ranks, whereas fixed carbon content has a wider range in higher-rank coals, but little (relative) change in the lower-ranks. The most widely used classification scheme outside of North America is that developed under the jurisdiction of the International Standards Organization, Technical Committee 27, Solid Mineral Fuels.

Coal Analysis

The composition of a coal is typically reported in terms of its **proximate analysis** and its **ultimate analysis.** The proximate analysis of a coal is made up of four constituents: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The measurement of these four properties of a coal must be carried out according to strict specifications codified by the ASTM.

Volatile matter in coal includes carbon dioxide, inorganic sulfur- and nitrogen-containing species, and organic compounds. The percentage of various species present depends on rank. Volatile matter content can typically be reported on a number of bases, such as moist; dry, mineral matter-free (dmmf); moist, mineral matter-free; moist, ash-free; and dry, ash-free (daf); depending on the condition of the coal on which measurements were made.

Mineral matter and ash are two distinct entities. Coal does not contain ash, even though the ash content of a coal is reported as part of its proximate analysis. Instead, coal contains mineral matter, which can be present both as distinct mineral entities or inclusions and intimately bound with the organic matrix of the coal. Ash, on the other hand, refers to the solid inorganic material remaining *after combusting* a coal sample. Proximate ash content is the ash remaining after the coal has been exposed to air under specific conditions (ASTM Standard Test Method D 3174). It is reported as the mass percent remaining upon combustion of the original sample on either a dry or moist basis.

Moisture content refers to the mass of water which is released from the solid coal sample when it is heated under specific conditions of temperature and residence time as codified in ASTM Standard Test Method D 3173.

The fixed carbon content refers to the mass of organic matter remaining in the sample after the moisture and volatile matter are released. It is primarily made up of carbon with lesser amounts of hydrogen, sulfur, and nitrogen also present. It is typically reported by difference from the total of the volatile matter, ash, and moisture contents on a mass percent of the original coal sample basis. Alternatively, it can be reported on a dry basis; a dmmf basis; or a moist, mineral matter-free basis.

The values associated with the proximate analysis vary with rank. In general, volatile matter content decreases with increasing rank, while fixed carbon content correspondingly increases. Moisture and ash also decrease, in general, with rank. Typical values for proximate analysis as a function of the rank of a coal are provided in Table 7.3.3.

The ultimate analysis of a coal reports the composition of the organic fraction of coal on an elemental basis. Like the proximate analysis, the ultimate analysis can be reported on a moist or dry basis and on

TABLE 7.3.2 Classification of Coals by Rank

Class	Group	Fixed Carbon Limits, % (dmmf)		Volatile Matter limits, % (dmmf)		Gross Calorific Value Limits, Btu/lb (moist, mmf)		Agglomerating Character
		Equal or Greater Than	Less Than	Greater Than	Equal or Less Than	Equal or Greater Than	Less Than	
Anthracitic	Meta-anthracite	98	—	—	2	—	—	Nonagglomerating
	Anthracite	92	98	2	8	—	—	Nonagglomerating
	Semianthracite	86	92	8	14	—	—	Nonagglomerating

an ash-containing or ash-free basis. The moisture and ash reported in the ultimate analyis are found from the corresponding proximate analysis. Nearly every element on Earth can be found in coal. However, the important elements which occur in the organic fraction are limited to a few. The most important of these include carbon, hydrogen, oxygen, sulfur, nitrogen, and, sometimes, chlorine. The scope, definition of the ultimate analysis, designation of applicable standards, and calculations for reporting results on different moisture bases can be found in ASTM Standard Test Method D 3176M. Typical values for the ultimate analysis for various ranks of coal found in the United States are provided in Table 7.3.4.

Coal Properties

Other important properties of coal include swelling, caking, and coking behavior; ash fusibility; reactivity; and calorific value.

Calorific value measures the energy available in a unit mass of coal sample. It is measured by ASTM Standard Test Method D 201 5M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. In the absence of a directly measured value, the gross calorific value, Q, of a coal (in Btu/lb) can be estimated using the Dulong formula (Elliott and Yohe, 1981):

$$Q = 14,544\text{C} + 62,028\left[\text{H} - (\text{O}/8)\right] + 4,050\text{S}$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur, respectively, obtained from the ultimate analysis.

Swelling, caking, and coking all refer to the property of certain bituminous coals, when slowly heated in an inert atmosphere to between 450 and 550 or 600°F, to change in size, composition, and, notably, strength. Under such conditions, the coal sample initially becomes soft and partially devolatilizes. With further heating, the sample takes on a fluid characteristic. During this fluid phase, further devolatilization causes the sample to swell. Still further heating results in the formation of a stable, porous, solid material with high strength. There are several tests which have been developed based on this property to measure the degree and suitability of a coal for various processes. Some of the more popular are the free swelling index (ASTM Test Method D 720), the Gray-King assay test (initially developed and extensively used in Great Britain), and the Gieseler plastometer test (ASTM Test Method D 2639), as well as a whole host of dilatometric methods (Habermehl et al., 1981). The results of these tests are often correlated with the ability of a coal to form a coke suitable for iron making. In the iron-making process, the high carbon content and high surface area of the coke are utilized to reduce iron oxide to elemental iron. The solid coke must also be strong enough to provide the structural matrix upon which the reactions take place. Bituminous coals which have good coking properties are often referred to as metallurgical coals. (Bituminous coals which do not have this property are, alternatively, referred to as steam coals because of their historically important use in raising steam for motive power or electricity generation.)

Ash fusibility is another important property of coals. This is a measure of the temperature range over which the mineral matter in the coal begins to soften and eventually to melt into a slag and to fuse together. This phenomenon is important in combustion processes; it determines if and at what point the resultant ash becomes soft enough to stick to heat exchanger tubes and other boiler surfaces or at what temperature it becomes molten so that it flows (as slag), making removal as a liquid from the bottom of a combustor possible.

Reactivity of a coal is a very important property fundamental to all coal conversion processes (the most important of which are combustion, gasification, and liquefaction). In general, lower-rank coals are more reactive than higher-rank coals. This is due to several different characteristics of coals, which vary with rank as well as with type. The most important characteristics are the surface area of the coal, its chemical composition, and the presence of certain minerals which can act as catalysts in the conversion reactions. The larger surface area present in lower-rank coals translates into a greater degree of penetration of gaseous reactant molecules into the interior of a coal particle. Lower-rank coals have a less aromatic structure than higher-rank coals, which, along with contributing to larger surface area, also corresponds to a higher proportion of lower-energy, more-reactive chemical bonds. Lower-rank coals also tend to have higher proximate ash contents, and the associated mineral matter is more distributed — down to the atomic level. Any catalytically active mineral matter is thus more highly dispersed, also. However, the reactivity of a coal also varies depending upon what conversion is being attempted. That is, the reactivity of a coal toward combustion (oxidation) is not the same as its reactivity toward liquefaction, and the order of reactivity established in a series of coals for one conversion process will not necessarily be the same as for another process.

Coal Reserves

Coal is found throughout the United States and the world. It is the most abundant fossil energy resource in the United States and in the world. It comprises 95% of United States fossil energy resources and

70% of world fossil energy resources on an energy content basis. All coal ranks can be found in the continental United States. The largest resources in the United States are made up of lignite and subbituminous coals, which are found primarily in the western United States and Alaska. Bituminous coals are found principally in the Midwest, northern Alaska, and the Appalachian region. Principal deposits of anthracite coal are found in northeastern Pennsylvania. The Alaskan coals have not been extensively mined because of their remoteness and the harsh climate. Of the other indigenous coal resources, the anthracite coals have been extensively mined to where there is little economic resource left; the bituminous coals are being heavily mined in the lower 48 states, especially those with low sulfur contents (less than 2.5 wt%); and the low-rank coals in the West have historically been less heavily mined because of their low calorific value, high moisture and ash contents, and their distance from large markets, although with the enactment of the 1990 Amendments to the Clean Air Act of 1970, these coals are replacing high-sulfur Eastern coals in the marketplace. A map showing the general distribution of coal in the lower 48 states is included as Figure 7.3.1.

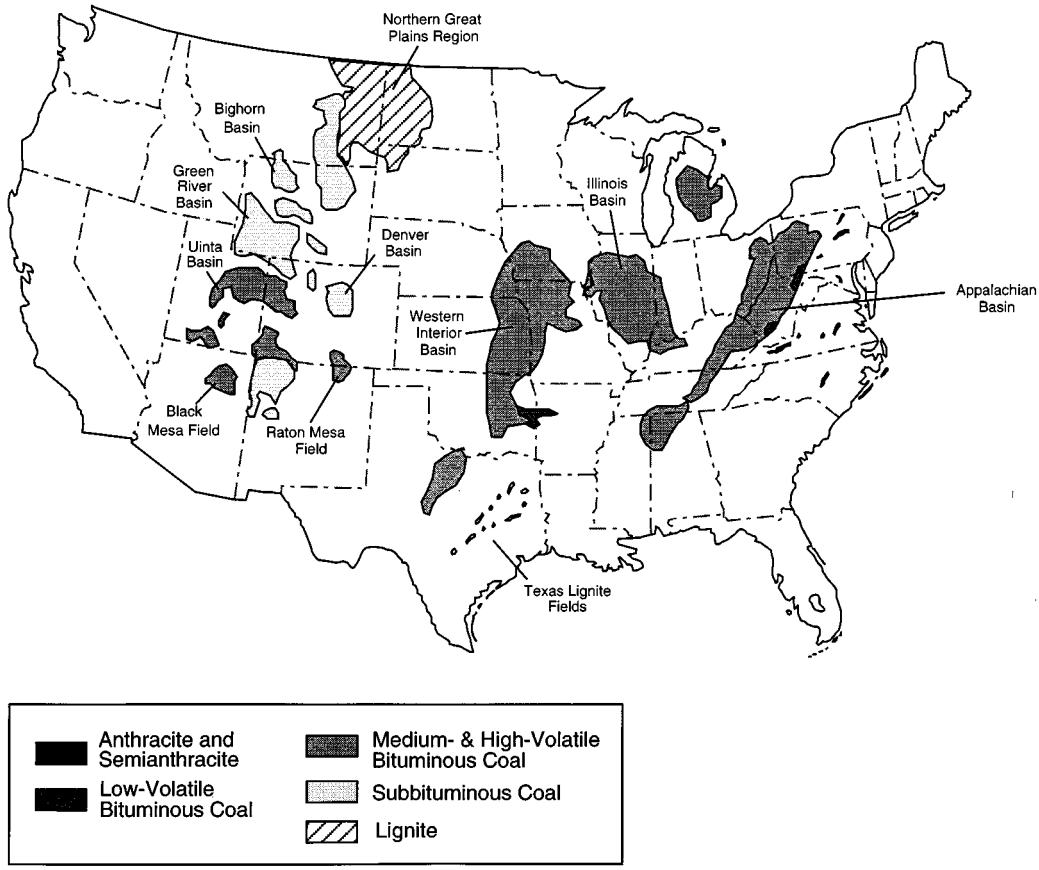

FIGURE 7.3.1 Coal fields of the conterminous (From Averitt, P., Coal Resources of the United States, January 1, 1974. U.S. Geological Survey Bulletin 1412, Government Printing Office, Washington, D.C., 1975.)

The amount of coal (or, for that matter, any minable resource) that exists is not known exactly and is continually changing as old deposits are mined out and new deposits are discovered or reclassified. Estimates are published by many different groups throughout the world. In the United States, the Energy Information Administration, an office within the U.S. Department of Energy, gathers and publishes estimates from various sources, including the World Energy Council and British Petroleum, Ltd. These

latter groups subscribe to a set of definitions for classifying the estimates which are acknowledged both in the United States and the United Kingdom. The most commonly used terms are defined below (as taken from Averitt, (1981):

Resources: The total quantity of coal in the ground within specified limits of thickness of bed overburden. The thickness of overburden defining this term varies from region to region in the world.

Hypothetical Resources: The quantity of coal estimated to be in the ground in unmapped and unexplored parts of known coal basins to an overburden depth of 6000 ft; determined by extrapolation from the nearest areas of identified resources.

Identified Resources: The quantity of coal in the measured, indicated, and inferred resource categories.

Measured Resources: The quantity of coal in the ground based on assured coal bed correlations and on observations spaced about 0.5 mi apart.

Indicated Resources: The quantity of coal in the ground based partly on specific observations and partly on reasonable geological projections; the points of observation and measurement are about 1 mi apart but may be 1.5 mi apart for beds of known continuity.

Inferred Resources: The quantity of coal in the ground based on continuity of coal beds downdip from and adjoining areas containing measured and indicated resources. Generally, inferred resources lie 2 mi or more from outcrops or from points of more precise information.

Demonstrated Reserve Base: The quantity of coal in the ground in the measured and indicated resources categories; restricted primarily to coal in thick and intermediate beds less than 1000 ft below the surface and deemed to be economically and legally available for mining.

Reserves, or Recoverable Reserves: The quantity of coal in the ground that can be recovered from the demonstrated reserve base by application of the recoverability factor.

Recoverability Factor: The percentage of coal in the demonstrated reserve base that can be recovered by established mining practices.

The demonstrated reserve base for coals in the United States as of January 1, 1993, is approximately 474.1 billion (short) tons. It is broken out by rank, state, and mining method (surface or underground) in Table 7.3.5. As of December 31, 1990 (December 30, 1991, for the United States), the world recoverable reserves are estimated to be 1145 billion (short) tons. A breakdown by region and country is provided in Table 7.3.6. The recoverability factor for all coals can vary from approximately 40% to over 90% depending on the individual deposit. The recoverable reserves in the United States represent approximately 56% of the demonstrated reserve base. Thus, the United States contains (by weight) approximately 23% of the recoverable reserves of coal in the world.

Environmental Aspects

Richard Bajura

Along with coal production and use comes a myriad of potential environmental problems, most of which can be ameliorated or effectively addressed during recovery, processing, conversion, or reclamation.

Underground coal reserves are recovered using the two principal methods of room-and-pillar mining (60%) and longwall mining (40%). In room-and-pillar mining, coal is removed from the seam in a checkerboard pattern (the “room”) as viewed from above, leaving pillars of coal in an alternate pattern to support the roof of the mine. When using this technology, generally half of the reserves are left underground. Depending upon the depth of the seam and characteristics of the overburden, subsidence due to the removal of the coal may affect the surface many years after the mining operation is completed. Because of the danger of collapse and movement of the surface, undermined lands are not used as building sites for large, heavy structures.

Longwall mining techniques employ the near-continuous removal of coal in rectangular blocks with a vertical cross section equal to the height of the seam multiplied by the horizontal extent (width) of the panel being mined. As the longwall cutting heads advance into the coal seam, the equipment is

[1] See Note 3 at end of Section.
[2] U.S. data are more current than other data on this table. They represent recoverable reserves as of December 31, 1991; data for the other countries are as of December 31, 1990, the most recent period for which they are available. U.S. reserves represent both measured and indicated tonnage. The U.S. term "measured" approximates the term "proved," which is used by the World Energy Council and British Petroleum. The U.S. "measured and indicated" data have been combined prior to depletion adjustments and cannot be recaptured as "measured alone."

— = Not applicable.

Notes: The EIA does not certify the international reserves data but reproduces the information as a matter of convenience for the reader.

Totals may not equal sum of components due to independent rounding.

Source: EIA, *International Energy Annual 1992* (January 1994), Table 37.

automatically moved forward. The roof of the mine collapses behind the shields, and most of the effects of subsidence are observed on the surface within several days of mining. If the longwall mining operation proceeds in a continuous fashion, subsidence may occur smoothly so that little damage occurs to surface structures. Once subsidence has occurred, the surface remains stable into the future. Longwall mining operations may influence water supplies as a result of fracturing of water-bearing strata far removed from the panel being mined.

When coal occurs in layers containing quartz dispersed in the seam or in the overburden, miners are at risk of being exposed to airborne silica dust, which is inhaled into their lungs. Coal workers pneumonoconiosis, commonly called black lung disease, reduces the ability of a miner to breathe because of the effects of fibrosis in the lungs.

Surface mining of coal seams requires the removal of large amounts of overburden, which must eventually be replaced into the excavated pit after the coal resource is extracted. When the overburden contains large amounts of pyrite, exposure to air and water produces a discharge known as acid mine drainage, which can contaminate streams and waterways. Iron compounds formed as a result of the chemical reactions precipitate in the streams and leave a yellow- or orange-colored coating on rocks and gravel in the streambeds. The acid caused by the sulfur in the pyrite has been responsible for significant destruction of aquatic plants and animals. New technologies have been and continue to be developed to neutralize acid mine drainage through amendments applied to the soil during the reclamation phases of the mining operation. Occasionally, closed underground mines fill with water and sufficient pressure is created to cause “blowouts” where the seams reach the surface. Such discharges have also been responsible for massive fish kills in receiving streams.

The potential for acid rain deposition from sulfur and nitrogen oxides released to the atmosphere during combustion is a significant concern. About 95% of the sulfur oxide compounds can be removed through efficient stack gas cleaning processes such as wet and dry scrubbing. Also, techniques are available for removing much of the sulfur from the coal prior to combustion. Combustion strategies are also being developed which reduce the formation and subsequent release of nitrogen oxides.

The potential for greenhouse warming due to emissions of carbon dioxide during combustion (as well as methane during mining and mine reclamation) has also been raised as a significant concern. Since coal is largely composed of carbon with relatively little hydrogen, its combustion leads to a higher level of carbon dioxide emissions per unit of energy released than for petroleum-based fuels or natural gas.

Transportation

Larry Grayson

According to figures compiled by the United States Department of Energy’s Energy Information Administration (Coleman, 1994), 878 million (short) tons of coal were distributed domestically in 1993, primarily via rail (59.6%), followed by barge (13.9%), truck (13.2%), and conveyor and slurry pipeline (10.8%). Shipments to electric utilities amounted to 773.5 million (short) tons during the same year, with 61.5% transported by rail, followed by 14.0% by barge, 11.7% by truck, and 11.0% by conveyor and slurry pipeline.

Villagran (1989) compared the cost advantage of barge transportation over rail transportation. For distances between 100 and 300 mi, the advantage is between $11 and 38/kilo ton-mi; while the advantage drops to $7 to 11/kilo ton-mi for distances greater than 300 mi. For distances less than 100 mi, rail hauls are very expensive, leading to the predominance of truck haulage in this range when river transportation is not possible.

Defining Terms:

Coalification: The physicochemical transformation which coal undergoes after being buried and subjected to elevated temperature and pressure. The classification of a particular coal by rank is a measure of the extent of its coalification. Thus, coalification is a measure of the “age” of a particular coal.

Fixed carbon content: Fixed carbon content is one of the constituents which make up the proximate analysis of a coal. It is normally measured by difference. That is, one measures the volatile matter content and the moisture and ash contents, if the fixed carbon content is reported on a basis containing one or both of those constituents, and subtracts the result(s) from 100% to find the fixed carbon content. One should not confuse the fixed carbon content of a coal with its (elemental) carbon content found in the ultimate analysis. Although there is certainly carbon in the material making up the fixed carbon content, it is not all of the carbon present in the original coal, and other elements are also present.

Gross calorific value: Calorific value is a measure of the energy content of a material, in this case, a coal sample. Calorific value is measured by ASTM Standard Test Method D 2015M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. The *gross* calorific value takes into account the additional heat gained by condensing any water present in the products of combustion, in contrast to the *net* calorific value, which assumes that all water remains in the vapor state.

Maceral: Macerals are organic substances or optically homogeneous aggregates of organic substances in a coal sample that possess distinctive physical and chemical properties.

Proximate Analysis: Proximate analysis is a method to measure the content of four separately identifiable constituents in a coal: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The standard method for obtaining the proximate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3172.

Rank: Coal rank is a classification scheme for coals which describes the extent of coalification which a particular coal has undergone. The structure, chemical composition, and many other properties of coals vary systematically with rank. The standard method for determining the rank of a coal sample is defined by the ASTM in Standard Test Method D 388.

Type: Coal type is a classification scheme for coals which references the original plant material from which the coal was derived.

Ultimate Analysis: Ultimate analysis is a method to measure the elemental composition of a coal sample. Typical ultimate analyses include carbon, hydrogen, oxygen, sulfur, and nitrogen contents, but other elements can also be reported. These other elements are usually not present to any appreciable extent. However, if they are reported, the sum of all the elements reported (including moisture and ash content) should equal 100%. The standard method for the ultimate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3176.

Volatile matter content: Volatile matter content measures the mass of material released upon heating the coal sample under specific conditions, defined by the ASTM Standard Test Method D 3175.

Further Information

An excellent resource for understanding coal, its sources, its uses, and its limitations and potential problems is the book by Elliott referenced above under Averitt (1981), Habermehl et al. (1981), and Neavel (1981). A reader wishing an understanding of coal topics could find no better resource.

Another comprehensive book which includes more-recent information but is not quite as weighty as Elliott's (664 pages vs. 2374 pages) is *The Chemistry and Technology of Coal*, edited (second edition, revised and expanded) by James G. Speight.

For up-to-date information specific to the environmental problems associated with the use of coal, the reader is referred to Norbert Berkowitz's chapter entitled "Environmental Aspects of Coal Utilization" in *An Introduction to Coal Technology.*

For information on the standards for coal analyses and descriptions of the associated procedures, the reader is referred to any recent edition of the American Society for Testing and Materials's *Annual Book of ASTM Standards.* Section 5 covers petroleum products, lubricants, and fossil fuels, including coal and coke.

Oil

Philip C. Crouse, P.E.

Overview

Fossil fuel energy accounted for 86.3% of all world energy in 1990. The Energy Information Administration (EIA) of the U.S. Department of Energy estimates that in the year 2010, fossil fuels will account for 85.9% of all world energy consumption — only a 0.4% percentage decrease in usage (Figure 7.3.2). According to EIA estimates, coal is expected to decline slightly from about a 27% to about a 25% share of consumption, and consumption of natural gas is expected to increase from 21 to 24% over the 20-year period. Over the same period, oil is forecasted to continue to be world major energy source with only slight declines from the present 39% of consumption.

Recent efforts in the United States have been to foster growth in natural gas usage as an energy source, causing an estimated growth of 2.3% per year. Total energy usage is expected to grow from 345.6 to 476.0 quadrillion Btu — or a 38% growth in energy usage over 20 years.

Crude Oil Classification and World Reserves

Obtaining accurate estimates of world petroleum and natural gas resources and reserves is difficult and uncertain. Terminology used by industry to classify resources and reserves has no broadly accepted standard classification. Such classifications have been a source of controversy in the international oil and gas community. Confusion persists in regard to classification. This section uses information provided by the Department of Energy classification system. The next chart shows the relationship of resources to reserves. **Recoverable resources** include discovered and undiscovered resources. **Discovered resources** are those resources that can be economically recovered (Figure 7.3.3).

Discovered resources include all production already out of the ground and reserves. Reserves are further broken down into proved reserves and other reserves. Again, there are many different groups that classify reserves in different ways, such as *measured*, *indicated*, *internal*, *probable*, and *possible.* Most groups break reserves into producing and nonproducing categories. Each of the definitions is quite voluminous and the techniques for qualifying reserves vary globally.

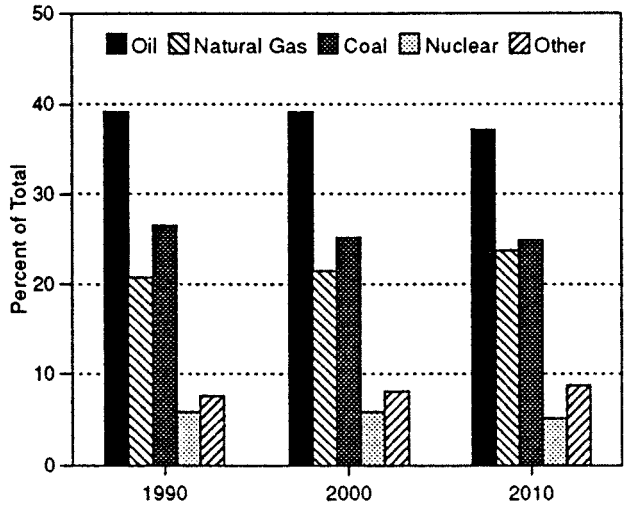

FIGURE 7.3.2 Share of world energy consumption by primary energy source, 1990–2010. (From EIA, *International Energy Outlook 1994*, EIA, Washington, D.C., July 1994.)

Source: EIA, International Oil and Gas Exploration and Development 1991, Washington, D.C., December 1993, 30–33.

Proved reserves are generally defined as: "Those volumes of oil and gas that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions."

OPEC (the Organization of Petroleum-Exporting Countries) has been key in setting global fossil fuel prices over the last two decades. With very large reserves, OPEC can provide much of the world future needs for crude oil and petroleum products. About two-thirds of the world known petroleum reserves are located in the Middle East as shown in Table 7.3.7.

Table 7.3.8 shows that the annual world crude oil production has steadily grown from 16.7 billion barrels in 1970 to 22 billion barrels in 1990.

Both crude oil demand and production are forecast to increase over the next 20 years. OPEC production is relatively level at 8.6 billion barrels in 1990 compared with 8.5 billion barrels in 1970. During the same time, non-OPEC production increased from 8.1 to 13.6 billion barrels. As the "swing producer", OPEC's production in 1980 increased by over 1 billion barrels when non-OPEC production could not meet total demand. They then decreased production by a similar amount in 1990 when production in the rest of the world increased by 1 billion to a non-OPEC total of 13.6 billion barrels. With a low price environment, OPEC is expected to gain market share in global production over the next 20 years.

Standard Fuels

Petroleum is refined into petroleum products that are used to meet individual product demands. The general classifications of products are

1. NATURAL GAS LIQUIDS AND LIQUEFIED REFINERY GASES
   This category includes ethane (C_2H_6), ethylene (C_2H_4), propane (C_3H_8), propylene (C_3H_6), butane and isobutane (C_4H_{10}), and butylene and isobutylene (C_4H_8).
2. FINISHED PETROLEUM PRODUCTS
   This category includes motor gasoline, aviation gasoline, jet fuel, kerosene, distillate, fuel oil, residual fuel oil, petrochemical feed stock, naphthas, lubricants, waxes, petroleum coke, asphalt and road oil, and still gas.
   - *Motor gasoline* includes reformulated gasoline for vehicles and oxygenated gasoline such as gasohol (a mixture of gasoline and alcohol).
   - *Jet fuel* is classified by use such as industrial or military and naphtha and kerosene-type. Naphtha fuels are used in turbo jet and turbo prop aircraft engines and excludes ram-jet and petroleum rocket fuel.
   - *Kerosene* is used for space heaters, cook stoves, wick lamps, and water heaters.
   - *Distillate fuel oil* is broken into subcategories: No. 1 distillate, No. 2 distillate, and No. 4 fuel oil which is used for commercial burners.
   - *Petrochemical feedstock* is used in the manufacture of chemicals, synthetic rubber, and plastics.
   - *Naphthas* are petroleums with an approximate boiling range of 122 to 400°F.
   - *Lubricants* are substances used to reduce friction between bearing surfaces, used as process materials, and as carriers of other materials. They are produced from distillates or residues. Lubricants are paraffinic or naphthenic and separated by viscosity measurement.
   - *Waxes* are solid or semisolid material derived from petroleum distillates or residues. They are typically a slightly greasy, light colored or translucent, crystallizing mass.
   - *Asphalt and road oil*. Asphalt is a cementlike material containing bitumens. Road oil is any heavy petroleum oil used as a dust pallatine and road surface treatment.
   - *Still Gas* is any refinery by-product gas. It consists of light gases of methane, ethane, ethylene, butane, propane, and the other associated gases. Still gas typically used as a refinery fuel.

World Refining Capacity. Refining capacity grew from 48 million barrels per day in 1970 to about 75 million barrels per day in 1990 — a 55% growth in capacity. Table 7.3.9 shows world refining capacity beginning in 1970. The peak year was 1982 in which capacity was 81.4 million barrels per day. Utilization of refinery capacity was about 80% in 1990, pointing to underutilization.

TABLE 7.3.9 World Refining Capacity

	1970	1980	1990
North America	13.2	20.2	17.4
Latin America	4.8	8.6	7.2

Middle East	2.2	3.6	4.2
Africa	0.7	1.7	2.6
Asia-Pacific	5.1	10.4	10.3
Central Planned Economies	7.5	15.4	17.6
Total world	48.2	80.0	73.4

Natural Gas

Philip C. Crouse, P.E.

Natural gas has been called the environmentally friendly fossil fuel since it releases fewer harmful contaminants. World production of dry natural gas was 73.7 trillion ft^3 and accounted for over 20% of world energy production. In 1990 Russia accounted for about one third of world natural gas. The second largest producer was the United States having about one quarter of world 1990 natural gas production.

Natural Gas Production Measurement

Natural gas production is generally measured as "dry" natural gas production. It is determined as the volume of natural gas withdrawn from a reservoir less (1) the volume returned for cycling and repressuring reservoirs; (2) the shrinkage resulting from the removal of lease condensate and plant liquids; (3) the nonhydrocarbon gases. The parameters for measurement are 60°F and 14.73 lb standard per square inch absolute.

World Production and Reserves of Dry Natural Gas

From 1983 to 1992, dry natural gas production rose from 54.4 to 75 trillion ft^3. The breakdown by region of world is shown in Table 7.3.10.

TABLE 7.3.10 World Dry Natural Gas Production — trillion ft^3

	1983	1992
North, Central, and South America	21.20	25.30
Western Europe	6.20	7.85
Eastern Europe and former U.S.S.R.	21.09	28.60
Middle East and Africa	2.95	6.87
Far East and Oceania	2.96	6.38
World total	54.40	75.00

Source: EIA, *Annual Energy Review 1993*, EIA, Washington, D.C., July 1994, 305.

World natural gas reserves estimated by the *Oil and Gas Journal* as of December 31, 1991 are in Table 7.3.11. OPEC accounted for 40% of world reserves yet processes only about 12% of the world production. The former U.S.S.R. accounts for about 40% and Iran another 15% of world reserves.

TABLE 7.3.11 World Natural Gas Reserves — billion ft^3

North America	343,677
South America	166, 850
Western Europe	177,844
Eastern Europe	1,766,358
Middle East	1,319,823
Africa	310,241
Asia-Pacific	299,288
Total	4,384,081
OPEC	1,729,205
Non-OPEC	2,654,876

Compressed Natural Gas

Environmental issues have countries examining and supporting legislation to subsidize the development of cleaner vehicles that use compressed natural gas (CNG). Even with a push toward the use of CNG-burning vehicles, the numbers are quite small when compared with gasoline vehicles. Italy has used

CNG since 1935 and has the largest usage with 300,000 vehicles. The United States ranked fifth with an estimated 30,000 vehicles in 1994. Argentina, which ranked sixth, had 15,000 vehicles.

Liquefied Natural Gas (LNG)

Natural gas can be liquefied by lowering temperature until a liquid state is achieved. It can be transported by refrigerated ships. The process of using ships and providing special-handling facilities adds significantly to the final LNG cost. If oil prices stay low, prospects for LNG development will remain low in the future. However, LNG projects planned by OPEC member countries may become significant over the next 20 years with shipments of LNG exports ultimately accounting for up to 25% of all gas exports.

Physical Properties of Hydrocarbons

The most important physical properties from a crude oil classification standpoint are density or specific gravity and the viscosity of liquid petroleum. Crude oil is generally lighter than water. A Baume-type scale is predominantly used by the petroleum industry and is called the **API** (American Petroleum Institute) **gravity** scale (see Table 7.3.12). It is related directly to specific gravity by the formula:

$$\varphi = (141.5)/(131.5 + {}^{\circ}\text{API})$$

where φ = specific gravity. Temperature and pressure are standardized at 60°F and 1 atm pressure.

TABLE 7.3.12 Relation of API Gravity, Specific Gravity, and Weight per Gallon of Gasoline

Degree API	Specific Gravity	Weight of gallon in lbs.
8	1.014	8.448
9	1.007	8.388
10	1.000	8.328
15	0.966	8.044
20	0.934	7.778
25	0.904	7.529
30	0.876	7.296
35	0.850	7.076
40	0.825	6.870
45	0.802	6.675
50	0.780	6.490
55	0.759	6.316
58	0.747	6.216

Note: The specific gravity of crude oils ranges from about 0.75 to 1.01.

Other key physical properties involve the molecular weight of the hydrocarbon compound and the boiling point and liquid density. Table 7.3.13 shows a summation of these properties.

Defining Terms

API Gravity: A scale used by the petroleum industry for specific gravity.

Discovered resources: Discovered resources include all production already out of the ground and reserves.

Proved resources: Resources that geological and engineering data demonstrate with reasonable certainly to be recoverable in future years from known reservoirs under existing economic and operating conditions.

Recoverable resources: Recoverable resources include discovered resources.

TABLE 7.3.13 Other Key Physical Properties of Hydrocarbons

Compound	Molecular Weight	Boiling Point at 14.7 psia in °F	Liquid Density at 14.7 psia and 60°F-lb/gal
Methane	16.04	–258.7	2.90
Ethane	30.07	–125.7	4.04
Propane	44.09	–43.7	4.233
Isobutane	58.12	10.9	4.695
n-Butane	58.12	31.1	4.872
Isopentane	72.15	82.1	5.209
n-Pentane	72.15	96.9	5.262

n-Heptane	100.2	209.2	5.738
n-Octane	114.2	258.2	5.892
n-Nonane	128.3	303.4	6.017
n-Decane	142.3	345.4	6.121

Further Information

The Energy Information Agency of the U.S. Department of Energy, Washington, D.C., publishes *International Energy Outlook* periodically.

7.4 Biomass Energy

Michael C. Reed, Lynn L. Wright, Ralph P. Overend, and Carlton Wiles

Biomass energy encompasses a wide variety of renewable energy technologies that use plant matter, plant residues, or plant-derived process wastes as fuel. These biomass resources can be used directly as solid fuels to produce heat, or they can be converted to other energy carriers such as liquid and gaseous fuels and electricity. Because the energy in biomass is less concentrated than the energy in fossil fuels, high-efficiency conversion technologies are necessary to make this energy resource cost competitive.

Photosynthesis

Biomass fuels are derived from green plants which capture solar energy and store it as chemical energy through the **photosynthetic** reduction of atmospheric carbon dioxide. Plant leaves are biological solar collectors while the stems, branches, and roots are the equivalent of batteries storing energy-rich complex carbon compounds. Elemental analysis shows both wood and grasses to be about 50% carbon. The average photosynthetic efficiency of converting solar energy into organic carbon compounds on an annual basis varies from less than 0.5% in temperate and tropical grasslands to about l.5% in moist tropical forests (Cralle and Vietor, 1989). While quite low, it represents stored energy on an annual basis and the diversity and adaptability of plants allows this solar collection to occur on most parts of Earth's surface. The worldwide annual storage of photosynthetic energy in terrestrial biomass is huge, representing approximately ten times world annual use of energy (Hall et al., 1993).

Biomass Production, Yield, and Potential

Forest Land

The amount of harvestable woody biomass produced by natural forests on an annual basis ranges from about 2 to 6 dry t/ha/year (metric ton/hectare/year), or 0.9 to 2.7 dry ton/acre/year with the higher yields usually in tropical regions. Managed forests often accumulate biomass at approximately double the rate of natural unmanaged stands. The productivity rates of natural forests could be increased to 4 to 12 dry t/ha/year (1.8 to 5.4 dry t/acre/year) if brought under active management. Such management might include optimizing harvesting strategies for production, fertilization, and replanting natural stands with faster-growing species. At present 10% of world forests, or 355 million ha (876 million acres), are actively managed. If managed forests were increased to 20%, and if 20% of the harvested material were used for energy, the annual worldwide resource of wood for energy from currently forested land would amount to somewhere between 284 and 852 million t (315 to 946 million dry tons) of available wood or about 5.6 to 17 Exajoules (5 to 14.5 quadrillion Btu) of primary energy based on potential yield ranges of managed forests. The most optimistic estimates of biomass potential would provide a total primary energy resource of about 30 Exajoules from managed forests (Sampson et al., 1993).

Cropland and Grassland

The production of perennial plants (either woody crops grown for 3 to 10 years between harvests or perennial grasses), using genetically superior materials, established on agricultural land and managed as an agricultural crop is believed to be the method of choice for producing biomass for energy on a large scale. Temperate shelterbelts and tropical agroforestry plantings could also contribute greatly to biomass energy resources. Energy crop yields are highest in locations where genetically superior material is planted on land with plenty of access to sunshine and water. Operational yields in the range of 20 to 30 dry t/ha/year (9 to 13 dry ton/acre/year) are achievable now. Such yields have been observed over large areas with eucalyptus and tropical grasses in the moist tropics and subtropics, and with hybrid poplars in irrigated portions of the dry Pacific Northwest of the United States. In many areas, however, suitable genetically superior materials are not yet available, water is a limiting factor, and irrigation may not be an economically or environmentally desirable alternative. Temperate wood energy yields are more

commonly in the range of 9 to 13 dry t/ha/year (4 to 6 dry ton/acre/year) today with the expectation that they could increase to the 12 to 20 dry t/ha/year (5.5 to 9 dry ton/acre/year) relatively rapidly with continued genetic improvement and clonal selection (Wright, 1994). Yields of properly managed perennial grasses in field test plots are currently in the range of 11 to 22 dry t/ha/year (5 to 10 dry ton/acre/year) with the expectation that yields of 16 to 27 dry t/ha/year (7 to 12 dry ton/ac/year) could be attained with further breeding and improvement of management regimes. The best current perennial grass yields on nonirrigated test plots have averaged around 25 dry t/ha/year (11 dry ton/acre/year) for 6 years in the southeastern U.S. where a long growing season favors warm season grasses.

The total amount of biomass potentially available from cropland conversion can only be speculated on since it requires making a number of assumptions involving such issues as land availability, food crop requirements, development of biomass energy markets, and crop yields. Such speculations have been made to attempt to evaluate the potential effect of biomass energy use on carbon emission reduction. These speculations have assumed that 10 to 15% of cropland worldwide could be available for the production of biomass resources as energy crops, shelterbelts, or for agroforestry use with energy as one product (Hall et al., 1993; Sampson et al., 1993). The primary energy resource potential of cropland conversion has been estimated to range from a low of 18 Exajoules to a high of 49 Exajoules (Sampson et al., 1993). Another 25 to 110 Exajoules has been estimated to be available from the conversion of grasslands and degraded areas to the production of biomass energy resources worldwide (Sampson et al., 1993).

Biomass Residues

Biomass residues are the organic by-products of food, fiber, and forest production and processing. Major sources of residues include the residues of grain crops such as corn, wheat, rice; animal dung; and forest roundwood harvest and processing. A signifiant portion of residues is not economically collectible for energy because of wide dispersal and low bulk density, which makes recovery, transport, and storage too costly. In many cases, residues have greater economic value being left on the land to restore nutrients, reduce erosion, and stabilize soil structure, or they may be recovered for other domestic, industrial, or agricultural uses. Recoverable crop residues in the United States are estimated to range between 70 and 190 million dry tons (Day, 1989) and recoverable forest residues are about double the level of crop residues (Hall et al., 1993). Recoverable crop and forest residues worldwide are estimated to have an energy value of 12.5 and 13.5 Exajoules respectively (Hall et al., 1993).

Terrestrial Limitations

The biomass productivity of forests, grasslands, and energy crop plantings is considerably less than theoretically possible based on calculations of maximum photosynthetic potential. Under artificially optimal conditions of temperature, water, and nutrients, average solar radiation near Des Moines, Iowa, would theoretically be aufficient to produce maximum total tree dry weight yields (above and below ground) as high as 102 t/ha/year (45 ton/acre/year) (Sampson et al., 1993). Actual seasonal temperature variations alone, however, reduce the maximum yield potential to 60 t/ha/year (27 ton/acre/year). Of that, the usable biomass portion of trees (the stems and branches only) amounts to only about 35 t/ha/year (15 ton/acre/year). Yet this is many times the harvestable biomass dry weight yield of trees from natural forest stands and more than double the best tree yields observed in experimental trials in that region. Water stress is a major reason for reduced yields. Perennial grasses may have a slightly higher harvestable yield potential in the region because of their higher water use efficiency and the more-efficient carbon metabolism of warm season grasses in temperate climates (Jones, 1985). While water stress, pests outbreaks, and inadequate nutrients all contribute to reduced yields, it is also clear that the genetic potential of perennials is yet to be fully explored. Genetic improvement of perennials for energy is only beginning in most regions of the United States; thus, the potential for finding substantially higher-yielding varieties and clones is excellent.

Environmental Impact

An emerging consensus of environmentalists, forestry organizations, researchers, and others is that if energy crops are treated as an agricultural crop and established and tended in a considered and informed way on appropriate land, environmental damage can be avoided. In fact, preliminary data suggests that there can be significant environmental and ecological benefits achieved in association with the development of a fully sustainable energy resource. Global benefits include the reduced emission of carbon into the atmosphere, while local benefits include soil conservation, reduction of chemical use, and wildlife biodiversity in an agricultural setting.

Biomass Conversion Technologies

As noted previously, biomass can be used to produce heat, electricity, and prepared fuels such as charcoal and liquid fuels. To do this, the biomass conversion technologies have to treat a wide range of biomass resources efficiently and convert them into the desired products. For example, biomass resources may include fuelwood, agricultural residues, farm animal wastes, forest industry processing residues (e.g., sawdust, black liquor from pulping processes), agricultural processing by-products (e.g., bagasse from sugarcane processing, food-processing by-products such as olive pits), and crops (e.g., grains, oil seeds, energy crops).

Each of these resources has different handling requirements and different process characteristics. Worldwide, the most common biomass resources are fuelwood and agricultural residues such as cereal straws. However, many other biomass resources offer opporturuties notjust for heat, but also in improving the environment (as when animal wastes are converted into methane and fertilizer through anaerobic fermentation processes). Each conversion process must take into account the differences in biomass composition which can vary widely in terms of moisture and ash content.

Biomass Composition

As received, biomass can range from very clean wood chips at 50% moisture to urban wood residues that are dry but contaminated with ferrous and other materials, animal residues, sludges, and the organic component of murucipal solid waste (MSW). Most biomass is a **lignocellulosic** material, such as wood or straw, which is composed of **cellulose**, **hemicellulose**, and **lignin**. Although different plant species have differing proportions of these polymers, it turns out that on a moisture and ash-free basis, the majority have essentially the same calorific values in the range of 16 to 19.6 GJ/t (8000 to 8500 Btu/lb). Biomass ash content varies considerably, being lowest in the clean wood fraction and very high in cereal straws such as rice straw, as can be seen in Table 7.4.1.

TABLE 7.4.1 Some Fuel Properties of Four Different Biomass Types

Property	Pine Shavings	Switchgrass	Rice Hull	Rice Straw
Ash %	1.43	10.10	18.34	15.90
Carbon	48.54	47.79	40.96	41.78
Hydrogen	5.85	5.76	4.30	4.63
Nitrogen:	0.47	1.17	0.40	0.70
Sulfur	0.01	0.10	0.02	0.08
Oxygen	43.69	35.07	35.86	36.57
Btu/lb	8337	7741	6944	7004
GJ/t	19.38	17.99	16.14	16.28

Direct Combustion, Combined Heat, and Power and Steam Electric Generation

By far the most frequent use of biomass is in direct-combustion applications, with combustion devices ranging from 5 kW cook stoves (Prasad, 1985) to 125 MW boilers burning wood chips and producing 150 thm/hr of steam at 11 MPa and 540°C superheat temperatures (Anonymous, 1994). The available types of combustors range from pile burners or Dutch-oven-type burners, which can accept biomass in

a large size range, to units that are suspension fired and require not only extensive fuel preparation but also fuel drying. The most popular types of boilers seem to be stoker-fired units with moving grates. More recently, the trend has been to bubbling and circulating fluidized-bed units, which offer a high degree of fuel flexibility by accepting fuel mixes ranging from coal to paper mill sludges that have very high moisture and ash contents. Boiler efficiency for typically moist biomass feedstocks ranges from 65 to 75%.

Biomass-fired steam turbine power generation technology is very similar to that of conventional fossil-fueled cycles. Biomass is combusted in a boiler, and the heat which is liberated is used to produce steam with conditions ranging from 28 bar and 398°C (400 psig and 750°F) for typical 25 MW units to 86 bar and 510°C (1250 psig and 950°F) for larger systems. The superheated steam generated in the boiler is used to drive a steam turbine generator. Net plant efficiency ranges from 20 to 30% (17,060 to 11,373 Btu/kWhr). Larger-scale boilers would permit several stages of reheat and the use of supercritical steam cycles. Developers of the Whole Tree Energy™ System have proposed the combustion of whole trees that are dried in a flue gas-assisted dome in order to provide supercritical steam to a turbine. System efficiencies are projected to be in the range of 40% (heat rate 8530 Btu/kWhr) and would be comparable to gas turbine-based combined-cycle units. The ability to utilize whole trees, as opposed to having to process wood feedstocks to "chip" size is a key advantage of the Whole Tree Energy System, as it can significantly reduce feedstock-handling costs.

Gasification

Biomass gasification processes can convert biomass materials into gaseous fuels (carbon- and hydrogen-rich fuel gases) that can be more easily utilized, often with a gain in efficiency and environmental performance. Gasification is a two-step, endothermic process in which a solid fuel (biomass or coal) is thermochemically converted into a low- or medium-Btu gas (see Figure 7.4.1). In the first reaction, pyrolysis, the volatile components of the fuel are vaporized at temperatures below 600°C (1100°F) by a set of complex reactions. Included in the volatile vapors are hydrocarbon gases, hydrogen, carbon monoxide, carbon dioxide tar, and water vapor. Because biomass fuels tend to have more volatile components (70 to 86% on a dry basis) than coal (30%), pyrolysis plays a larger role in biomass gasification than in coal gasification. Char (fixed carbon) and ash are the by-products of pyrolysis which are not vaporized. The second reaction, char conversion, involves the gasification and/or combustion of the carbon that remains after pyrolysis. In this reaction a portion of the char is burned to provide the heat required for pyrolysis and for gasification of any remaining char.

Thermal gasification is typically 80 to 85% efficient in converting the organic content of the feed into a fuel gas mixture mainly composed of hydrogen, carbon monoxide, and methane along with inert constituents. As a comparison, natural gas energy content, measured on a dry gas basis, is typically 37.8 $MJ \cdot m^{-3}$, or 1000 Btu/ft^3. Biomass gases produced through thermal gasification with air as the oxidant typically have gas energy content of less than 5.6 $MJ \cdot m^{-3}$ or 150 Btu/ft^3, while gasification with oxygen and steam or indirect gasification (which elimmintes the nitrogen dilution of the product) results in a heating value of 13 to 17 $MJ \cdot m^{-3}$ or about 350 to 450 Btu/ft^3. Typically, an air-blown gasifier would have over 50% nitrogen, a 25 to 30% by volume mix of hydrogen and carbon monoxide, and a small amount of methane, and the balance would be carbon dioxide.

Gasifier systems usually comprise the biomass fuel-handling and -feeding system which is coupled by means of air locks to the gasifier. In the thermal processes, the gasifier is usually a refractory-lined vessel and the gasification is carried out at high temperatures of approximately 850°C, at either atmospheric or elevated pressures. In a fluidized-bed gasifier, a continuous feed of biomass and inert heat-distributing material (e.g., sand) is "fluidized" by an oxidant and/or steam, and heat is supplied to the gasifier either "directly" or "indirectly" (U.S. Department of Energy, 1992).

In a directly heated fluidized-bed gasifier, heat required for gasification comes from char combustion in the gasifier reactor. The Institute of Gas Technology RENUGAS™ Pressurized Gasifier is an example of a direct-gasification technology. In the RENUGAS process, biomass is fed into a single, fluidized-bed gasifier vessel that operates at 300 to 500 psig. Inert solids in the vessel form the stable fluidized

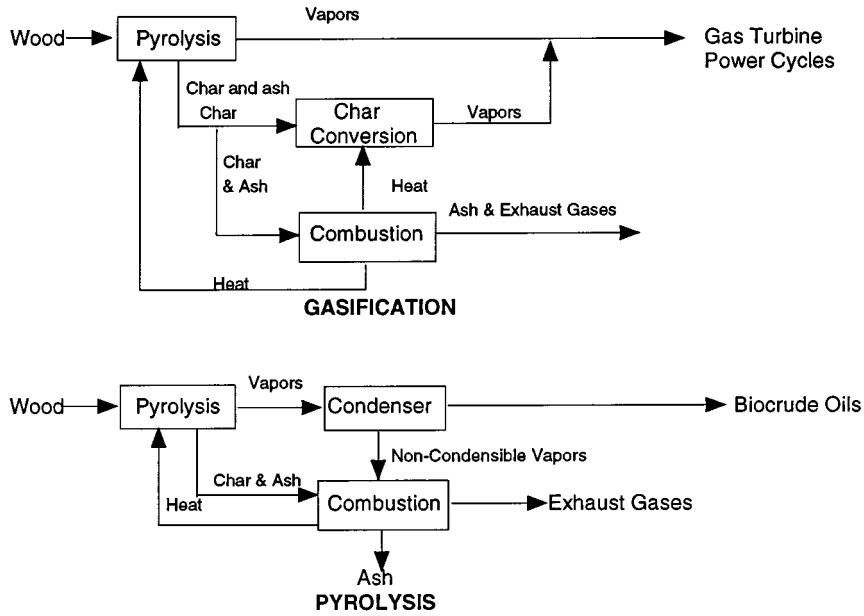

FIGURE 7.4.1. A diagram illustrating biomass gasification and pyrolysis processes. (From U.S. Department of Energy, *Electricity from Biomass: A Development Strategy.* DOE/CH10093-l52, DE920l0590. Washington, D.C., 1992.)

bed into which the biomass is fed. All of the biomass ash is carried overhead with the product gases. By using a deep, single-stage bed of inert solids, the RENUGAS process is able to achieve high carbon conversion with low oils and tars production. The gasifier is capable of producing either an industrial fuel gas or a chemical synthesis gas, depending on air- or oxygen-blown operation.

In an indirectly heated fluidized-bed gasifier, char is removed from the gasifier and burned in a separate vessel. The resulting heat is transferred to the gasifier by either in-bed heat exchangers or by recirculating the inert bed material heated in the char combustor. The advantage of indirect heating of the gasifier is that the gasification product is not diluted with the char combustion by-products (U.S. Department of Energy, 1992). The Battelle Gasification System is an example of an indirect gasification technology (see Figure 7.4.2). The Battelle system is a two-zone circulating-bed gasifier that produces a medium-energy content gas with a heating value of 500 Btu/ft^3 (18.63 MJ/m^3). The product gas can be used in existing natural gas-fired equipment including boilers, kilns, or gas turbines. The Battelle process produces this medium-Btu gas without the need for an oxygen plant, and uses two physically separate reactors (a gasification reactor in which biomass is converted into the product gas and residual char, which is then burned in a separate combustion reactor to provide the heat required for gasification). Heat transfer between the reactors is accomplished by circulating sand between the gasifier reactor and the combustor reactor. The separation of the gasifier from the combustor provides a means to maintain a constant heating value of the product gas regardless of changes in the feed moisture or ash content.

Biomass fuels can provide significant environmental advantages over competing fossil fuels, especially with regard to coal products. These advantages include little or no sulfur content and zero net carbon dioxide production. Additionally, chemicals produced during biomass combustion are absorbed in the photosynthesis process of new biomass growth. However, the fuel conversion process (gasification/combustion) generates emissions such as particulates, tar, and alkali that can cause erosion, corrosion, and deposition problems within the components of advanced conversion systems, especially combustion turbines. As such, some form of gas cleanup must be employed to ensure dependable system performance.

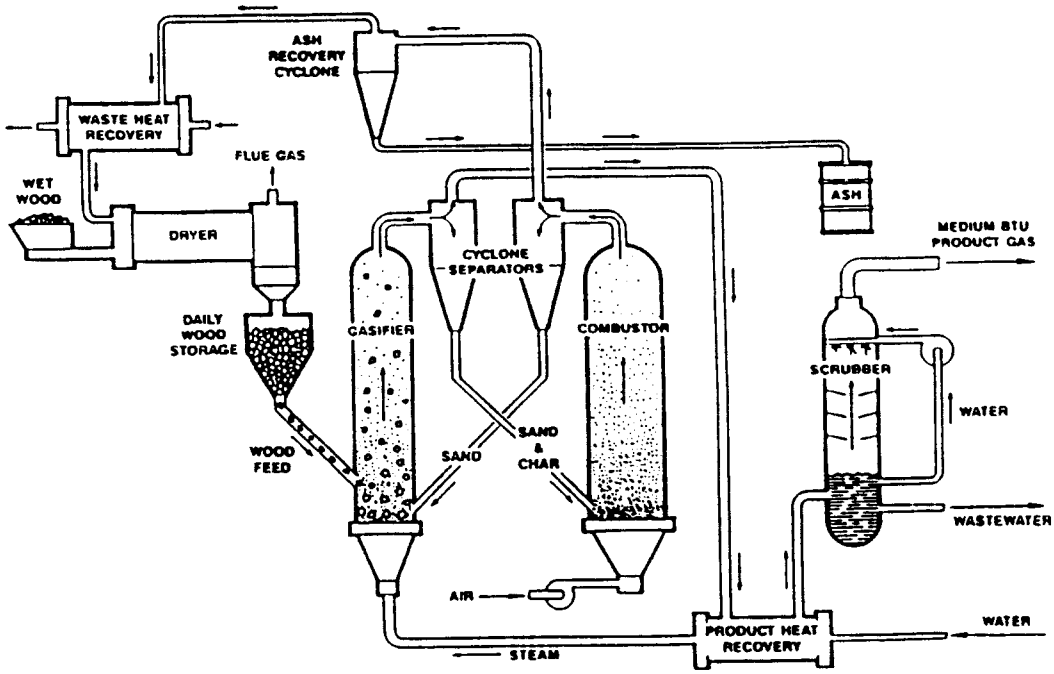

FIGURE 7.4.2. A diagram illustrating the Battelle Biomass Indirect Gasification System.

Biological Gasification or Anaerobic Digestion

The biological gasification process is carried out on feedstock which is either dissolved or slurried in water and typically produces a medium-energy-content gas composed of methane and carbon dioxide. A variety of designs are available, but all of them put anaerobic and methane-forming bacteria in contact with the biomass, the products are the gas (a mixture of methane and carbon dioxide) and a slurry of nonreacted feedstock which can usually be converted into a compost/fertilizer. In the case of landfill gas, the landfill "naturally" produces methane, which is currently being managed for greenhouse gas emissions. The contaminants, which can be highly odoriferous and include hydrogen sulfide, are removed with available technology prior to combustion in either a medium-speed diesel or turbine engine.

Liquefaction to Produce a Biofuel Oil

Biomass feedstocks can also be utilized to create biofuel oils, also known as biocrude. Through a process known as rapid pyrolysis, biofuel oils can be produced and used as fuel for gas turbines, diesel engines, or by co-firing the oil in an existing pulverized coal- or oil-fired boiler. Rapid pyrolysis occurs when heat is transferred to prepared biomass feedstocks (typical thickness <2 mm, moisture <8%) and the solid particles are thermochemically converted to a mixture of noncondensible gases, water vapor, char particles, and pyrolysis oil vapors. The pyrolysis oil vapors typically have a yield of 60 to 80% and are condensed to form a black, viscous, medium-Btu (9000 Btullb or 18.6 MJ/kg) mixture of organic compounds. Because the fuel oils can be stored and transported, the pyrolysis process can be decoupled from the power generation cycle, increasing the flexibility with respect to the proximity of the pyrolysis process to the end user.

Biofuel oil can be produced by pyrolyzing dried wood chips in a **vortex reactor**, followed by removal of solids and condensation of the vapors to recover the higher-molecular-weight hydrocarbons (see Figure 7.4.3). Noncondensible and light hydrocarbons are recycled as carrier gas, or burned with char to generate steam and/or electricity for internal use and export. Table 7.4.2 contains a comparison of biocrude oil characteristics and those of No. 6 fuel oil.

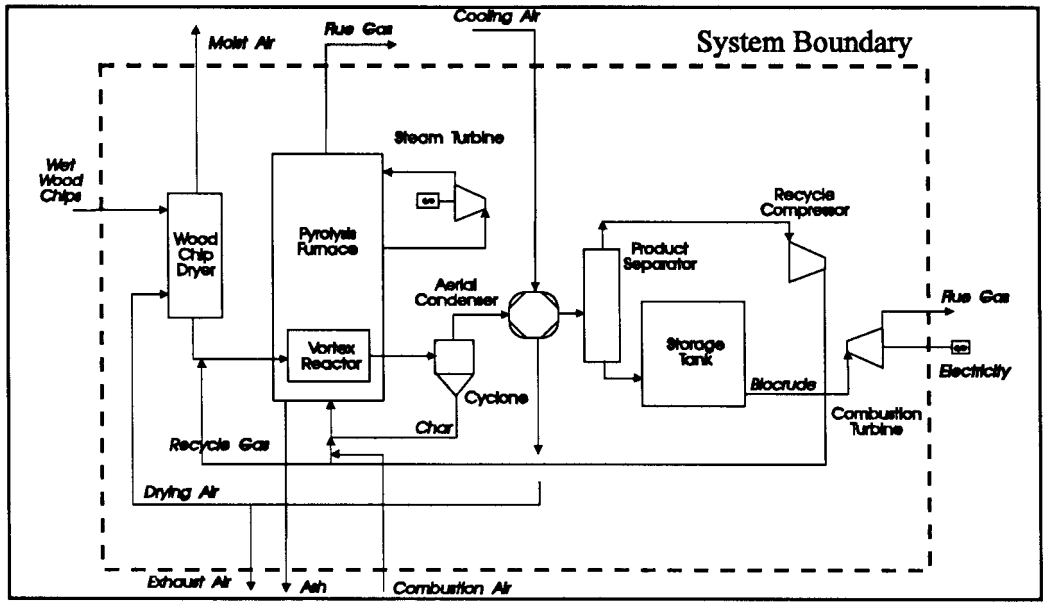

FIGURE 7.4.3. A diagram illustrating the biomass fast pyrolysis process for biocrude oil production.

TABLE 7.4.2 Fuel Oil Characteristics

Type	Biocrude Oil	No. 6 Fuel Oil
Source	Biomass pyrolysis	Petroleum distillation
Sulfur, ppm	5	3,000–30,000
Ash %	0.1–1.0	0.2–1.5
HHV, MJ/kg (BTU/lb)	21–24 (9,000–10,300)	43 (18,400)
HHV, MJ/l (Btu/gal)	25.2 (90,000)	42.1 (150,500)
Density, kg/m^3 @ 16°C (lb/gal @ 60°F)	1,200 (10.14)	950 (8.0)

Biomass Liquefaction

Ethanol

Ethanol (CH_3CH_2OH) is a renewable liquid fuel that can be produced by fermenting a wide range of biomass materials, including sugars, starches, and lignocellulosics. It is an excellent fuel for spark-ignition internal combustion engines with a high octane number. The automobile industry has developed specifications for E85, an 85% by volume blend with gasoline. Lower-level blends such as El0 are in broad commercial use. Heavy-duty compression ignition engines are usually modified to provide ignition assistance such as glow or spark plugs because of the low cetane and poor autoignition qualities. Although the volumetric energy density of ethanol is two thirds that of gasoline, it has properties, such as the increased octane number, that allow the use of more-efficient high-compression engines. The heat of vaporization is twice that of gasoline, thus increasing the cooled fuel/air mixture that reaches each cylinder. This same property, however, increases cold-starting difficulties.

Currently, corn is used to provide the starch substrate for ethanol production in the United States which is about 1.4 billion gal. Lignocellulosic materials, such as short-rotation woody crops (SRWC) and herbaceous energy crops (HEC), offer an alternative feedstock, one that is dependent on the development of new technology that will allow the cellulose and hemicelluloses that make up

approximately 70% of the lignocellulosic feedstocks to produce ethanol. Technology developments in the last decade in lignocellulosic-to-ethanol conversion have shown major potential for cost reductions that have positioned ethanol from lignocellulosics as a near commercial opportunity. These improvements have been in pretreatment, cellulase enzyme production, xylose fermentation, and cellulose conversion.

A typical flow sheet for ethanol production from lignocellulosics such as SRWC or HEC comprises the following operations: feedstock handling; pretreatment to expose the polymers such as hemicellulose and cellulose; production of the biocatalysts such as **cellulase** and hemicellulase that liberate the sugars glucose and xylose; fermentation to convert sugars into ethanol; ethanol recovery process such as distillation; and waste treatment with combined heat and power production from the lignin and other unconverted process residues. A combination of revolutionary advances and incremental improvements in this process chain has reduced costs of ethanol from $3.60 in 1980 to an estimated $1.27/gal in 1996; this latter is already below the cost of production of ethanol from corn. Further development promises to bring the cost into the range of $0.7 to 0.8/gal. This projected cost is competitive with equivalent fuels produced from oil costing $25/barrel.

Pretreatments to expose the carbohydrate polymers have been systematically optimized and developed to be low cost and to have low environmental impact. Dilute acid **hydrolysis** has been found to be effective at exposing cellulose for further hydrolysis. This pretreatment step is followed by a separation of the soluble hemicellulose sugars from the lignin and cellulose fiber. The cellulose material is used both to produce the cellulase enzymes for the hydrolysis and as the major source of sugar that produces ethanol in a combined saccharification and fermentation step. This combines the release of glucose with its immediate fermentation to ethanol in a single process step that results in a large capital cost saving, decreased fermentation times, and increased enzyme productivity, factors that have made a major reduction in overall cost. Work continues on improving the cellulase productivity, the tolerance of the fermentation yeasts to ethanol, and increases in the solids concentration in the fermenters. The current yield of xylose from the hemicellulose polymer, xylan, is also being improved from 80 to 90% (Zhang et al., 1995).

Methanol from Biomass

Methanol (CH_3OH) can easily be produced by gasifying biomass and then catalytically combining the carbon monoxide and the hydrogen. It is the one-carbon analog of ethanol and shares many of the same fuel properties such as a very high octane number. For spark-ignition engine use, M85, an 85% by volume blend with gasoline, is usually specified. The 15% gasoline provides added fuel volatility, which assists cold starting and adds luminosity to the flame for added safety since neat methanol (M100) burns with a nearly invisible flame.

Methanol is very toxic to humans, but is not a great threat to either soil or water environments, and like ethanol, it is essentially nonthreatening to the environment. In any case, methanol is an important industrial chemical and represents one third of the mass of the MTBE (methyl tertiarybutylether) oxygenate used in auto-fuel oxygenate programs. Currently, it is produced from natural gas using technology that has existed for over 50 years.

Biodiesel

Biodiesel is a diesel fuel that in the United States is derived from oil seed crops such as sunflower, soybean, and rape seed (canola). The oil is esterified in a simple process by reacting it with an alcohol such as methanol or ethanol to produce an ester that has been shown to be an attractive diesel fuel with an excellent cetane number and with much-reduced particulate emissions. The oil is isolated by pressing and solvent extraction from the seed cake, and the meal that remains is a nutritious animal feed. The esterification process produces a glycerine by-product. Both the meal and the glycerine have to be marketed in parallel with the oil production and currently the basic price of the oil seed — a food or feedstuff — is still too high, even though in subsidized markets in Europe production is increasing.

Municipal Solid Waste

Quantities, Characteristics, and Fuel Value

MSW contains energy, typically ranging from about 4000 to 6500 Btu/lb. MSW includes waste discarded from residential, commercial, institutional, and industrial sources. In 1993, over 200 million tons were generated with approximately 16% combusted for energy recovery. The quantities and heating values available will vary depending on the materials collected and processed into fuel. For instance, tires may be defined as MSW, but most will not be collected and processed into refuse-derived fuel (RDF). Yard waste contains some fuel value but may be composted. Of the approximate 207 million tons of MSW generated in the United States in 1993, paper and paperboard contributed about 77.8 million tons; plastics, 19.3 million tons; wood, 13.7 million tons. Paper has a typical heating value of 7200 Btu/lb; cardboard, 7000 Btu/lb; plastics, 14,000 Btu/lb; and wood, 8500 Btu/lb. Other components, such as leather, textiles, yard trimmings, rubber, etc., also have significant heating values. Processed RDF will have higher heating values depending on the degree of processing to remove noncombustibles and the components used to prepare the fuel. The average passenger tire has a heating value of 13,000 to 15,000 BtuAb. However, there are only two dedicated tires-to-energy facilities in the United States combusting tires for energy recovery; a third was scheduled to begin operation some time in 1995. There are a number of cement kilns, pulp and paper mills, electric-generating utility boilers, and industrial boilers that use tire-derived fuel as a portion of their fuel.

Refuse-Derived Fuels

Fuels derived from MSW have been classified according to the degree of processing. They range from waste used as a fuel in its discarded form with only bulky waste removed (RDF-1) to the combustible fraction of the waste processed into gaseous fuel (RDF-7). Some RDF may be densified (d-RDF) into pellets, cubes, or briquets for use in industrial and utility boilers as a supplement to coal.

MSW-to-Energy Conversion Technologies

Although there are several potential methods to recover energy from MSW (e.g., conversion to ethanol, anaerobic digestion, gasification, pyrolysis, etc.), combustion is the most-advanced and the most-applied conversion technology.

Combustion. Direct combustion is the most prevalent technology used to reclaim the energy value in MSW. In 1993, there were 125 municipal waste-to-energy facilities in the United States with a rated MSW capacity of approximately 2500 MW of energy. The most common options are mass burn and RDF facilities, with mass burn being the most prevalent.

In a typical mass burn facility, waste is received into a pit where an overhead crane mixes the waste and removes oversize materials. The waste is fed onto a grate of the furnace, which agitates and moves the waste across the combustion chamber. Air for combustion is introduced from under the grate (underfire air) and from nozzles located above the grate (overfire air). The formation and emission of pollutants (e.g., CO, NO_x, SO_x, hydrocarbons, dioxins, etc.) are affected significantly by the design and operation of the combustor. Energy is recovered from the hot flue gases in a waterwall boiler and is recovered as hot water and steam.

The cooled flue gases then pass through air pollution control (APC) equipment which normally includes combinations of scrubbers to remove acid gases (e.g., HCl) electrostatic precipitators (particulate removal), and/or fabric filters (fine particulates).

Anaerobic Digestion. Anaerobic digestion is the biological degradation of biodegradable materials, in the absence of oxygen. Anaerobic microorganisms convert the biodegradable fraction of the waste to carbon dioxide and methane, which can be collected and used as an energy source. Commercial-scale anaerobic digestion of MSW has not been successful in the U.S. There are approximately 24 plants operating outside of the U.S.

Defining Terms

Cellulase: A group of enzymes, found in many fungi and bacterial organisms, that hydrolyze the cellulose molecule into the component glucose molecules.

Cellulose: A complex carbohydrate found in stems, bark, and fibrous parts of plants and in products such as paper made from plant material. The insoluble molecule is a long chain of six carbon, glucose molecules linked together.

Hemicellulose: A complex carbohydrate molecule also found in plant material. This molecule is more soluble than cellulose and made up of five carbon sugars such as xylose.

Hydrolysis: Chemical decomposition involving the formation of water. Enzymes are capable of catalyzing the breakdown of cellulose resulting in the release of a water molecule and glucose molecules.

Lignin: A hard material embedded in the cellulose matrix of vascular plant cell walls. The molecule is a branched chain of organic rings, and gives strength to the fibers. This material is insoluble and must be removed in order to hydrolyze the cellulose.

Lignocellulosics: Substances composed of lignin and cellulose and/or hemicellulose, for example, wood. Lignocellulosic materials are the initial form of biomass feedstock before pretreatment removes or loosens the lignin and liberates the cellulose for further treatment

Photosynthesis: A process by which plants combine water and carbon dioxide in the presence of light and chlorophyll to make carbohydrates for food.

Vortex reactor: A pyrolysis reaction chamber design whereby a carrier gas and a dry feed stream are injected into a cylindrical reaction chamber, entering the reactor in a helical pattern and flowing over the inside surface of the cylinder, where heat is transferred to the biomass.

7.5 Nuclear Resources

James S. Tulenko

The Nuclear Fuel Cycle

Sources of Nuclear Fuels and World Reserves

Nuclear power can use two naturally occurring elements, uranium and thorium, as the sources of its fissioning energy. Uranium can be a fissionable source (fuel) as mined (Candu Reactors in Canada), while thorium must be converted in a nuclear reactor into a fissionable fuel. Uranium and thorium are relatively plentiful elements ranking about 60th out of 80 naturally occurring elements. All isotopes of uranium and thorium are radioactive. Today, natural uranium contains, in atomic abundance, 99.2175% Uranium-238 (U^{238}); 0.72% Uranium-235 (U^{235}); and 0.0055% Uranium-234 (U^{234}). Uranium has atomic number 92, meaning all uranium atoms contain 92 protons, with the rest of the mass number being composed of neutrons. Uranium-238 has a half-life of 4.5×10^9 years (4.5 billion years), U-235 has a half-life of 7.1×10^8 years (710 million years), and U-234 has a half-life of 2.5×10^5 years (250 thousand years). Since the age of the earth is estimated at 3 billion years, roughly half of the U-238 present at creation has decayed away, while the U-235 has changed by a factor of sixteen. Thus, when the earth was created, the uranium-235 enrichment was on the order of 8%, enough to sustain a natural reactor of (there is evidence of such an occurrence in Africa). The U-234 originally created has long disappeared, and the U-234 currently present occurs as a product of the decay of U-238.

Uranium was isolated and identified in 1789 by a German scientist, Martin Heinrich Klaproth, who was working with pitchblend ores. No one could identify this new material he isolated, so in honor of the planet Uranus which had just been discovered, he called his new material Uranium. It wasn't until 1896, when the French scientist Henri Becquerel accidentally placed some uranium salts near some paper-wrapped photographic plates, that radioactivity was discovered.

Until 1938, when the German scientists Otto Hahn and Fritz Shassroen succeeded in uranium fission by exposure to neutrons, uranium had no economic significance except in coloring ceramics, where it proved valuable in creating various shades of orange, yellow, brown, and dark green. When a uranium atom is fissioned it releases 200 million electron volts of energy; the burning of a carbon (core) atom releases 4 electron volts. This diffenence of 50 million times in energy release shows the tremendous difference in magnitude between chemical and nuclear energy.

Uranium is present in the earth's crust to the extent of four parts per million. This concentration makes uranium about as plentiful as beryllium, hafnium, and arsenic; and greater in abundance than tungsten, molybdenum, and tantalum. Uranium is an order of magnitude more plentiful than silver and a hundred times more plentiful than gold. It has been estimated that the amount of uranium in the earth's crust to a depth of 12 miles is of the order of 100 trillion tons.

Thorium, which is composed of only one isotope, Thorium-232, has a half-life of 14 billion years (1.4×10^{10} yr), is more than three times more abundant than uranium, and is in the range of lead and gallium in abundance. Thorium was discovered by Berjelius in 1828 and named after Thor, the Scandinavian god of war. For reference, copper is approximately five times more abundant than thorium and twenty times more abundant than uranium.

Uranium is chemically a reactive element; therefore, while it is relatively abundant, it is found chemically combined as an oxide (U_3O_8 or UO_2) and never as a pure metal. Uranium is obtained in three ways, either by underground mining, open pit mining, or in situ leaching. An economic average ore grade is normally viewed as .2% (4 pounds per short ton), though recently ore grades as low as .1% have been exploited. A large quantity of uranium exists in sea-water which has an average concentration of 3×10^{-3} ppm, yielding an estimated uranium quantity available in sea-water of 4000 million tons. A pilot operation was successfully developed by Japan to recover uranium from sea-water, but the cost was about $900/lb, and the effort was shut down as uneconomical.

The major countries with reserves of urnaium in order of importance are Australia, United States, Russia, Canada, South Africa, and Nigeria. The countries with major thorium deposits are India, Brazil, and the United States. It is estimated that for a recovery value of $130/kg ($60/lb), the total uranium reserves in these countries are approximately 1.5 million tonnes of uranium in the U.S., 1 million tonnes of uranium in Australia, .7 million tonnes of uranium in Canada, and 1.3 million tonnes of uranium in the former Soviet Union. As mentioned earlier, thorium reserves are approximately four times greater. With the utilization of breeder reactors, there is enough uranium and thorium to provide electrical power for the next thousand years at current rates of usage.

Processing of Nuclear Fuel

Once the uranium ore is mined it is sent to a concentrator (mill) where it is ground, treated, and purified. Since the ore is of a grade of .1 to .2% uranium, a ton of ore contains only between 1 to 2 kilograms of uranium per 1000 kilograms of ore. Thus, thousands to tonnes of ore have to be extracted and sent to a mill to produce a relatively small quantity of uranium. In the concentration process approximately 95% of the ore is recovered as U_3O_8 (yellowcake) to a purity grade of about 80%. Thus, assuming 0.15% uranium ore, the milling and processing of a metric ton (1000 kg) of ore yields a concentrate of 1.781 kg (1.425 kg of uranium and 0.356 kg of impurities). For this reason the mills must be located relatively close to the mine site. The ore tailings (waste) amounts to 998.219 kg and contains quantities of radon and other urnaium decay products and must be disposed of as a radioactive waste.

The U_3O_8 concentrate is then taken to a conversion plant where the concentrate is further purified (the 20% impurities are removed) and the uranium yellowcake is converted to uranium hexafluoried UF_6). The uranium hexafluoride is a gas at fairly low temperature and is an ideal material for the U-235 isotope enriching processes of either gaseous diffusion or gaseous centrifuge. The UF_6 is shipped in steel cylinders in a solid state, and UF_6 is vaporized by putting the cylinder in a steam bath.

If the uranium is to be enriched to 4% U^{235}, then 1 kilogram of 4% U^{235} product will require 7.4 kilograms of natural uranium feed and will produce 6.4 kilograms of waste uranium (tails or depleted uranium) with a U^{235} isotope content of 0.2%. This material is treated as a radioactive waste. Large quantities of tails (depleted uranium) exist as UF_6 in their original shipping containers at the enriching plants. Depleted uranium (a dense material) has been used as shields for radioactive sources, armor piercing shells, balancing of helicopter rotor tips, yacht hold ballast, and balancing of passenger aircraft.

The enriched UF_6 is then sent to a fabrication plant where it is converted to a uranium dioxide (UO_2) powder. The powder is pressed and sintered into cylindrical pellets which are placed in zircaloy tubes (an alloy of zirconium), pressurized with helium, and sealed. The rods are collected in an array (~17 × 17) bound together by spacer grids, with top and bottom end fittings connected by tie rods or guide tubes. Pressurized water reactor fuel assemblies, each containing approximately 500 kilograms of uranium, are placed in a reactor for 3 to 4 years. A single fuel assembly produces 160,000,000 kilowatt hours of electricity and gives 8,000 people their yearly electric needs for its three years of operation. When the fuel assembly is removed from the reactor it must be placed in a storage pond to allow for removal of the decay heat. After approximately five years of wet storage, the fuel assembly can be removed to dry storage in concrete or steel containers. In the United States the current plan is to permanently store the nuclear fuel, with the Department of Energy assuming responsiblility for the "spent" fuel. The money for the government to handle the storage comes from a fee of 1 mill per kilowatt hour paid by consumers of nuclear-generated electricity. A mill is a thousandth of a dollar or a tenth of a penny. Thus, the fuel assembly described above would have collected $160,000 in the waste fund for the Department of Energy to permanently store the fuel. In Europe, when the fuel is taken out of wet storage it is sent to a reprocessing plant where the metal components are collected for waste disposal; and the fuel is chemically recovered as 96% uranium, which is converted to uranium dioxide for recycling to the enrichment plant, 1% plutonium, which is converted to fuel or placed in storage, and 3% fission products which are encased in glass and permanently stored.

The important thing to remenber about the fuel cycle is the small quantitiy of radioactive fission products (1.5 kilograms) which are created as radioactive waste in producing power which can serve the yearly eletricity needs of 8,000 people for the three years that it operates. The schematic of the entire fuel cycle showing both the United States system (once-through) and the European (recycle) system is given in Figure 7.5.1.

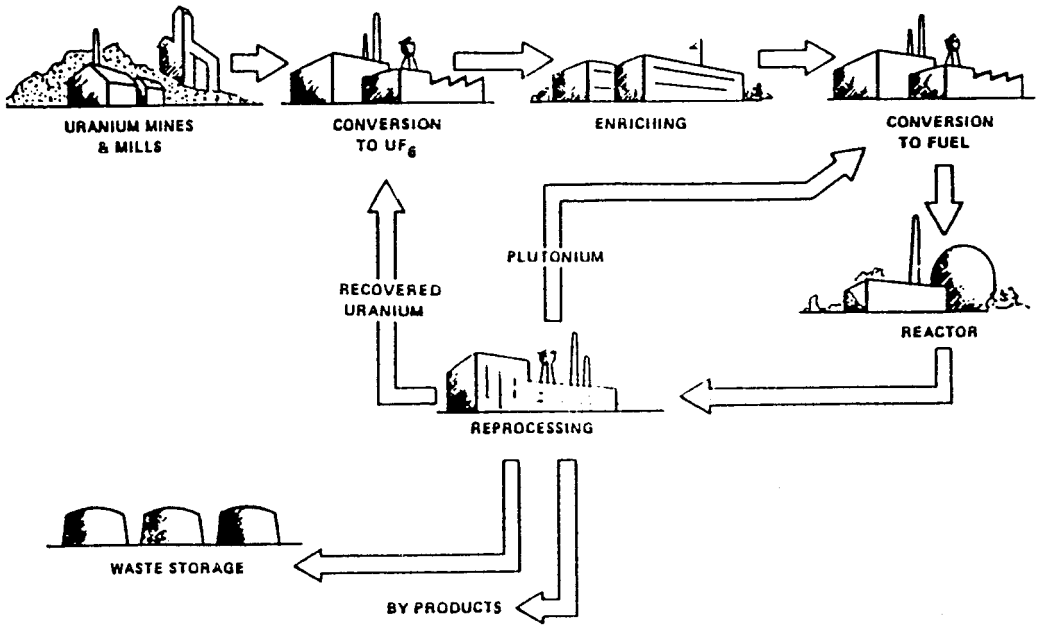

FIGURE 7.5.1 The nuclear fuel cycle.

7.6 Solar Energy Resources

D. Yogi Goswami

The sun is a vast nuclear power plant of the fusion variety which generates power in the form of radiant energy at a rate of 3.8×10^{23} kW. An extremely small fraction of this is intercepted by Earth, but even this small fraction amounts to the huge quantity of 1.8×10^{14} kW. On the average, about 60% of this energy, incident at the outer edge of the atmosphere, reaches the surface. To compare these numbers with our energy needs, consider the present electrical-generating capacity in the United States, which is approximately of 7×10^8 kW. This is equivalent to an average solar radiation falling on only 1000 square miles in a cloudless desert area. It must, however, be remembered that solar energy is distributed over the entire surface of Earth facing the sun, and it seldom exceeds 1.0 kW/m^2. Compared to other sources, such as fossil fuels or nuclear power plants, solar energy has a very low energy density. However, solar radiation can be concentrated to achieve very high energy densities. Indeed, temperatures as high as 3000 K have been achieved in solar furnaces.

Solar energy technology has been developed to a point where it can replace most of the fossil fuels or fossil fuel-derived energy. In many applications it is already economical, and it is a matter of time before it becomes economical for other applications as well.

This section deals in the availability of solar radiation, including methods of measurement, calculation, and available data.

Solar Energy Availability

Detailed information about solar radiation availability at any location is essential for the design and economic evaluation of a solar energy system. Long-term measured data of solar radiation are available for a large number of locations in the United States and other parts of the world. Where long-term measured data are not available, various models based on available climatic data can be used to estimate the solar energy availability. The solar energy is in the form of electromagnetic radiation with the wavelengths ranging from about 0.3 μm (10^{-6} m) to over 3 μm, which correspond to ultraviolet (less than 0.4 μm), visible (0.4 and 0.7 μm), and infrared (over 0.7 μm). Most of this energy is concentrated in the visible and the near-infrared wavelength range (see Figure 7.6.1). The incident solar radiation, sometimes called **insolation**, is measured as irradiance, or the energy per unit time per unit area (or power per unit area). The units most often used are watts per square meter (W/m^2), British thermal units per hour per square foot (Btu/hr-ft^2), and Langleys (calories per square centimeter per minute, cal/cm^2-min).

The amount of solar radiation falling on a surface normal to the rays of the sun outside the atmosphere of the earth (extraterrestrial) at mean Earth-sun distance (D) is called the **solar constant**, I_o. Measurements by NASA indicated the value of solar constant to be 1353 W/m^2 (±1.6%). This value was revised upward and the present accepted value of the solar constant is 1377 W/m^2 (Quinlan, 1979) or 437.1 Btu/hr-ft^2 or 1.974 langleys. The variation in seasonal solar radiation availability at the surface of Earth can be understood from the geometry of the relative movement of Earth around the sun.

Earth-Sun Relationships

Figure 7.6.2 shows the annual motion of Earth around the sun. The **extraterrestrial solar radiation** varies throughout the year because of the variation in the Earth-sun distance (D) as:

$$I = I_o\left(D/D_o\right)^2 \tag{7.6.1}$$

which may be approximated as (Spencer, 1971)

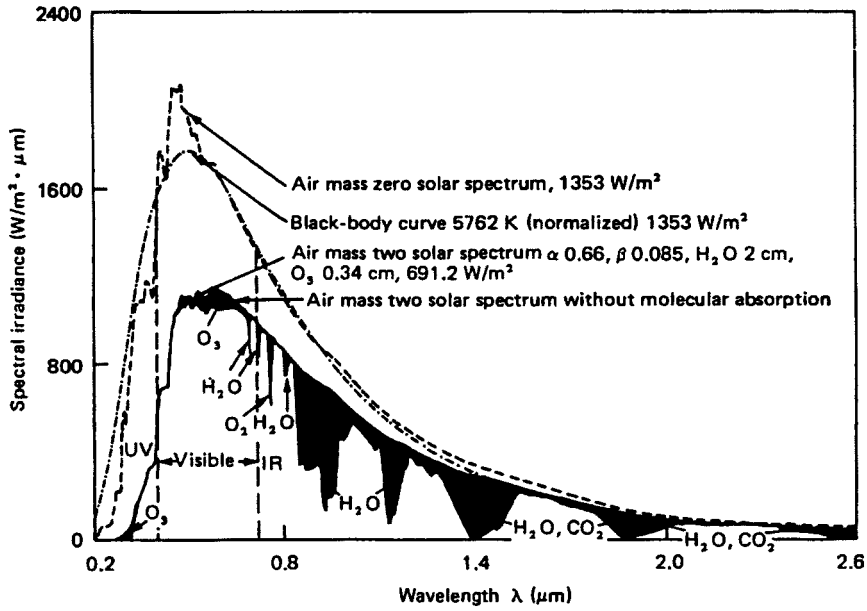

FIGURE 7.6.1 Spectral distribution of solar energy at sea level. (Reprinted by permission from Kreith, F. and Kreider, J.F., *Principles of Solar Engineering*, Hemisphere, Washington, D.C., 1978.)

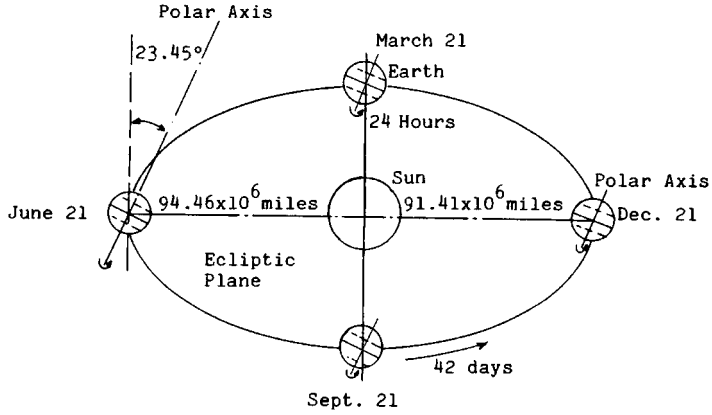

FIGURE 7.6.2 Annual motion of the Earth around the sun.

$$\left(D/D_o\right)^2 = 1.00011 + 0.034221\cos(x) + 0.00128\sin(x) + 0.000719\cos(2x) + 0.000077\sin(2x) \quad (7.6.2)$$

where

$$x = 360(N-1)/365° \quad (7.6.3)$$

and N = Day number (starting from January 1 as 1). The axis of the Earth is tilted at an angle of 23.45° to the plane of its elliptic path around the sun. This tilt is the major cause of the seasonal variation of solar radiation available at any location on Earth. The angle between the Earth-sun line and a plane through the equator is called **solar declination**, δ. The declination varies between –23.45° to +23.45° in 1 year. It may be estimated by the relation:

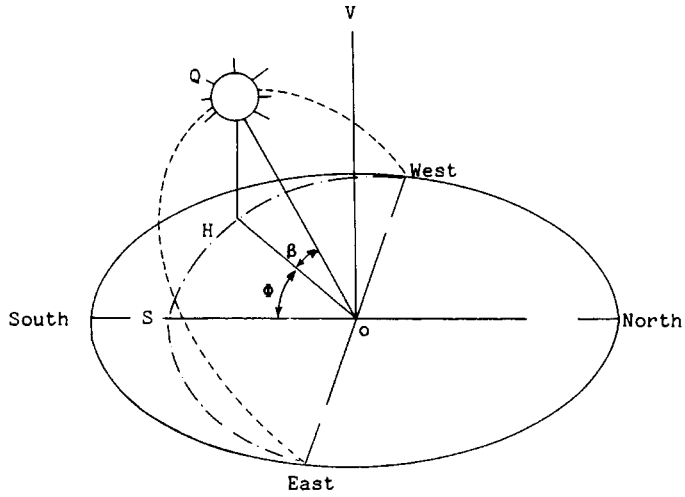

FIGURE 7.6.3 Apparent daily path of the sun across the sky from sunrise to sunset, showing the solar altitude and azimuth angles.

$$\delta = 23.45^\circ \sin\left[360(284 + N)/365^\circ\right] \tag{7.6.4}$$

The apparent motion of the sun around the earth is shown in Figure 7.6.3. The **solar altitude angle**, β, and the **solar azimuth angle**, Φ, describe the position of the sun at any time.

Solar Time

The sun angles are found from the knowledge of solar time, which differs from the local time. The relationship between solar time and local standard time (LST) is given by

$$\text{Solar Time} = \text{LST} + \text{ET} + 4\left(L_{st} - L_{loc}\right) \tag{7.6.5}$$

where ET is the **equation of time**, which is a correction factor in minutes that accounts for the irregularity of the motion of the Earth around the sun. L_{st} is the standard time meridian and L_{loc} is the local longitude. ET can be calculated from the following empirical equation:

$$\text{ET(in minutes)} = 9.87\sin 2B - 7.53\cos B - 1.5\sin B \tag{7.6.6}$$

where $B = 360(N - 81)/365^\circ$.
The sun angles β (altitude) and Φ (azimuth) can be found from the equations:

$$\sin\beta = \cos\ell\cos\delta\cos H + \sin\ell\sin\delta \tag{7.6.7}$$

where ℓ = latitude angle,

$$\sin\Phi = \cos\delta\sin H/\cos\beta \tag{7.6.8}$$

and

$$H = \text{Hour angle} = \frac{\text{Number of minutes from local solar noon}}{4 \text{ min/degree}} \tag{7.6.9}$$

(At solar noon, $H = 0$, so $\beta = 90 - |\ell - \delta|$ and $\Phi = 0$.)

Solar Radiation on a Surface

As solar radiation, I, passes through the atmosphere, some of it is absorbed by air and water vapor, while some gets scattered by molecules of air, water vapor, aerosols, and dust particles. The part of solar radiation that reaches the surface of the Earth with essentially no change in direction is called **direct or beam normal radiation**, I_{bN}. The scattered radiation reaching the surface from the atmosphere is called **diffuse radiation**, I_d.

I_{bN} can be calculated from the extraterrestrial solar irradiance, I, and the atmospheric optical depth τ as (Goswami et al., 1981; ASHRAE, 1995)

$$I_{\text{bN}} = Ie^{-\tau \sec\theta_z} \tag{7.6.10}$$

where θ_z is the solar zenith angle (angle between the sun rays and the vertical). The atmospheric optical depth determines the attenuation of the solar radiation as it passes through the atmosphere. Threlkeld and Jordan (1958) calculated values of τ for average atmospheric conditions at sea level with a moderately dusty atmosphere and amounts of precipitable water vapor equal to the average value for the United States for each month. These values are given in Table 7.6.1. To account for the differences in local conditions from the average sea level conditions Equation (7.6.10) is modified by a parameter called Clearness Number, Cn, introduced by Threlkeld and Jordan (1958):

$$I_{\text{bN}} = \text{Cn}Ie^{-\tau \sec\theta_z} \tag{7.6.11}$$

values of Cn vary between 0.85 and 1.15.

TABLE 7.6.1 Average Values of Atmospheric Optical Depth (τ) and Sky Diffuse Factor (C) for 21st Day of Each Month

Solar Radiation on a Horizontal Surface

Total incident solar radiation on a horizontal surface is given by

$$I_{t,\text{Horizontal}} = I_{\text{bN}} \cos\theta_z + CI_{\text{bN}} \tag{7.6.12}$$

$$= I_{\text{bN}} \sin\beta + CI_{\text{bN}} \tag{7.6.13}$$

where θ_z is called the solar zenith angle and C is called the sky diffuse factor, as given in Table 7.6.1.

Solar Radiation on a Tilted Surface

For a surface of any orientation and tilt as shown in Figure 7.6.4, the angle of incidence, θ, of the direct solar radiation is given by

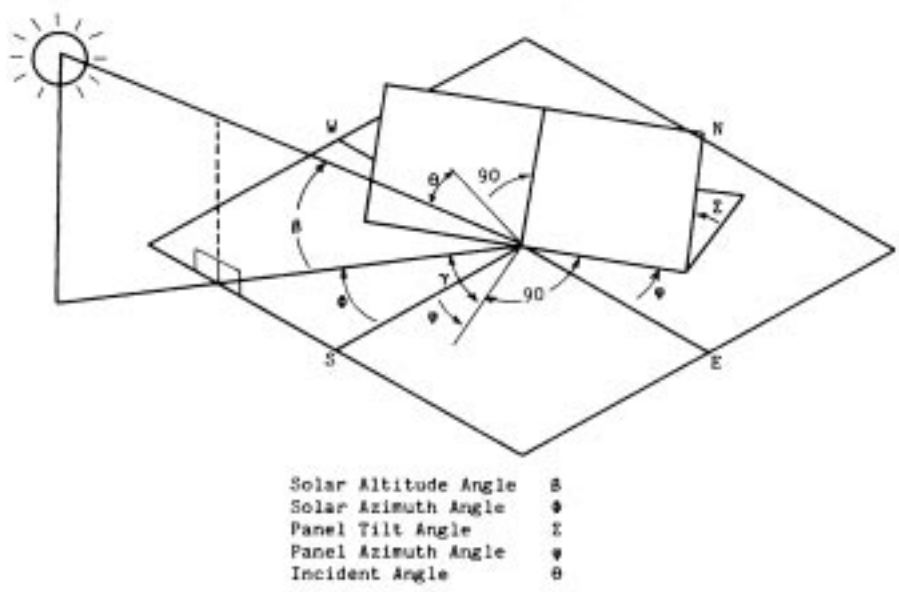

FIGURE 7.6.4 Definitions of solar angles for a tilted surface.

$$\cos\theta = \cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma \tag{7.6.14}$$

where γ is the angle between horizontal projections of the rays of the sun and the normal to the surface. Σ is the tilt angle of the surface from the horizontal.
For a tilted surface with angle of incidence θ, the total incident solar radiation is given by

$$I_b = I_{bN}\cos\theta + I_{diffuse} + I_{reflected} \tag{7.6.15}$$

where

$$I_{diffuse} = CI_{bN}(1+\cos\Sigma)/2 \tag{7.6.16}$$

and

$$I_{reflected} = \rho I_{bN}(C+\sin\beta)(1-\cos\Sigma)/2 \tag{7.6.17}$$

where ρ is the reflectivity of the surroundings. For ordinary ground or grass, ρ is approximately 0.2 while for ground covered with snow it is approximately 0.8.

Solar Radiation Measurements

Two basic types of instruments are used in measurements of solar radiation. These are (see Figure 7.6.5):

1. *Pyranometer:* An instrument used to measure global (direct and diffuse) solar radiation on a surface. This instrument can also be used to measure the diffuse radiation by blocking out the direct radiation with a shadow band.
2. *Pyrheliometer:* This instrument is used to measure only the direct solar radiation on a surface normal to the incident beam. It is generally used with a tracking mount to keep it aligned with the sun.

More-detailed discussions about these and other solar radiation measuring instruments can be found in Zerlaut (1989).

FIGURE 7.6.5 Two basic instruments for solar radiation: (a) pyranometer; (b) pyrheliometer.

Solar Radiation Data

Measured values of solar radiation data for locations in the United States are available from the National Climatic Center in Asheville, NC. A number of states have further presented solar radiation data for locations in those states in readily usable form. Weather services and energy offices in almost all the countries have available some form of solar radiation data or climatic data that can be used to derive solar radiation data for locations in those countries. Tables 7.6.2 to 7.6.8 give solar radiation data for clear days for south-facing surfaces in the Northern Hemisphere (and northern-facing surfaces in the Southern Hemisphere) tilted at 0°, 15°, 30°, 45°, 60°, 75°, and vertical, for latitudes 0°, 10°, 20°, 30°, 40°, 50°, and 60°. The actual average solar radiation data at a location is less than the values given in these tables because of the cloudy and partly cloudy days in addition to the clear days. The actual data can be obtained either from long-term measurements or from modeling based on some climatic parameters, such as percent sunshine. Tables 7.6.9 to 7.6.12 give hourly solar angles for northern latitudes 0°, 20°, 40°, and 60°.

Defining Terms

Diffuse radiation: Scattered solar radiation coming from the sky.

Direct or beam normal radiation: Part of solar radiation coming from the direction of the sun on a surface normal to the sun's rays.

Equation of time: Correction factor in minutes, to account for the irregularity of the Earth's motion around the sun.

Extraterrestrial solar radiation: Solar radiation outside Earth's atmosphere.

Insolation: Incident solar radiation measured as W/m^2 or $Btu/hr\text{-}ft^2$.

Solar altitude angle: Angle between the solar rays and the horizontal plane.

Solar azimuth angle: Angle between the true south horizontal line and the horizontal projection of the sun's rays.

Solar constant: Extraterrestrial solar radiation at the mean Earth-sun distance.

Solar declination: Angle between the Earth-sun line and a plane through the equator.

7.7 Wind Energy Resources*

Dale E. Berg

The mechanical devices that are used to convert kinetic energy in the wind into useful shaft power are known as windmills (the earliest machines were used to mill grain), wind machines, or wind turbines. The earliest use of wind machines appears to have been in ancient Persia, where they were used for grinding grain and pumping water. By the 14th century, completely different types of mills known as post and cap mills had become a major source of energy for milling, water pumping, and other tasks throughout northern Europe, and they remained so well into the 19th century, when the steam engine displaced them in many applications.

A new form of windmill appeared in United States in the second half of the 19th century — the multivane or annular windmill, also sometimes known as the American windmill (see Figure 7.7.1). These small, lightweight machines were designed to survive high winds with no human intervention by automatically shedding power, and they played a large role in the settlement of the American West — an arid country where little surface water is available. Many windmills of this basic type are still in use for water pumping around the world today.

FIGURE 7.7.1 The multiblade American windmill Photograph by Paul Gipe. (Adapted from *Wind Power for Home & Business*, Chelsea Green Publishing. 1993).

By the end of the 19th century, efforts to adapt wind power to electricity generation were underway in several countries. In the early 20th century, small wind turbine generators utilizing only two or three aerodynamic blades and operating at a higher rotational speed than the multibladed windmills were developed. Many thousands of generators of this type have been used to provide electricity in the remote areas of the world over the past 85 years.

Large-scale wind turbines designed to generate electrical power were built and tested in several European countries and the U.S. between 1935 and 1970. However, economic studies showed that the electricity generated by the machines would be every expensive, and no effort was made to develop the machines as a serious alternative energy source.

* This work was supported by the United States Department of Energy under Contract DE-AC04-94AL85000.

As a result of research and development since the mid 1970s, the cost of energy or wind-generated electricity has decreased from around 30¢ per kilowatt-hour (kWhr) in the early 1980s to less than 5¢/kWhr for a modern wind farm at a good site in 1995, and wind turbine availability (the fraction of time the machine is operational; i.e., not disabled for repairs or maintenance) has increased from 50 to 60% to better than 95% over the same period. At the end of 1995, there were over 26,000 wind turbines operating worldwide with an installed capacity of over 5000 MW. Twenty-five percent of that capacity was installed in 1995, and plans for 1996 call for the installation of an additional 25%. About 2500 MW of the 5000 MW was in Europe, 1700 MW was in the U.S., and over 400 MW was in India.

Wind Characteristics

Wind Speed and Shear

The primary cause of atmospheric air motion, or wind, is uneven heating of Earth by solar radiation. For example, land and water along a coastline absorb radiation differently, and this creates the light winds or breezes normally found along a coast. Earth's rotation is also an important factor in creating winds.

Wind moving across Earth's surface is slowed by trees, buildings, grass, rocks, and other obstructions in its path. The effect of these obstructions decreases with increasing height above the surface, typically resulting in a wind speed that varies with height above the Earth's surface — phenomenon known as **wind shear**. For most situations, wind shear is positive and wind speed increases with height, but situations in which the wind shear is negative or inverse are not unusual. In the absence of actual data for a specific site, a commonly used approximation for wind shear is

$$U/U_o = \left(h/h_o\right)^{\alpha} \tag{7.7.1}$$

where U is the velocity at a height h, U_o is the measured velocity at height h_o, and α is the non-dimensional wind shear exponent.

The wind shear, α, varies with terrain characteristics, but usually is between 0.10 and 0.25. Over a smooth, level, grass-covered terrain such as the United States Great Plains, α is normally about 0.14. For wind over row crops or low bushes with a few scattered trees, a value of 0.20 is more common while a value of 0.25 is normally a good value for wind over a heavy stand of trees, several buildings, or hilly or mountainous terrain.

A specific site may display much different wind shear behavior than that given in Equation 7.7.1, and that will dramatically affect site energy capture, making it important to measure the wind resource at the specific site and height where the wind turbine will be located, if at all possible.

Wind Energy Resource

The available power in the wind passing through a given area at any given velocity is due to the kinetic energy of the wind and is given by

$$\text{Power} = \frac{1}{2}\rho A U^3 \tag{7.7.2}$$

where the power is in watts, ρ is the air density in kg/m^3, A is the area of interest perpendicular to the wind in m^2, and U is the wind velocity in m/sec.

Air density decreases with increasing temperature and increasing altitude. The effect of temperature on density is relatively weak and is normally ignored, as these variations tend to average out over the period of a year. The density difference due to altitude, however, is significant and does not average out. For example, the air density at sea level is approximately 14% higher than that at Denver, CO (elevation 1600 m or 5300 ft above sea level), so wind of any velocity at sea level contains 14% more power than wind of the same velocity at Denver.

From Equation 7.7.2, it is obvious that the most important factor in the available power is the velocity of the wind — available wind power is proportional to the cube of the wind speed, so doubling the wind speed increases the available power by a factor of 8. An increase in wind velocity of only 20%, say, from 5 to 6 m/sec (11.2 to 13.4 mph), yields a 73% increase in available power.

The available wind power at a site can vary dramatically with height due to wind shear. For example, for $\alpha = 0.20$, Equations (7.7.1) and (7.7.2), reveal that the available power at a height of 30 m is approximately $\{(30/10)^{0.2}\}^3 = 1.93$ times the available power at 10 m. The amount of energy available from the wind (the **wind energy resource**) is the average amount of power available from the wind over a specified period of time, frequently a year. If the wind speed is 20 m/sec, the available power is very large, but if it only blows at that speed for 10 h/year and the rest of the time the wind speed is 0, the resource for the year is very small. Therefore, the site **wind speed distribution**, or frequency at which each wind speed occurs, is very important. The distribution is often presented in histogram form as the probability that the wind occurs at any particular wind speed between 0 and the maximum wind speed (see Figure 7.7.9). If the actual wind speed distribution is not available, it is frequently approximated with a Rayleigh distribution based on the yearly average wind speed. The Rayleigh distribution is given by

$$f(U) = \frac{\pi}{4} \cdot \frac{U}{\overline{U}} \exp\left[\frac{-\pi U^2}{4\overline{U}^2}\right] \tag{7.7.3}$$

where $f(U)$ is the frequency of occurrence of wind speed U and $\overline{U}$ is the yearly average wind speed.

How big is the wind energy resource? It varies dramatically from site to site. In 1981, scientists at Battelle Pacific Northwest Laboratory (PNL) in the U.S. analyzed national weather data, ship data, and terrain and made an estimate of the world-wide wind energy resource. That estimate is summarized in Figure 7.7.2. Very little data is available over much of the world, but even where excellent data is available, only very crude estimates can be portrayed on a map of this scale. More detailed analysis of available data for a specific country can yield a much better estimate of the wind resource for that country.

For example, the PNL scientists have carefully analyzed and interpreted the available long-term wind data for the U.S. and have summarized their estimate of the wind energy resource in a series of maps in the *Wind Energy Resource Atlas of the United States* (Elliott et al., 1987). A summary for the entire U.S. is reproduced in Figure 7.7.3 which presents the resource in terms of the power class rating. Sites with power class 4 (at least 250 W/m^2 at 10 m height or 500 W/m^2 at 50 m height) and above are considered economic for utility-scale wind power development with available wind technology, while sites with power class 3 are not considered economic today but are likely to become economic with near-term wind technology advances. Sites in power classes 2 or lower are not considered economic for utility-scale wind power development, but may well be economic for remote or hybrid wind power systems.

Much of the land in the United States is not available for wind energy development because it is in environmental exclusion areas such as parks, monuments, wilderness areas, wildlife refuges, and other protected areas, or only a portion of it may be developed because of land-use restrictions for forest, agriculture, range, and urban lands. Schwartz et al. (1992) estimated the wind energy that could be generated (the **wind energy potential**) for the United States land available for wind energy development. For the purposes of this study, they assumed that turbines with a 50-m hub height, arranged in arrays with 10 diameter by 5 diameter spacing, operating at 25% efficiency, and experiencing 25% power losses, were used to capture the available wind. Their results for power class 4 and above are summarized in Figure 7.7.4 and Table 7.7.1. They estimate that the average power that could be produced from this resource is 512,000 MW, significantly above the 1994 U.S. average electricity generation of 350,000 MW. They also estimate that the available windy lands with power class 3 or better resources could yield an average power of 1,241,000 MW, more than three times the current United States electricity generation. However, since wind energy is intermittent, is typically concentrated away from the major

TABLE 7.7.1 Estimates of Class 4 Wind Land Area and Wind Energy Potential

State	Average Power, MW	Windy Land, km^2
North Dakota	108,000	98,000
South Dakota	70,900	66,500
Wyoming	49,800	39,600
Montana	48,400	42,800
Minnesota	44,800	42,100
Kansas	35,700	33,600
Texas	28,900	27,100
Oklahoma	27,200	25,500
Colorado	26,400	24,300
Nebraska	22,200	20,900
Iowa	15,800	14,900
New Mexico	5,200	4,600
National	512,300	464,200

Note: The top 12 states and total for 48 contiguous states. Wind resource class 4 and above, for a 30-m hub height.

population centers where the electricity demand is highest, and is not always available when the demand is great, it will probably never supply more than 15 to 20% of the U.S. electricity needs.

Similar assessments may be performed for any country of interest. The PNL scientists have recently performed a similar assessment of the available long-term wind data for Mexico and have estimated the wind resource there (Schwartz and Elliott, 1995), as shown in Figure 7.7.5. While wind resources in class 2 are too low to be economic for grid-connected wind power, they are useful for rural power applications. Scientists at Denmark's Risø National Laboratory have done similar work in Europe,

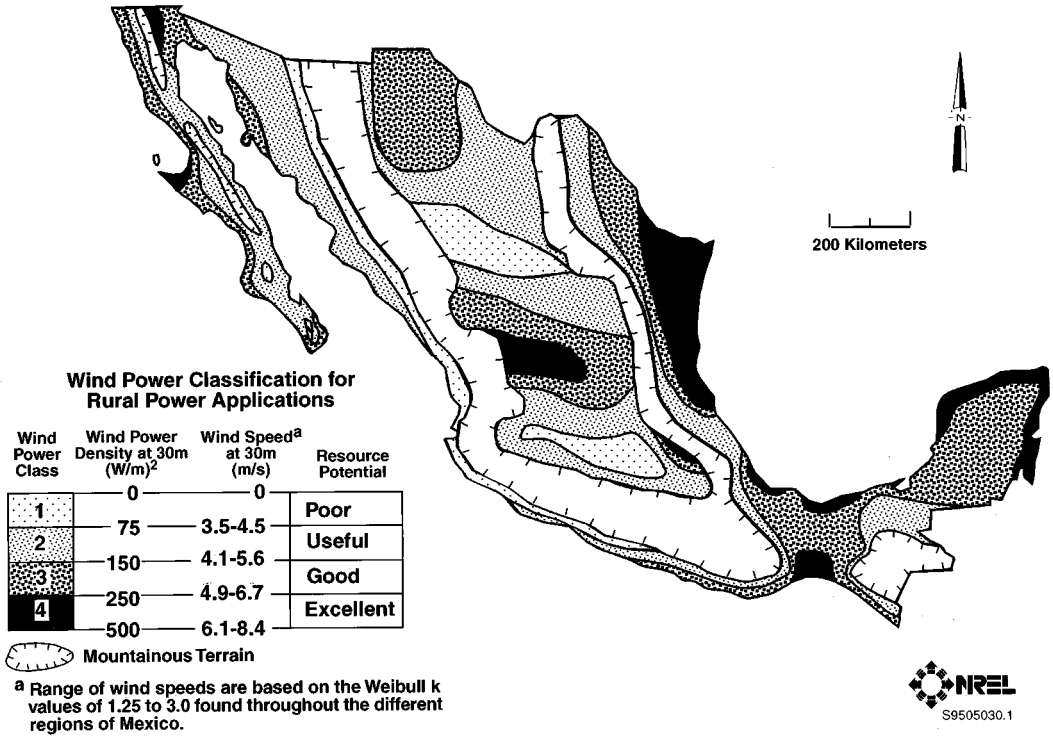

FIGURE 7.7.5 Map of Mexican remote application wind energy resources. Reproduced from Schwartz and Elliott, 1995. *Mexico Wind Resource Assessment Project*. (Courtesy of National Renewable Energy Laboratory, Golden, Colorado.)

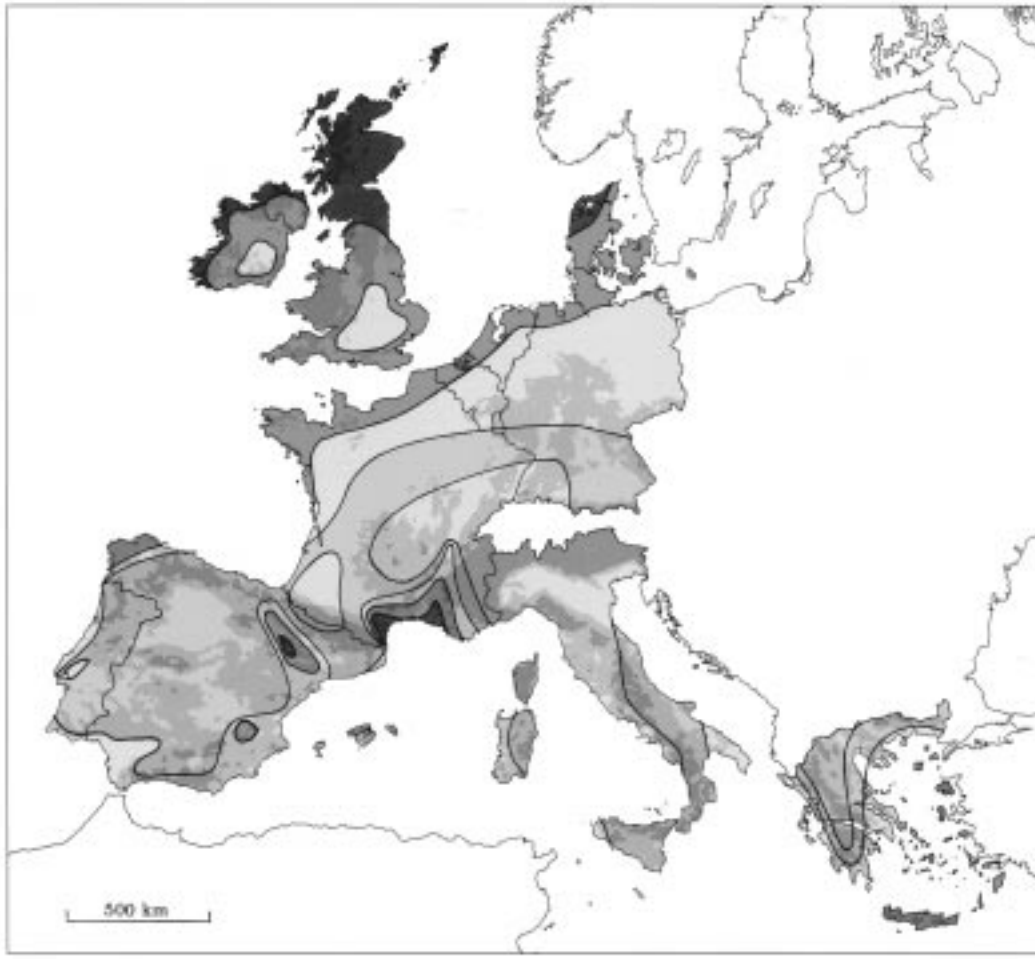
producing a *European Wind Atlas* (Troen and Petersen, 1989) that examines the wind resources of the European Community countries and summarizes the resource available at a 50 m height above smooth, flat terrain, with no obstacles. These results are presented in Figure 7.7.6. Finland, Sweden, Algeria, and Jordan have produced similar reports, and atlases for Poland, Canada, Egypt, Syria, and Turkey are currently in preparation. Resource maps for several other countries may be found in Rohatgi and Nelson (1994).

Existing meteorological station data, in general, significantly underestimate the wind energy resources because of lack of maintenance of wind sensors, poor locations at which they are placed, and cursory methods used in analyzing these data. Assessments such as these only identify the wind energy resource or potential on a very coarse grid. The actual wind resources in any specific area can vary dramatically from those estimates and must be determined with site-specific measurements. Even areas with a very low large-scale resource may contain small areas with a very high resources.

Site Analysis and Selection

Biological Indicators

Many different methods may be used to identify areas of high wind resource. Persistent winds can cause plant deformation, and careful observation of these plants can be used to compare candidate sites and, in at least some cases, to estimate the average wind speed. The Griggs-Putnam index, shown in Figure 7.7.7 and explained in Hewson, Wade, and Baker (1979), is an example of a genus-specific correlation of tree deformation with wind speed. It should be noted that although wind-flagged trees (i.e., trees with branches bent away from a prevailing wind) may indicate that the annual average wind speed is quite strong, unflagged trees do not necessarily indicate that the winds are light. Unflagged trees may be



Wind resources[1] at 50 metres above ground level for five different topographic conditions

	< 3.5	< 50	< 4.5	< 100	< 5.0	< 150	< 5.5	< 200	< 7.0	< 400

1. The resources refer to the power present in the wind. A wind turbine can utilize between 20 and 30% of the available resource. The resources are calculated for an air density of 1.23 $kg\,m^{-3}$, corresponding to standard sea level pressure and a temperature of 15°C. Air density decreases with height but up to 1000 m a.s.l. the resulting reduction of the power densities is less than 10%.
2. Urban districts, forest and farm land with many windbreaks (roughness class 3).
3. Open landscapes with few windbreaks (roughness class 1). In general, the most favourable inland sites on level land are found here.
4. The classes pertain to a straight coastline, a uniform wind rose and a land surface with few windbreaks (roughness class 1). Resources will be higher, and closer to open sea values, if winds from the sea occur more frequently, i.e. the wind rose is not uniform and/or the land protrudes into the sea. Conversely, resources will generally be smaller, and closer to land values, if winds from land occur more frequently.
5. More than 10 km offshore (roughness class 0).
6. The classes correspond to 50% overspeeding and were calculated for a site on the summit of a single axisymmetric hill with a height of 400 metres and a base diameter of 4 km. The overspeeding depends on the height, length and specific setting of the hill.

exposed to strong winds from all directions, with insufficient persistence in any one direction to cause flagging.

Effects of Topography

The effects of surrounding terrain on the wind speed at a specific site can be significant. If the proposed site is flat, the terrain texture is the area of most concern. The rougher the terrain, the more the wind flowing over it is retarded near the surface. Flat terrain, such as a large area of flat, open grassland, is the simplest type of terrain for selecting a turbine site. If there are no nearby obstacles (i.e., buildings, trees, or hills), the wind speed at a given height is nearly the same over the entire area, and the best way to increase the available power is to raise the rotor higher above the ground to take advantage of positive wind shear.

Siting turbines on elevated terrain such as hills, ridges, and cliffs takes advantage of the generally higher wind speed at increased altitudes. It may also help keep the turbine exposed to the winds above the calm, cool air that frequently accumulates in valleys and lowlands at night. In some cases, the elevated terrain may cause an acceleration of the wind and thus further improve the resource available to the turbine (see Figure 7.7.8). Depressions include such terrain features as valleys, basins, gorges, and passes. If the depressions channel the wind flow, they may provide good turbine sites. However, the power is

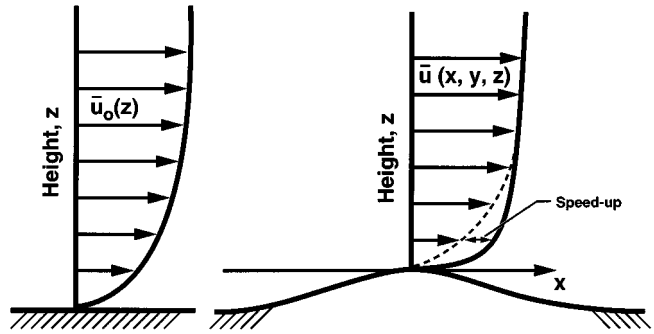

FIGURE 7.7.8 Effect of wind flow over a hill.

more likely to vary by time-of-day or by season than it is for elevated terrain. The impact of terrain on the wind resource and the best places to site turbines for various types of terrain are discussed by Wegley, et al. (1980).

Wind Speed Measurements

The amount of wind energy that can be captured at a site depends on the characteristics of the wind speed at that site. Wind characteristics (speed, direction, distribution, and shear) can vary widely over fairly short distances in either the horizontal or vertical direction. Therefore, in order to predict the energy capture of a turbine with the greatest possible accuracy, wind measurements at the precise site where the turbine will be located are needed. If the rotor, is relatively small, measurements at the hub height (or middle of the rotor) will suffice; for larger rotors, simultaneous measurements at several heights will be required to model the wind speed variation across the rotor disk.

Complete characterization of the wind resource at a specific site is a very time-consuming and expensive effort. A comprehensive site characterization normally requires measuring the wind for at least 12 months, according to Wegley et al. (1980). Even after acquiring the data, questions remain. Long-term data from the nearest airport or long-term weather recording station can help determine whether or not this was a normal wind year for the site and whether the winds were higher or lower than the long-term average (Gipe, 1993). If the costs and time requirements for on-site measurement are excessive, Wegley et al. (1980) and Gipe (1993) give suggestions on methods of using available data from nearby sites, together with a minimum of on-site data to estimate site wind speed.

In the absence of actual site data a Rayleigh distribution (Equation 7.7.3) for the proper yearly average wind speed may be used to estimate the site wind speed distribution. Wind resource estimates that are made with these approximations to the site wind speed and wind distribution will contain significantly larger errors than would be found if the measured site characteristics were used. Figure 7.7.9 illustrates the discrepancies between the measured wind speed distributions at the Amarillo, TX airport and a Bushland, TX test site 20 miles away, and a Rayleigh distribution for the same average wind speed. The measured distribution at the airport has far more energy in the 9 to 12 m/sec range, and this will yield far more energy production than that estimated with the Rayleigh distribution.

Wind Energy Capture Potential

With a wind speed distribution and a turbine power curve (power generated as a function of wind speed) properly adjusted for the local air density, the wind energy potential, or gross annual energy production for a specific site, can be estimated as:

$$\text{Energy} = 8760 \sum_{i=1}^{n} f(U_i) \cdot \Delta U_i \cdot P(U_i) \tag{7.7.4}$$

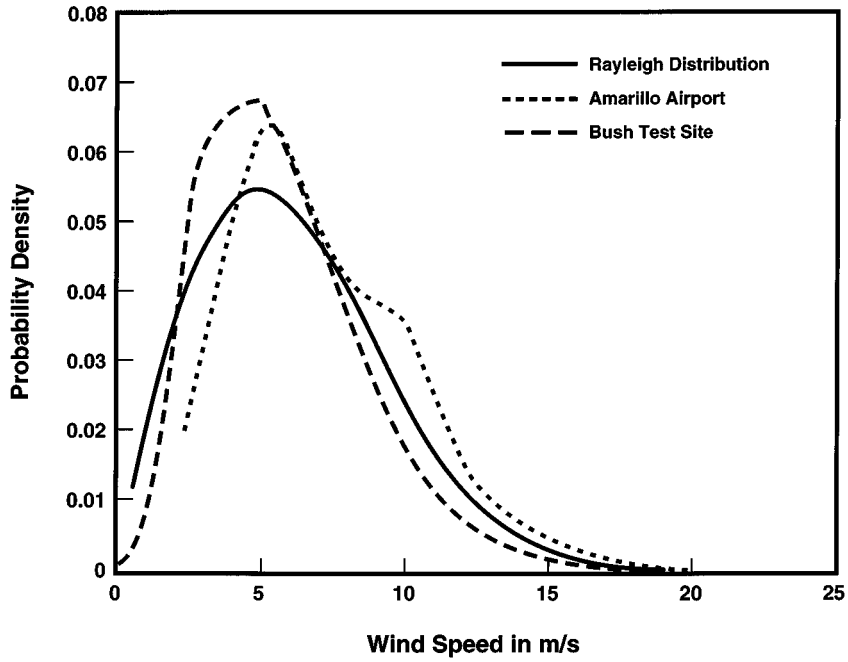

FIGURE 7.7.9 Rayleigh and measured wind frequency distributions.

where 8760 is the number of hours in a year, n is the number of wind speeds considered, $f(U_i) \cdot \Delta U_i$ is the probability of a given wind speed occurring, and $P(U_i)$ is the power produced by the turbine at wind speed U_i. If the measured wind speed distribution is used, replace $f(U_i) \cdot \Delta U_i$ by the probability for the appropriate wind speed (the height of the histogram bar for that wind speed times the wind speed increment). If the power curve is for the turbine aerodynamic or rotor power rather than the electrical power, subtract 10% to approximate the losses due to the turbine bearings and drivetrain. To estimate the net annual energy production, or amount of energy actually delivered to the grid by the turbine, subtract an additional 10% to approximate the electrical losses between the turbine and the grid, the control system losses, and the decreased performance due to dirty blades. If the turbine will be operated in an array, subtract another 5% for array-induced losses.

Environmental Impacts

Although wind turbines generate electricity without causing any air pollution or creating any radioactive wastes, they have an impact on the environment. Wind turbines require a lot of land, but most of that land (90% or so) will remain available for other uses such as farming or livestock grazing. Roads must be built to facilitate installation and maintenance of the wind turbines. Turbines generate noise, but newer turbines are much quieter than earlier models. Current industry standards call for characterization of turbine noise production and rate of decay with distance from the turbine as part of the turbine-testing process. In addition, turbines are large structures that will significantly change the landscape where they are installed, creating visual impact pollution. Another environmental issue facing the wind industry is that of bird deaths as a result of collisions with wind turbines. Preliminary studies indicate that the magnitude of the problem is site specific, and avoiding known bird migration corridors and areas of high bird concentrations when siting turbines and using tubular towers to offer fewer bird perch sites will help to minimize bird collisions with new turbine installations.

Defining Terms

Wind energy potential: The total amount of energy that can actually be extracted from the wind, taking into account the efficiency of the wind turbines and the land available for wind turbine siting.

Wind energy resource: The total amount of energy that is present in the wind.

Wind shear: The change in wind velocity with increasing height above the ground.

Wind speed distribution: The frequency of occurrence of each wind speed over the course of a year. This is site specific.

Further Information

Wind Characteristics — An Analysis for the Generation of Wind Power, by J. S. Rohatti and V. Nelson, Alternative Energy Institute, West Texas A&M University, Canyon, TX, 1994, is an excellent source for additional information on the wind resource. *Wind Turbine Technology, Fundamental Concepts of Wind Turbine Engineering*, D. Spera, editor, ASME Press, New York, 1994, contains a wealth of information on wind energy history and technology, together with extensive reference lists. Resources for European-community countries are given in the *European Wind Atlas*, by I. Troen and E. L. Petersen, Risø National Laboratory, Roskilde, Denmark, 1989.

7.8 Geothermal Energy

Joel L. Renner and Marshall J. Reed

The word *Geothermal* comes from the combination of the Greek words *gê*, meaning Earth, and *thérm*, meaning heat. Quite literally, geothermal energy is the heat of the Earth. Geothermal resources are concentrations of the Earth's heat, or geothermal energy, that can be extracted and used economically now or in the reasonable future. Currently, only concentrations of heat associated with water in permeable rocks can be exploited. Heat, fluid, and permeability are the three necessary components of all exploited geothermal fields. This section of Energy Resources will discuss the mechanisms for concentrating heat near the surface, the types of geothermal systems, and the environmental aspects of geothermal production.

Heat Flow

Temperature within the Earth increases with depth at an average of about 25°C/km. Spatial variations of the thermal energy within the deep crust and mantle of the Earth give rise to concentrations of thermal energy near the surface of the Earth that can be used as an energy resource. Heat is transferred from the deeper portions of the Earth by conduction of heat through rocks, by the movement of hot, deep rock toward the surface, and by deep circulation of water. Most high-temperature geothermal resources are associated with concentrations of heat caused by the movement of magma (melted rock) to near-surface positions where the heat is stored.

In older areas of continents, such as much of North America east of the Rocky Mountains, heat flow is generally 40 to 60 mWm^{-2} (milliwatts per square meter). This heat flow coupled with the thermal conductivity of rock in the upper 4 km of the crust yields subsurface temperatures of 90 to 110°C at 4 km depth in the Eastern United States. Heat flow within the Basin and Range (west of the Rocky Mountains) is generally 70 to 90 mWm^{-2}, and temperatures are generally greater than 110°C at 4 km. There are large variations in the Western United States, with areas of heat flow greater than 100 mWm^{-2} and areas which have generally lower heat flow such as the Cascade and Sierra Nevada Mountains and the West Coast. A more detailed discussion of heat flow in the United States is available in Blackwell et al. (1991).

Types of Geothermal Systems

Geothermal resources are hydrothermal systems containing water in pores and fractures. Most hydrothermal resources contain liquid water, but higher temperatures or lower pressures can create conditions where steam and water or only steam are the continuous phases (White et al., 1971; Truesdell and White, 1973). All commercial geothermal production is expected to be restricted to hydrothermal systems for many years because of the cost of artificial addition of water. Successful, sustainable geothermal energy usage depends on reinjection of the maximum quantity of produced fluid to augment natural recharge of hydrothermal systems.

Other geothermal systems that have been investigated for energy production are (1) geopressured-geothermal systems containing water with somewhat elevated temperatures (above normal gradient) and with pressures well above hydrostatic for their depth; (2) magmatic systems, with temperature from 600 to 1400°C; and (3) hot dry rock geothermal systems, with temperatures from 200 to 350°C, that are subsurface zones with low initial permeability and little water. These types of geothermal systems cannot be used for economic production of energy at this time.

Geothermal Energy Potential

The most recent report (Huttrer, 1995) shows that 6800 MW_e (megawatts electric) of geothermal electric generating capacity is on-line in 21 countries (Table 7.8.1). The expected capacity in the year 2000 is

9960 MW_e. Table 7.8.2 lists the electrical capacity of U.S. geothermal fields. Additional details of the U.S. generating capacity are available in DiPippo (1995) and McClarty and Reed (1992). Geothermal resources also provide energy for agricultural uses, heating, industrial uses, and bathing. Freeston (1995) reports that 27 countries had a total of 8228 MW_t (megawatts thermal) of direct use capacity. The total energy used is estimated to be 105,710 TJ/year (terajoules per year). The thermal energy used by the ten countries using the most geothermal resource for direct use is listed in Table 7.8.3.

The U.S. Geological Survey has prepared assessments of the geothermal resources of the U.S. Muffler(1979) estimated that the identified hydrothermal resource, that part of the **identified accessible base** that could be extracted and utilized at some reasonable future time, is 23,000 MW_e for 30 years. This resource would operate power plants with an aggregate capacity of 23,000 MW_e for 30 years. The undiscovered U.S. resource (inferred from knowledge of Earth science) is estimated to be 95,000 to 150,000 MW_e for 30 years.

Geothermal Applications

In 1991, geothermal electrical production in the United States was 15,738 GWh (gigawatt hours), and the largest in the world (McLarty and Reed, 1992).

Most geothermal fields are water dominated, where liquid water at high temperature, but also under high (hydrostatic) pressure, is the pressure-controlling medium filling the fractured and porous rocks of the reservoir. In water-dominated geothermal systems used for electricity, water comes into the wells from the reservoir, and the pressure decreases as the water moves toward the surface, allowing part of the water to boil. Since the wells produce a mixture of flashed steam and water, a separator is installed

between the wells and the power plant to separate the two phases. The flashed steam goes into the turbine to drive the generator, and the water is injected back into the reservoir.

Many water-dominated reservoirs below 175°C used for electricity are pumped to prevent the water from boiling as it is circulated through heat exchangers to heat a secondary liquid that then drives a turbine to produce electricity. **Binary geothermal plants** have no emissions because the entire amount of produced geothermal water is injected back into the underground reservoir. The identified reserves of lower-temperature geothermal fluids are many times greater than the reserves of high-temperature fluids, providing an economic incentive to develop more-efficient power plants.

Warm water, at temperatures above 20°C, can be used directly for a host of processes requiring thermal energy. Thermal energy for swimming pools, space heating, and domestic hot water are the most widespread uses, but industrial processes and agricultural drying are growing applications of geothermal use. In 1995, the United States was using over 500 TJ/year of energy from geothermal sources for direct use (Lienau, et al., 1995). The cities of Boise, ID; Elko, NV; Klamath Falls, OR; and San Bernardino and Susanville, CA have geothermal district-heating systems where a number of commercial and residential buildings are connected to distribution pipelines circulating water at 54 to 93°C from the production wells (Rafferty, 1992).

The use of geothermal energy through ground-coupled heat pump technology has almost no impact on the environment and has a beneficial effect in reducing the demand for electricity. Geothermal heat pumps use the reservoir of constant temperature, shallow groundwater and moist soil as the heat source during winter heating and as the heat sink during summer cooling. The energy efficiency of geothermal heat pumps is about 30% better than that of air-coupled heat pumps and 50% better than electric-resistance heating. Depending on climate, advanced geothermal heat pump use in the United States reduces energy consumption and, correspondingly, power-plant emissions by 23 to 44% compared to advanced air-coupled heat pumps, and by 63 to 72% compared with electric-resistance heating and standard air conditioners (L'Ecuyer et al., 1993).

Environmental Constraints

Geothermal energy is one of the cleaner forms of energy now available in commercial quantities. Geothermal energy use avoids the problems of acid rain, and it greatly reduces greenhouse gas emissions and other forms of air pollution. Potentially hazardous elements produced in geothermal brines are removed from the fluid and injected back into the producing reservoir. Land use for geothermal wells, pipelines, and power plants is small compared with land use for other extractive energy sources such as oil, gas, coal, and nuclear. Geothermal development projects often coexist with agricultural land uses, including crop production or grazing. The average geothermal plant occupies only 400 m^2 for the production of each gigawatt hour over 30 years (Flavin and Lenssen, 1991). The low life-cycle land use of geothermal energy is many times less than the energy sources based on mining, such as coal and nuclear, which require enormous areas for the ore and processing before fuel reaches the power plant. Low-temperature applications usually are no more intrusive than a normal water well. Geothermal development will serve the growing need for energy sources with low atmospheric emissions and proven environmental safety.

All known geothermal systems contain aqueous carbon dioxide species in solution, and when a steam phase separates from boiling water, CO_2 is the dominant (over 90% by weight) **noncondensible gas.** In most geothermal systems, noncondensible gases make up less than 5% by weight of the steam phase. Thus, for each megawatt-hour of electricity produced in 1991, the average emission of carbon dioxide by plant type in the United States was 990 kg from coal, 839 kg from petroleum, 540 kg from natural gas, and 0.48 kg from geothermal flashed-steam (Colligan, 1993). Hydrogen sulfide can reach moderate concentrations of up to 2% by weight in the separated steam phase from some geothermal fields.

At The Geysers geothermal field in California, either the Stretford process or the incineration and injection process is used in geothermal power plants to keep H_2S emissions below 1 ppb (part per billion). Use of the Stretford process in many of the power plants at The Geysers results in the production and disposal of about 13,600 kg of sulfur per megawatt of electrical generation per year. Figure 7.8.1, shows a typical system used in the Stretford process at The Geysers (Henderson and Dorighi, 1989).

The incineration process burns the gas removed from the steam to convert H_2S to SO_2, the gases are absorbed in water to form SO_3^{-2} and SO_4^{-2} in solution, and iron chelate is used to form $S_2O_3^{-2}$ (Bedell and Hammond, 1987). Figure 7.8.2 shows an incineration abatement system (Bedell and Hammond, 1987). The major product from the incineration process is a soluble thiosulfate which is injected into the reservoir with the condensed water used for the reservoir pressure-maintenance program. Sulfur emissions for each megawatt-hour of electricity produced in 1991, as SO_2 by plant type in the United

States was 9.23 kg from coal, 4.95 kg from petroleum, and 0.03 kg from geothermal flashed-steam (Colligan, 1993). Geothermal power plants have none of the nitrogen oxide emissions that are common from fossil fuel plants.

The waters in geothermal reservoirs range in composition from 0.1 to over 25 wt% dissolved solutes. The geochemistry of several representative geothermal fields is listed in Table 7.8.4. Temperatures up to 380°C have been recorded in geothermal reservoirs in the United States, and many chemical species have a significant solubility at high temperature. For example, all of the geothermal waters are saturated

in silica with respect to quartz. As the water is produced, silica becomes supersaturated, and, if steam is flashed, the silica becomes highly supersaturated. Upon cooling, amorphous silica precipitates from the supersaturated solution. The high flow rates of steam and water from geothermal wells usually prevent silica from precipitating in the wells, but careful control of fluid conditions and residence time is needed to prevent precipitation in surface equipment. Silica precipitation is delayed in the flow stream until the water reaches a crystallizer or settling pond. There the silica is allowed to settle from the water, and the water is then pumped to an injection well.

Operating Conditions

For electrical generation, typical geothermal wells in the United States have production casing pipe in the reservoir with an inside diameter of 29.5 cm, and flow rates usually range between 150,000 and 350,000 kg/hr of total fluid (Mefferd, 1991). The geothermal fields contain water, or water and steam, in the reservoir, and production rates depend on the amount of boiling in the reservoir and the well on the way to the surface. The Geysers geothermal field in California has only steam filling fractures in the reservoir, and, in 1987 (approximately 30 years after production began), the average well flow had decreased to 33,000 kg/hr of dry steam (Mefferd, 1991) supplying the maximum field output of 2000 MW_2. Continued pressure decline has decreased the production.

In the Coso geothermal field near Ridgecrest, CA initial reservoir conditions formed a steam cap at 400 to 500 m depth, a two-phase (steam and water) zone at intermediate depth, and a liquid water zone at greater depth. Enthalpy of the fluid produced from individual wells ranges from 840 to 2760 kJ/kg (Hirtz et al., 1993), reservoir temperatures range from 200 to 340°C, and the fluid composition flowing from the reservoir into the different wells ranges from 100% liquid to almost 100% steam. Production wells have a wide range of flow rates, but the average production flow rate is 135,000 kg/hr (Mefferd, 1991). Much of the produced fluid is evaporated to the atmosphere in the cooling towers of the power plant, and only about 65% of the produced mass is available for injection into the reservoir at an average rate of 321,000 kg/hr (Mefferd, 1991).

The Salton Sea geothermal system in the Imperial Valley of southern California has presented some of the most difficult problems in brine handling. Water is produced from the reservoir at temperatures between 300 and 350°C and total dissolved solid concentrations between 20 and 25% by weight at an average rate of 270,000 kg/hr (Mefferd, 1991). When up to 20% of the mass of brine boils during production, the salts are concentrated in the brine causing supersaturation with respect to several solid phases. Crystallizers and clarifier and thickener tanks are needed to remove solids from the injection water. Figure 7.8.3 shows the flow stream for removal of solids from the vapor and brine (Signorotti and Hunter, 1992). Other power plants use the addition of acid to lower the pH and keep the solutes in solution (Signorotti and Hunter, 1992). The output from the crystallizers and clarifiers is a slurry of brine and amorphous silica. The methods used to dewater the salt and silica slurry from operations in the Salton Sea geothermal system are described by Benesi (1992). Approximately 80% of the produced water is injected into the reservoir at an average rate of 310,000 kg/hr.

Defining Terms

Binary geothermal plant: A geothermal electric generating plant that uses the geothermal fluid to heat a secondary fluid that is then expanded through a turbine.

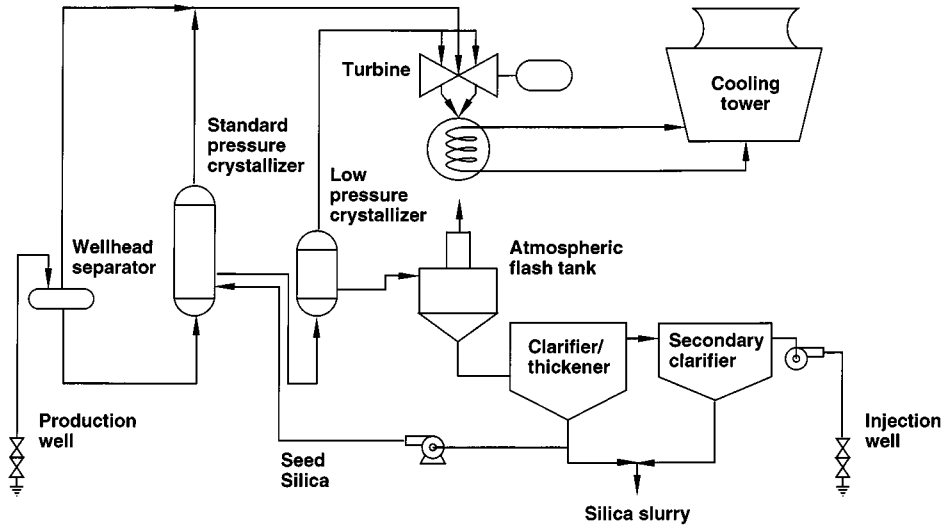

FIGURE 7.8.3 The flow stream for removal of solids from the vapor and brine in typical power plants in the Salton Sea geothermal field. (Modified from the diagram of Signorotti, V. and Hunter, C.C., *Geotherm. Resour. Counc. Bull.*, 21(9), 277–288, 1992).

Identified accessible base: That part of the thermal energy of the Earth that is shallow enough to be reached by production drilling in the foreseeable future. *Identifed* refers to concentrations of heat that have been characterized by drilling or Earth science evidence. Additional discussion of this and other resource terms can be found in Muffler (1979).

Noncondensible gases: Gases exhausted from the turbine into the condenser that do not condense into the liquid phase.

8.1 Steam Power Plant

Lawrence Conway

Introduction

This section provides an understanding, at an overview level, of the steam power cycle. References were selected for the next level of study if required. There are noteworthy omissions in the section: site selection, fuel handling, civil engineering-related activities (like foundations), controls, and nuclear power.

Thermal power cycles take many forms, but the majority are fossil steam, nuclear, simple cycle gas turbine, and combined cycle. Of those listed, conventional coal-fired steam power is predominant. This is especially true in developing third-world countries that either have indigenous coal or can import coal inexpensively. These countries make up the largest new product market. A typical unit is shown in Figure 8.1.1.

The Rankine cycle is overwhelmingly the preferred cycle in the case of steam power and is discussed first.

Topping and bottoming cycles, with one exception, are rare and mentioned only for completeness. The exception is the combined cycle, where the steam turbine cycle is a bottoming cycle. In the developed countries, there has been a move to the combined cycle because of cheap natural gas or oil. Combined cycles still use a reasonably standard steam power cycle except for the boiler. The complexity of a combined cycle is justified by the high thermal efficiency, which will soon approach 60%.

The core components of a steam power plant are boiler, turbine, condenser and feedwater pump, and generator. These are covered in successive subsections.

The final subsection is an example of the layout/and contents of a modern steam power plant.

As a frame of reference for the reader, the following efficiencies/effectivenesses are typical of modern fossil fuel steam power plants. The specific example chosen had steam conditions of 2400 psia, 1000°F main steam temperature, 1000°F reheat steam temperature: boiler thermal 92; turbine/generator thermal 44; turbine isentropic 89; generator 98.5; boiler feedwater pump and turbine combined isentropic 82; condenser 85; plant overall 34 (Carnot 64).

Nuclear power stations are so singular that they are worthy of a few closing comments. Modern stations are all large, varying from 600 to 1500 MW. The steam is both low temperature and low pressure (~600°F and ~1000 psia), compared with fossil applications, and hovers around saturation conditions

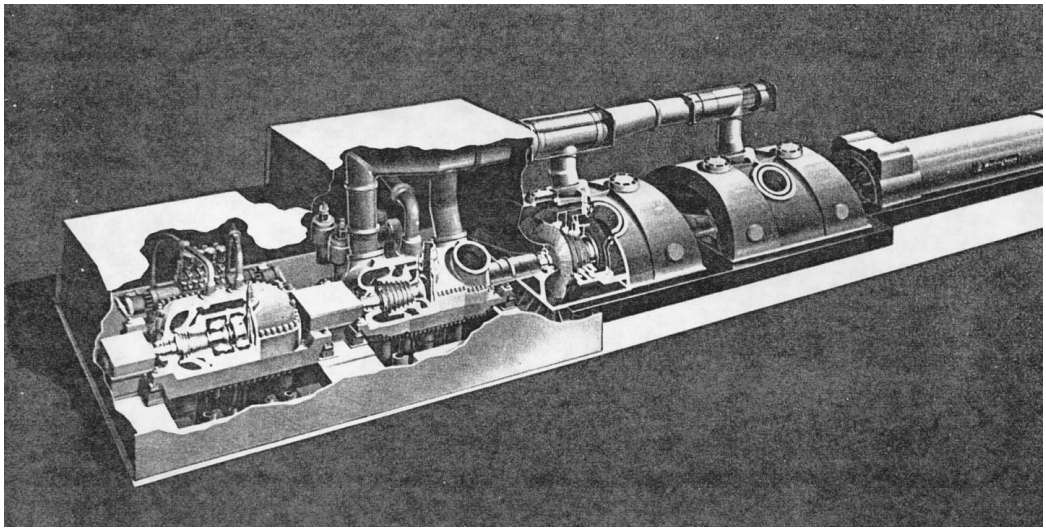

FIGURE 8.1.1 Modern steam turbine generator.

or is slightly superheated. Therefore, the boiler(s), superheater equivalent (actually a combined moisture separator and reheater), and turbines are unique to this cycle. The turbine generator thermal efficiency is around 36%.

Rankine Cycle Analysis

Modern steam power plants are based on the Rankine cycle. The basic, ideal Rankine cycle is shown in Figure 8.1.2. The ideal cycle comprises the processes from state 1:

1–2: Saturated liquid from the condenser at state 1 is pumped isentropically (i.e., $S_1 = S_2$) to state 2 and into the boiler.
2–3: Liquid is heated at constant pressure in the boiler to state 3 (saturated steam).
3–4: Steam expands isentropically (i.e., $S_3 = S_4$) through the turbine to state 4 where it enters the condenser as a wet vapor.
4–1: Constant-pressure transfer of heat in the condenser to return the steam back to state 1 (saturated liquid).

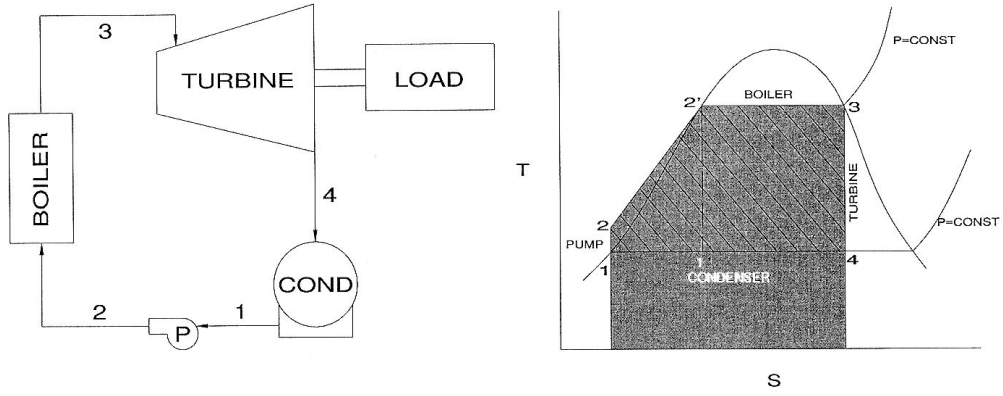

FIGURE 8.1.2 Basic Rankine cycle.

If changes in kinetic and potential energy are neglected, the total heat added to the rankine cycle can be represented by the shaded area on the T-S diagram in Figure 8.1.2, while the work done by this cycle can be represented by the crosshatching within the shaded area. The thermal efficiency of the cycle (η) is defined as the work (W_{NET}) divided by the heat input to the cycle (Q_H).

$$\eta = W_{NET}/Q_H = \left(h_3 - h_4\right)/\left(h_3 - h_2\right)$$

The Rankine cycle is preferred over the Carnot cycle for the following reasons:

The heat transfer process in the boiler has to be at constant temperature for the Carnot cycle, whereas in the Rankine cycle it is superheated at constant pressure. Superheating the steam can be achieved in the Carnot cycle during heat addition, but the pressure has to drop to maintain constant temperature. This means the steam is expanding in the boiler while heat added which is not a practical method.

The Carnot cycle requires that the working fluid be compressed at constant entropy to boiler pressure. This would require taking wet steam from point 1′ in Figure 8.1.2 and compressing it to saturated liquid condition at 2′. A pump required to compress a mixture of liquid and vapor isentropically is difficult to design and operate. In comparison, the Rankine cycle takes the saturated liquid and compresses it to boiler pressure. This is more practical and requires much less work.

The efficiency of the Rankine cycle can be increased by utilizing a number of variations to the basic cycle. One such variation is superheating the steam in the boiler. The additional work done by the cycle is shown in the crosshatched area in Figure 8.1.3.

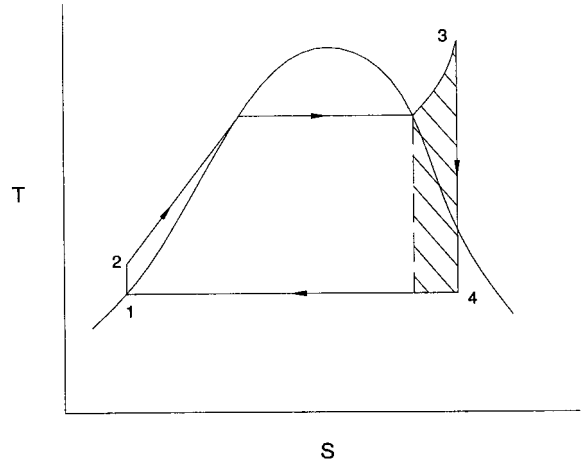

FIGURE 8.1.3 Rankine cycle with superheat.

The efficiency of the Rankine cycle can also be increased by increasing the pressure in the boiler. However, increasing the steam generator pressure at a constant temperature will result in the excess moisture content of the steam exiting the turbine. In order to take advantage of higher steam generator pressures and keep turbine exhaust moistures at safe values, the steam is expanded to some intermediate pressure in the turbine and then reheated in the boiler. Following reheat, the steam is expanded to the cycle exhaust pressure. The reheat cycle is shown in Figure 8.1.4.

Another variation of the Rankine cycle is the regenerative cycle, which involves the use of feedwater heaters. The regenerative cycle regains some of the irreversible heat lost when condensed liquid is pumped directly into the boiler by extracting steam from various points in the turbine and heating the condensed liquid with this steam in feedwater heaters. Figure 8.1.5 shows the Rankine cycle with regeneration.

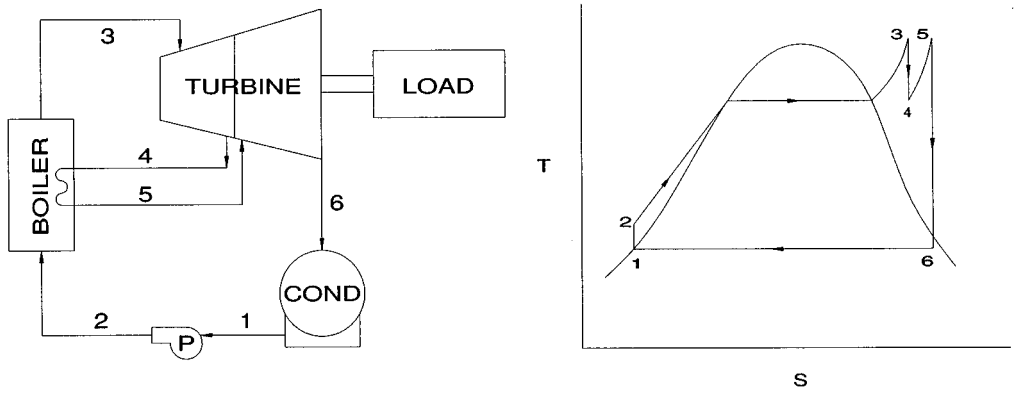

FIGURE 8.1.4 Rankine cycle with reheat.

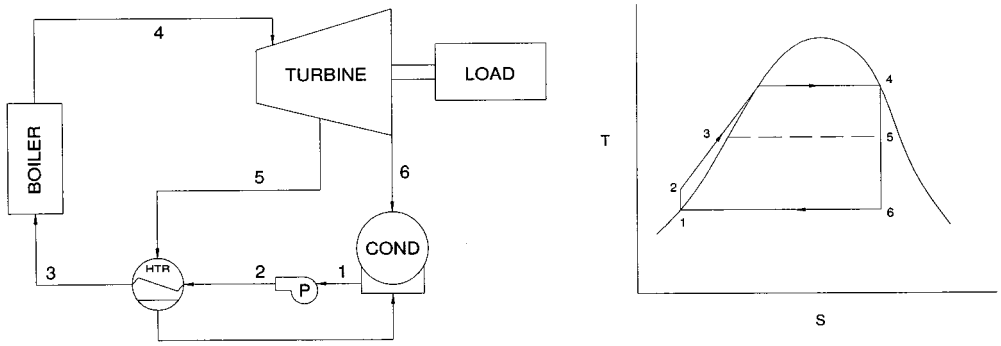

FIGURE 8.1.5 Rankine cycle with regeneration.

The actual Rankine cycle is far from ideal as there are losses associated with the cycle. They include the piping losses due to friction and heat transfer, turbine losses associated with steam flow, pump losses due to friction, and condenser losses when condensate is subcooled. The losses in the compression (pump) and expansion process (turbine) result in an increase in entropy. Also, there is lost energy in heat addition (boiler) and rejection (condenser) processes as they occur over a finite temperature difference.

Most modern power plants employ some variation of the basic Rankine cycle in order to improve thermal efficiency. For larger power plants, economies of scale will dictate the use of one or all of the variations listed above to improve thermal efficiency. Power plants in excess of 200,000 kW will in most cases have 300°F superheated steam leaving the boiler reheat, and seven to eight stages of feedwater heating.

Topping and Bottoming Cycles

Steam Rankine cycles can be combined with topping and/or bottoming cycles to form binary thermodynamic cycles. These topping and bottoming cycles use working fluids other than water. Topping cycles change the basic steam Rankine cycle into a binary cycle that better resembles the Carnot cycle and improves efficiency. For conventional steam cycles, state-of-the-art materials allow peak working fluid temperatures higher than the supercritical temperature for water. Much of the energy delivered into the cycle goes into superheating the steam, which is not a constant-temperature process. Therefore, a significant portion of the heat supply to the steam cycle occurs substantially below the peak cycle temperature. Adding a cycle that uses a working fluid with a boiling point higher than water allows more of the heat supply to the thermodynamic cycle to be near the peak cycle temperature, thus improving efficiency. Heat rejected from the topping cycle is channeled into the lower-temperature steam cycle. Thermal energy not converted to work by the binary cycle is rejected to the ambient-temperature reservoir. Metallic substances are the working fluids for topping cycles. For example, mercury was used as the topping cycle fluid in the 40-MW plant at Schiller, New Hampshire. This operated for a period of time but has since been dismantled. Significant research and testing has also been performed over the years toward the eventual goal of using other substances, such as potassium or cesium, as a topping cycle fluid.

Steam power plants in a cold, dry environment cannot take full advantage of the low heat rejection temperature available. The very low pressure to which the steam would be expanded to take advantage of the low heat sink temperature would increase the size of the low-pressure (LP) turbine to such an extent that it is impractical or at least inefficient. A bottoming cycle that uses a working fluid with a vapor pressure higher than water at ambient temperatures (such as ammonia or an organic fluid) would enable smaller LP turbines to function efficiently. Hence, a steam cycle combined with a bottoming cycle may yield better performance and be more cost-effective than a stand-alone Rankine steam cycle.

Steam Boilers

A boiler, also referred to as a steam generator, is a major component in the plant cycle. It is a closed vessel that efficiently uses heat produced from the combustion of fuel to convert water to steam. Efficiency is the most important characteristic of a boiler since it has a direct bearing on electricity production.

Boilers are classified as either drum-type or once-through. Major components of boilers include an economizer, superheaters, reheaters, and spray attemperators.

Drum-Type Boilers

Drum-type boilers (Figure 8.1.6) depend on constant recirculation of water through some of the components of the steam/water circuit to generate steam and keep the components from overheating. Drum-type boilers circulate water by either natural or controlled circulation.

Natural Circulation. Natural circulation boilers use the density differential between water in the downcomers and steam in the waterwall tubes for circulation.

Controlled Circulation. Controlled circulation boilers utilize boiler-water-circulating pumps to circulate water through the steam/water circuit.

Once-Through Boilers

Once-through boilers, shown in Figure 8.1.7, convert water to steam in one pass through the system.

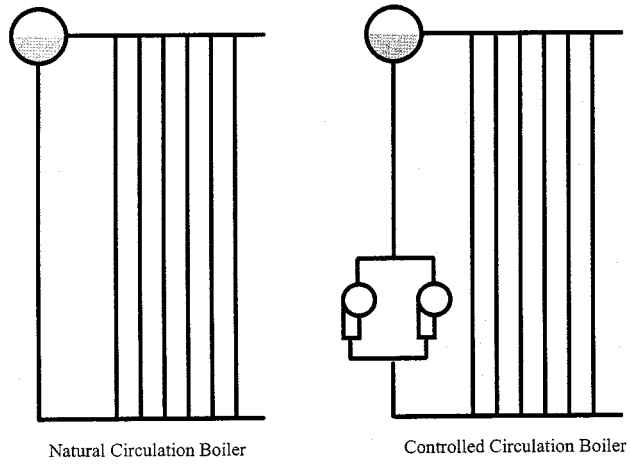

FIGURE 8.1.6 Drum boilers.

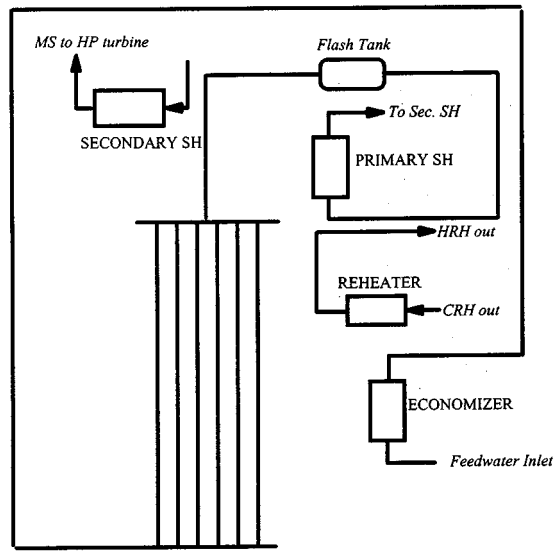

FIGURE 8.1.7 Once-through boilers.

Major Boiler Components

Economizer. The economizer is the section of the boiler tubes where feedwater is first introduced into the boiler and where flue gas is used to raise the temperature of the water.

Steam Drum (Drum Units Only). The steam drum separates steam from the steam/water mixture and keeps the separated steam dry.

Superheaters. Superheaters are bundles of boiler tubing located in the flow path of the hot gases that are created by the combustion of fuel in the boiler furnace. Heat is transferred from the combustion gases to the steam in the superheater tubes.

Superheaters are classified as primary and secondary. Steam passes first through the primary superheater (located in a relatively cool section of the boiler) after leaving the steam drum. There the steam receives a fraction of its final superheat and then passes through the secondary superheater for the remainder.

Reheaters. Reheaters are bundles of boiler tubes that are exposed to the combustion gases in the same manner as superheaters.

Spray Attemperators. Attemperators, also known as desuperheaters, are spray nozzles in the boiler tubes between the two superheaters. These spray nozzles supply a fine mist of pure water into the flow path of the steam to prevent tube damage from overheating. Attemperators are provided for both the superheater and reheater.

Steam Turbines

General

Each turbine manufacturer has unique features in their designs that impact efficiency, reliability, and cost. However, the designs appear similar to a non-steam-turbine engineer. Steam turbines for power plants differ from most prime movers in at least three ways. (1) All are extremely high powered, varying from about 70,000 to 2 million hp, and require a correspondingly large capital investment, which puts a premium on reliability. (2) Turbine life is normally between 30 and 40 years with minimal maintenance. (3) Turbines spend the bulk of their life at constant speed, normally 3600 or 1800 rpm for 60 Hz. These three points dominate the design of the whole power station, particularly of the steam turbine arrangement and materials.

In an earlier subsection it was shown that high steam supply temperatures make for more-efficient turbines. Even so, the range of steam conditions in modern service has narrowed because of these three points. Figure 8.1.8 shows the distribution of steam conditions of one manufacturer for turbines recently put in service. They are reasonably typical of the industry. This is one of the primary reasons that the steam turbines appear similar.

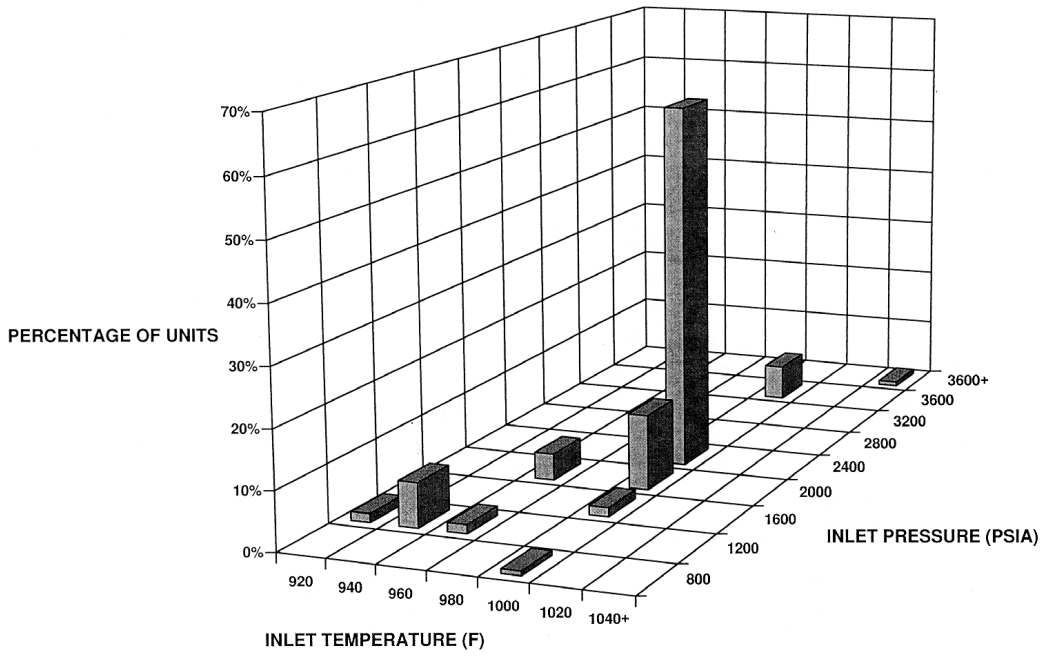

FIGURE 8.1.8 Steam turbine operating conditions.

Blading

The most highly stressed component in steam turbines are the blades. Blades are loaded by centrifugal and steam-bending forces and also harmonic excitation (from nonuniform circumferential disturbances

in the blade path). All blades are loaded by centrifugal and steam-bending loads, and, in general, blades are designed to run when the harmonic excitation is resonant with the natural modes of the blade. If harmonic excitation is permitted on very long blades, the blades become impractically big. Fortunately, as the turbine runs at constant speed, the blade modes can be tuned away from resonant conditions so that the harmonic loads are significantly reduced. This forms a split in blade design, commonly referred to as tuned and untuned blading.

Blades guide steam throughout the turbine in as smooth and collision-free a path as possible. Collisions with blades (incidence) and sudden expansions reduce the energy available for doing work. Until recently, designers would match flow conditions with radially straight blades (called parallel sided). Turbine physics does not recognize this convenience for several reasons. The most visually obvious is the difference in tangential velocity between blade hub and tip. Twisted blades better match the flow (and area) conditions. The manufacturing process was costly and this cost confined application to long blades. Now, with numerical control machine tools, twist is being spread throughout the turbine. Twisted blades are a two-dimensional adjustment for a three-dimensional steam flow. The latest blades address the full three-dimensional nature of the flow by curving in three dimensions (bowed blades). Examples of all three classes of blades are shown in Figure 8.1.9.

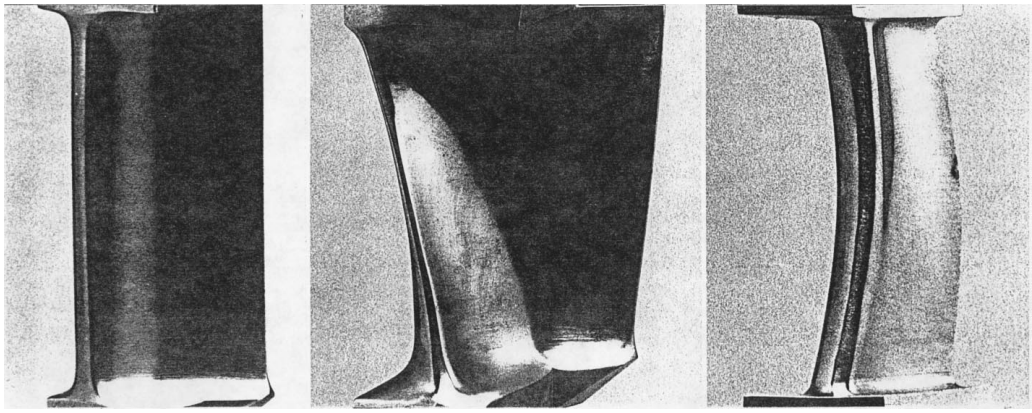

FIGURE 8.1.9 Typical steam turbine blades.

Rotors

After blades, steam turbine rotors are the second most critical component in the machine. Rotor design must account for (1) a large forging with uniform chemistry and properties in the high-strength alloys needed; (2) centrifugal force from the rotor itself and the increase from the centrifugal pull of the blades; (3) resistance to brittle fracture potentially occurring in the LP cylinder when the machine is at high speed, but the material is still not up to operational temperature; (4) creep of the high-pressure (HP) and intermediate-pressure (IP) rotors under steady high-temperature load. The life cycle is further complicated by the various transient fatigue loads occurring during load changes and start-up. Two further events are considered in rotor design: torsional and lateral vibrations caused by both harmonic steam and electrical loads. As with tuned blades, this is normally accommodated by tuning the primary modes away from running resonance.

Choosing the Turbine Arrangement

The turbine shaft would be too flexible in one piece if all the blades were to follow sequentially. It is therefore cut up into supportable lengths. The “cuts” in the shaft result in HP, IP, and LP cylinders. Manufacturers address the grouping of cylinders in many different ways, depending upon steam conditions. It is U.S. practice to combine HPs and IPs into one cylinder for the power range of about 250 to 600 MW (rare in the rest of the world). One manufacturer’s grouping, shown in Figure 8.1.10, is fairly

representative of the industry. So far, the text has discussed the steam flow as though it expanded monotonically through the turbine. This is usually not the case for two reasons. The most common steam conditions, shown in Figure 8.1.10, would cause the steam exiting the last row of blades to be very wet and cause excessive erosion. Thermal efficiency can be raised by removing the steam from the turbine, reheating, and then returning it to the blade path; this increases the "average" heat supply temperature. The turbine position for reheat is normally between the HP and IP turbines.

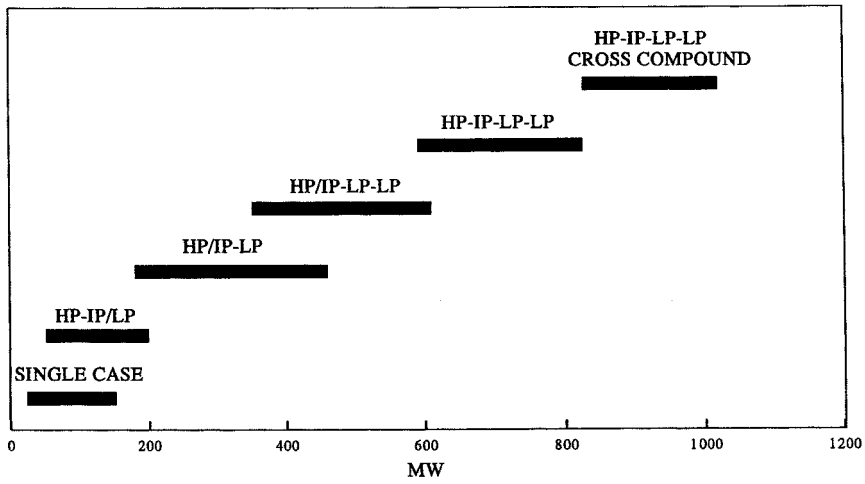

FIGURE 8.1.10 Steam turbine product combinations.

There is one further geometric arrangement. Cylinders need not be all on one shaft with a single generator at the end. A cross-compound arrangement exists in which the steam path is split into two separate parallel paths with a generator on each path. Commonly, the split will be with paths of HP-LP-generator and IP-LP-generator. Torsional and lateral vibration difficulties are more easily prevented with shorter trains, which make the foundation more compact. The primary shortcoming is the need for two generators and resultant controls.

Historically, steam turbines have been split into two classes, reaction and impulse, as explained in Basic Power Cycles. This difference in design makes an observable difference between machines. Impulse turbines have fewer, wider stages than reaction machines. As designs have been refined, the efficiencies and lengths of the machines are now about the same. For a variety of reasons, the longer blades in the LP ends are normally reaction designs. As each stage may now be designed and fabricated uniquely, the line between impulse and reaction turbines will probably disappear. Turbine blading is broadly split between machines as follows:

	Cylinder				
	HP			LP	
	Control Stage	Remainder	IP	Short Blades	End Blade(s)
Reaction turbines	Impulse	Reaction	Reaction	Reaction	Reaction
Impulse turbines	Impulse	Impulse	Impulse	Impulse	Reaction

Materials

Materials are among the most variable of all turbine parts with each manufacturer striving to improve performance by using alloying and heat-treatment techniques. It follows that accurate generalizations are difficult. Even so, the following is reasonably representative:

Item	Common Material Description								
High-temperature HP and IP blades	Moderate and cold temperature stator blades	Moderate temperature rotating blades	Cold LP rotating blades	High temperature rotors	Low temperature rotors	Hot	LP	High-temperature bolting	Cold bolting
Mod'd SS403	SS304	SS403	SS403 or 17/4 PH	1CrMoV, occasionally 12Cr	3.5 NiCrMoV	1.25Cr or 2.25Cr	Carbon, steel	SS422	B16

Cylinders and Bolting

These items are relatively straightforward, especially the LP cylinder, except for the very large sizes and precision required for the castings and fabrications. A large HP-IP cylinder has the temperature and pressure loads split between an inner and outer cylinder. In this case, finding space and requisite strength for the bolting presents a challenge for the designer.

Valves

The turbine requires many valves for speed control, emergency control, drains, hydraulics, bypasses, and other functions. Of these, there are four valves distinguished by their size and duty. They are throttle or stop, governor or control, reheat stop, and reheat interceptor.

The throttle, reheat stop, and reheat interceptor valves normally operate fully open, except for some control and emergency conditions. Their numbers and design are selected for the appropriate combination of redundancy and rapidity of action. The continuous control of the turbine is accomplished by throttling the steam through the governor valve. This irreversible process detracts from cycle efficiency. In some circumstances, the efficiency detraction is reduced by a combination of throttling and reducing the boiler pressure (normally called sliding pressure).

Heat Exchangers, Pumps, and Other Cycle Components

Heater Exchangers

Heaters. There are two classifications of condensate and feedwater heaters: the open or direct contact heater and the closed or tube-and-shell heater.

Open Heaters. In an open heater, the extraction or heating steam comes in direct contact with the water to be heated. While open heaters are more efficient than closed heaters, each requires a pump to feed the outlet water ahead in the cycle. This adds cost, maintenance, and the risk of water induction to the turbine, making the closed heater the preferred heater for power plant applications.

Closed Heaters. These employ tubes within a shell to separate the water from the heating steam (see Figure 8.1.11). They can have three separate sections where the heating of the feedwater occurs. First is the drain cooler section where the feedwater is heated by the condensing heating steam before cascading back to the next-lower-pressure heater. The effectiveness of the drain cooler is expressed as the drain cooler approach (DCA), which is the difference between the temperature of the water entering the heater and the temperature of the condensed heating steam draining from the heater shell. In the second section (condensing section), the temperature of the water is increased by the heating steam condensing around

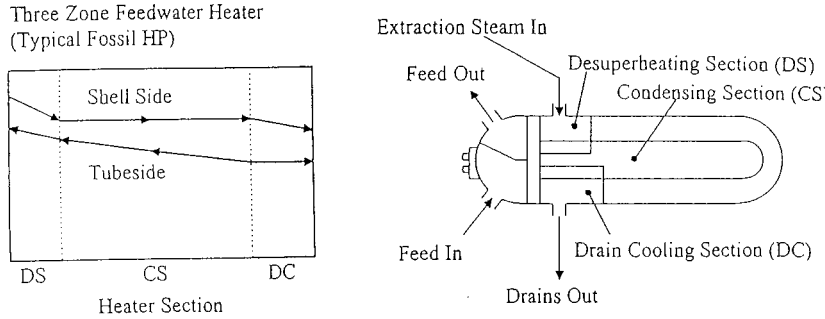

FIGURE 8.1.11 Shell and tube feedwater heater.

the tubes. In the third section (desuperheating section), the feedwater reaches its final exit temperature by desuperheating the extraction steam. Performance of the condensing and superheating sections of a heater is expressed as the terminal temperature difference (TTD). This is the difference between the saturation temperature of the extraction steam and the temperature of the feedwater exiting the heater. Desuperheating and drain cooler sections are optional depending on the location of the heater in the cycle (i.e., desuperheating is not necessary in wet extraction zones) and economic considerations.

The one exception is the deaerator (DA), which is an open heater used to remove oxygen and other gases that are insoluble in boiling water. The DA is physically located in the turbine building above all other heaters, and the gravity drain from the DA provides the prime for the boiler feed pump (BFP).

Two other critical factors considered in heater design and selection are (1) venting the heater shell to remove any noncondensable gases and (2) the protection of the turbine caused by malfunction of the heater system. Venting the shell is required to avoid air-bounding a heater, which reduces the performance or, in extreme cases, puts the heater out of service. Emergency drains to the condenser open when high water levels are present within the shell. Check valves on the heating steam line are also used, and a water detection monitor can be installed to enable operators to take prompt action when water is present.

Condenser. The steam turbines employ surface-type condensers comprising large shell-and-tube heat exchangers operating under vacuum. The condenser (1) reduces the exhaust pressure at the last-stage blade exit to extract more work from the turbine and (2) collects the condensed steam and returns it to the feedwater-heating system. Cooling water circulates from the cooling source to the condenser tubes by motor-driven pumps, which may be centrifugal, propeller, or mixed-flow type. Multiple pumps, each rated less than 100% of required pumping power, are used to allow to operation with one or more pumps out of service and operate more efficiently at part load. Cooling water is supplied from either a large heat sink water source, such as a river, or from cooling towers. The cooling in the cooling tower is assisted by evaporation of 3 to 6% of the cooling water. Airflow is natural draft (hyperbolic towers) or forced draft. The noncondensable gases are removed from the condenser by a motor-driven vacuum pump or, more frequently, steam jet air ejectors which have no moving parts.

Pumps

Condensate Pump. Condensate is removed from the hot well of the condenser and passed through the LP heater string via the condensate pump. Typically, there will be two or more vertical (larger units) or horizontal (medium and small units) motor-driven centrifugal pumps located near the condenser hot well outlet. Depending on the size of the cycle, condensate booster pumps may be used to increase the pressure of the condensate on its way to the DA.

Feedwater Booster Pump. The DA outlet supplies the feedwater booster pump which is typically a motor-driven centrifugal pump. This pump supplies the required suction head for the BFP.

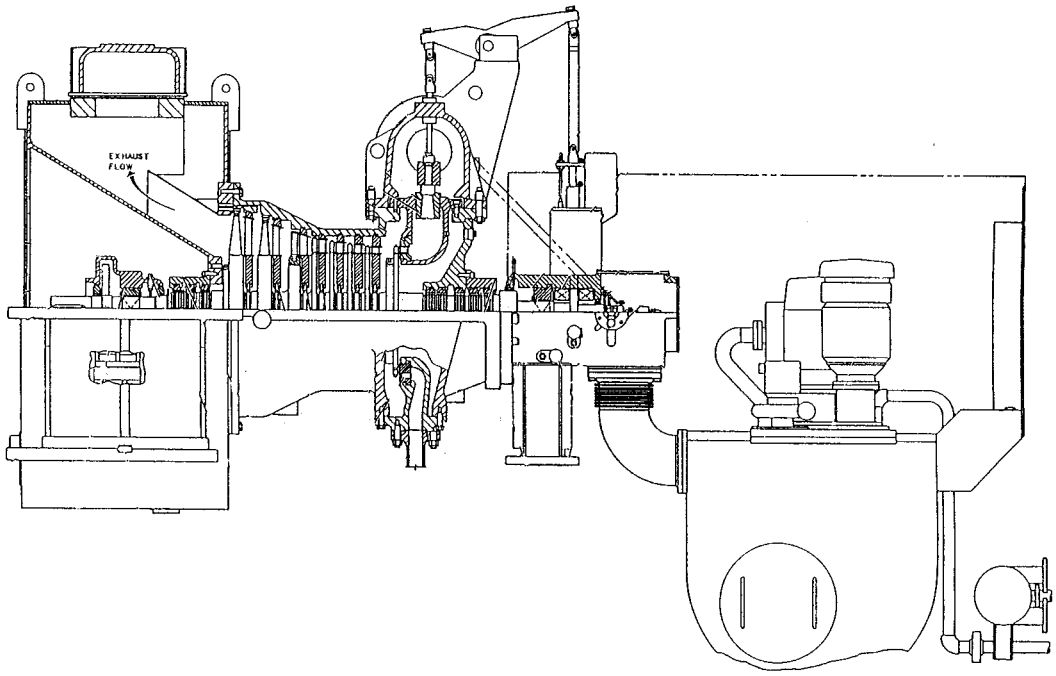

FIGURE 8.1.12 Boiler feed pump turbine.

Boiler Feed Pump. These pumps are multiple-stage centrifugal pumps, which, depending on the cycle, can be turbine or motor driven. BFP turbines (BFPT), Figure 8.1.12, are single-case units which draw steam from the main turbine cycle and exhaust to the main condenser. Typical feedpump turbines require 0.5% of the main unit power at full-load operation. Multiple pumps rated at 50 to 100% each are typically used to allow the plant to operate with one pump out of service.

Generators

The electric generator converts rotating shaft mechanical power of the steam turbine to three-phase electrical power at voltages of between 13.8 and 26 kV, depending upon the power rating. The generator comprises a system of ventilation, auxiliaries, and an exciter. Figure 8.1.13 shows an installed hydrogen-cooled generator and brushless exciter of about 400 MW. Large generators greater than 25 MW usually have a solid, high-strength steel rotor with a DC field winding embedded in radial slots machined into the rotor. The rotor assemblage then becomes a rotating electromagnet that induces voltage in stationary conductors embedded in slots in a laminated steel stator core surrounding the rotor (see Figure 8.1.14).

The stator conductors are connected to form a three-phase AC armature winding. The winding is connected to the power system, usually through a step-up transformer. Most steam turbines driven by fossil-fired steam use a two-pole generator and rotate at 3600 rpm in 60-Hz countries and 3000 rpm in

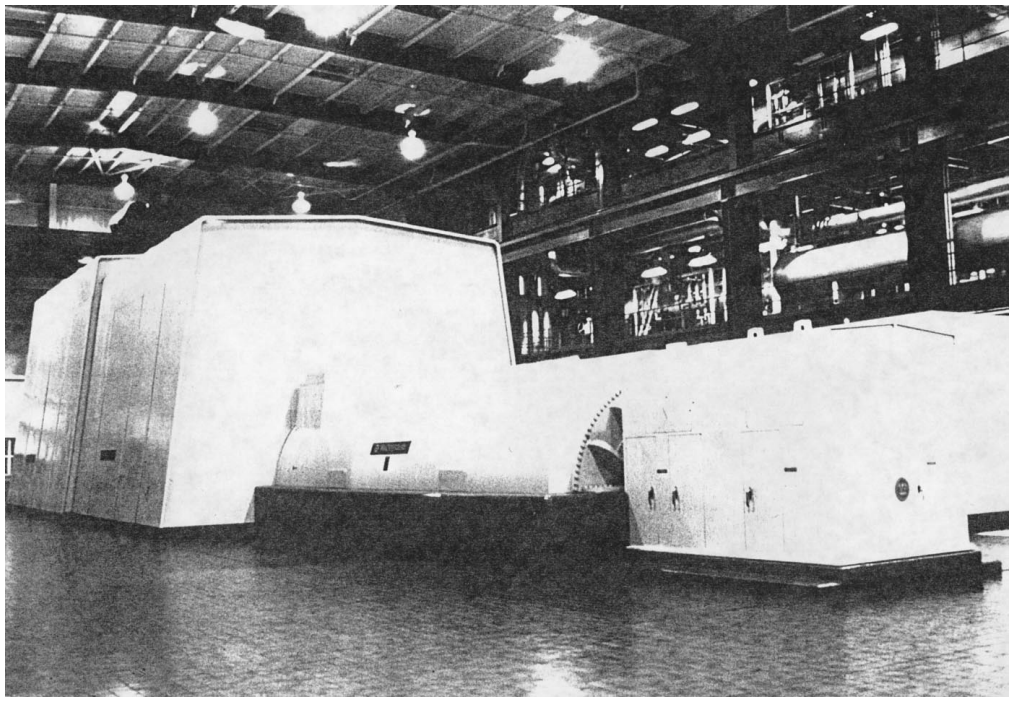

FIGURE 8.1.13 Generator and exciter.

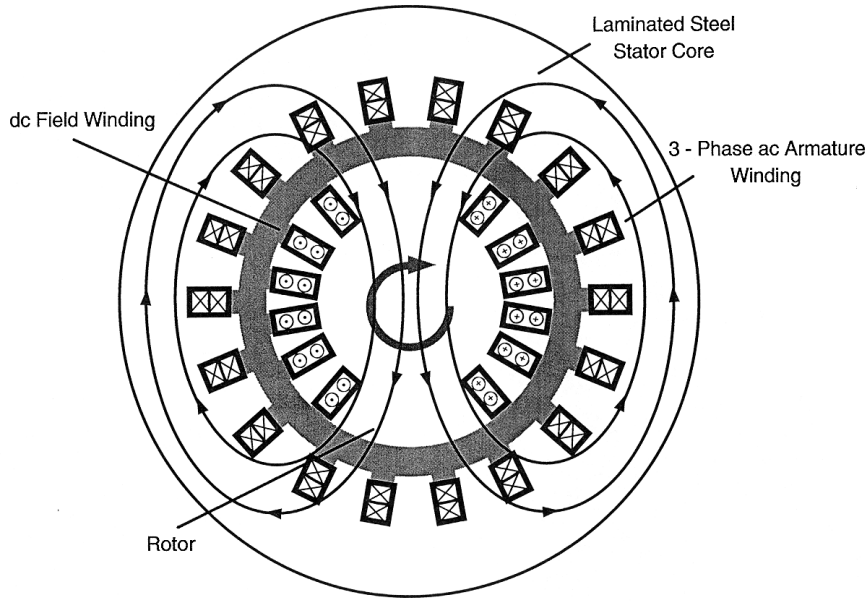

FIGURE 8.1.14 Generator magnetic paths.

50-Hz countries. Most large steam turbines driven by nuclear steam supplies use a four-pole generator and rotate at 1800 or 1500 rpm for 60 and 50 Hz, respectively.

Generator Ventilation

Cooling the active parts of the generator is so important that generators are usually classified by the type of ventilation. Air-cooled generators are used commonly up to 100 MW, though some applications exist up to 200 MW. Some use ambient air drawing air through filters and others recirculate air through air-to-water heat exchangers. Above 100 MW, most manufacturers offer hydrogen for the overall cooling, sometimes up to 1400 MW. Hydrogen has 14 times the specific heat of air and is used at lower density. This contributes to much better cooling and much lower windage and blower loss. The frame must be designed to withstand the remote circumstance of a hydrogen explosion and requires shaft seals. Hydrogen is noncombustible with purities greater than 70%. Generator purities are usually maintained well above 90%. Depending upon the manufacturer, generators with ratings above 200 to 600 MW may have water-cooled stator winding, while the remaining components are cooled with hydrogen.

Generator Auxiliaries

Large generators must have a lubrication oil system for the shaft journal bearings. Major components of this system are pumps, coolers, and a reservoir. In most cases, the turbine and generator use a combined system. For hydrogen-cooled generators, a shaft seal system and hydrogen supply system are needed. The shaft seal system usually uses oil pumped to a journal seal ring at a pressure somewhat higher than the hydrogen pressure. Its major components are pumps, coolers, and reservoir, similar to the lubrication system. The hydrogen supply system consists of a gas supply and regulators. A CO_2 supply is used to purge the generator when going from air to hydrogen or vice versa to avoid a combustible hydrogen/air mixture. The stator winding water supply again uses pumps, coolers, and a reservoir. It needs demineralizers to keep the water nonconducting and provisions to control oxygen content to avoid copper oxide corrosion which might break off and clog water passages.

Excitation

The rotor field winding must have a DC source. Many generators use rotating "collector" rings with stationary carbon brushes riding on them to transfer DC current from a stationary source, such as a thyristor-controlled "static" excitation system, to the rotor winding.

A rotating exciter, known as a brushless exciter, is used for many applications. It is essentially a small generator with a rotating rectifier and transfers DC current through the coupling into the rotor winding without the need for collectors and brushes.

Modern Steam Power Plant — An Example

The purpose of a power plant is to generate electric power. It does so by converting chemical energy contained in fuel into thermal energy in steam; thermal energy in steam into mechanical energy in the turbine/generator; and mechanical energy in the turbine/generator into electrical energy.

Operating efficiency of a typical modern steam plant is about 35 to 45%. The primary losses result from (1) heat sink losses in the condenser, (2) boiler losses, and (3) electrical losses.

Steam plant capacities have ranges from 50 to 1600 MW; however, modern plants are being designed for more than 250 MW due to energy demands, system load requirements, and economies of scale in the larger centralized stations.

Major Steam Plant Components

Steam plants comprise three major components (1) boiler, (2) turbine, and (3) main steam condenser. The boiler and turbine are covered in earlier subsections and neither will be repeated here. A graphic of the entire fluid or work cycle is shown in Figure 8.1.15.

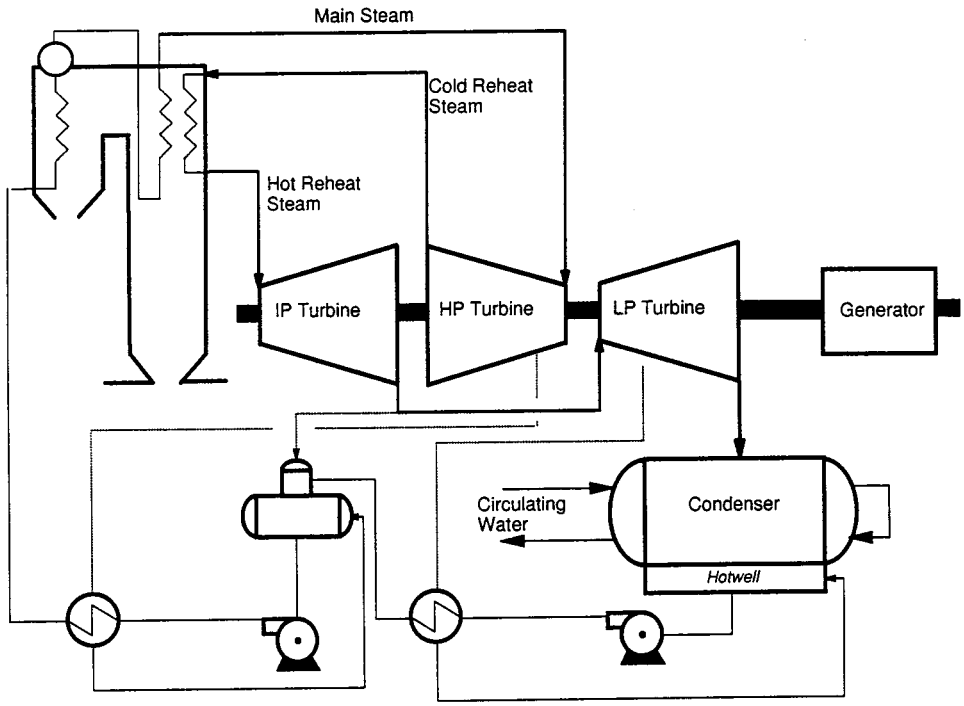

FIGURE 8.1.15 Steam power plant schematic.

Condenser. The condenser (also discussed earlier) is a large heat exchanger that takes the LP turbine exhaust steam and converts it back to water. The steam passes over a bundle of tubes located in the condenser and is cooled by the circulating water which passes through the tubes. The steam is condensed into water drops and collected in the condenser hot well. The condensate is delivered from the condenser hot well through the condensate and feedwater systems and back to the boiler where it becomes steam again.

Fuels. Coal, oil, and gas are used to fuel fossil plants. Although coal possesses the highest carbon content, it also possesses the highest sulfur, nitrogen, and ash content, thereby requiring air pollution-control equipment. Controlling these pollutants requires the installation of scrubbers for sulfur control; overfire air or gas recirculation for in-furnace nitrous oxides (NO_x) control; selective catalytic reduction (SCR) for post-combustion NO_x control; electrostatic precipitators (ESP) or baghouse for fly ash control; and pneumatic, hydraulic, or mechanical ash-handling systems for bottom ash removal. Fuel oil and natural gas are chiefly composed of compounds of hydrogen and carbon (hydrocarbons) with very low percentages of sulfur, nitrogen, and ash and do not require pollution-control equipment.

Power Plant System

Power plants comprise the following main systems: fuel handling, air handling, gas handling, main steam, reheat steam, auxiliary steam, extraction steam, condensate, feedwater, circulating water, and air removal.

Fuel-Handling System. The fuel-handling system consists of delivery, transfer, and processing. Fuel is delivered to the plant from the fuel source by truck, boat, rail (coal and oil), or pipeline (oil and gas). Once delivered, the fuel is transferred from the delivery point to various locations throughout the fuel-handling system. For coal and oil, the fuel is either transferred to storage or sent directly to the boiler. For gas, the fuel is directly transferred to the boiler without any storage. Prior to delivery to the boiler for burning, the fuel must be processed so that it will readily mix with air and burn completely. Coal must be broken down into smaller pieces by breakers and crushers. Oil requires steam, air, or mechanical atomization. Gas requires no processing.

Air/Gas-Handling Systems. Steam plants are classified as either pressurized or balance draft. Pressurized systems include forced-draft fans to provide the necessary air for fuel, an air heater to transfer heat from the exit gas to the inlet air, and a wind box where the air is stored and then directed to the individual burner ports. A balanced draft system includes all of the components of the pressurized systems and induced-draft fans to exhaust the combustion products from the boiler, thus maintaining the furnace under slightly negative pressure.

Main Steam System. The main steam system controls and regulates the flow of high-temperature, HP steam generated in the boiler furnace as it moves from the boiler to the turbine. The components in this system include main steam piping, safety valves, main steam stop valve, steam chest, and turbine control valve.

Reheat Steam System. The reheat steam system improves overall plant efficiency by increasing the energy of steam that has been exhausted from the HP turbine. Steam from the hot reheat steam system is delivered to the IP turbine. The components of the reheat steam system are cold reheat piping, the reheater section of the boiler, hot reheat piping, safety relief valves, reheat stop valves, reheater desuperheater, and intercept valves.

Auxiliary Steam System. The auxiliary steam system directs and regulates auxiliary steam from the cold reheat line to the auxiliary steam users. The auxiliary steam system users are typically steam/air preheating coils, outdoor freeze protection/heat tracing, deaerating heater pegging, turbine-driven BFP testing, turbine seals, and plant heating.

Extraction Steam System. The extraction steam system directs and regulates the flow of the extraction steam from the turbine to the feedwater heaters, BFPT, and auxiliary steam system. The extraction steam heats the feedwater that flows through the heaters, thus improving overall plant efficiency. In large steam plants, six to eight stages of feedwater heating are typical.

Condensate System. The condensate system consists of condensate pumps, LP feedwater heaters, and DA. The condensate pumps remove condensate from the main condenser hot well, increase condensate pressure, and deliver it through the LP heaters to the DA. During this process, the condensate is heated, deaerated, and chemically treated.

Feedwater System. The feedwater system consists of BFPs, HP feedwater heaters, piping, and valves. The boiler feedwater pumps deliver water from the DA storage tank, through the HP heaters, and into the boiler. Feedwater is supplied at sufficient quantities and pressure to satisfy unit demands during startups, shutdowns, and normal operation. The BFP is also the primary source of spray water for the superheater and reheater desuperheaters for control of the main and reheat steam temperatures, respectively.

BFPs can either be turbine or motor driven. Booster pumps may be required to provide additional net positive suction head (NPSH) to the main and start-up BFPs for plants designed with a low DA setting.

Circulating Water System. The circulating water system pumps cooling water through the condenser tubes at sufficient capacity, temperature, and pressure to absorb the latent heat in the LP exhaust steam.

Circulating water systems are classified as once-through systems, when a large water source is available, or recirculating systems employing cooling towers. In once-through systems, circulating water pumps deliver water from the plant water supply (river, lake, or ocean) through the condenser tubes to absorb latent heat in the exhaust steam. Water flows through the system once and is returned to its source. The major parts of this system are screens, pumps, expansion joints, valves, and piping. In recirculating systems, the cooling tower cools the heated circulating water from the main condenser by exposing it to air. The cooled water is stored in a basin located below the tower and is then circulated back through the system by the circulating water pumps.

Air Evacuation System. The air evacuation system removes air and noncondensable gases in the main steam condenser and helps maintain the vacuum created by the volume reduction of the condensing steam during normal operation. The system also establishes a normal vacuum in the condenser prior to turbine start-up.

8.2 Gas Turbines

Steven I. Freedman

Overview

Gas turbines are steady-flow power machines in which a gas (usually air) is compressed, heated, and expanded for the purpose of generating power. The term *turbine* is the component which delivers power from the gas as it expands; it is also called an expander. The term *gas turbine* refers to a complete power machine. The term gas turbine is often shortened to simply turbine, which can lead to confusion with the term for an expander.

The basic thermodynamic cycle on which the gas turbine is based is known as the Brayton cycle. Gas turbines may deliver their power in the form of torque or one of several manifestations of pneumatic power, such as the thrust produced by the high-velocity jet of an aircraft propulsion gas turbine engine.

Gas turbine machines vary in size from large, 250,000-hp utility machines, to small automobile, truck, and motorcycle turbochargers producing as little as 5 hp.

Gas turbines are used in electric power generation, propulsion, and compressor and pump drives. The most efficient power generation systems in commercial service are gas turbine combined cycle plants with power-to-fuel energy efficiencies of more than 50% (higher heating value basis) or 55% (lower heating value basis). Systems five points higher in efficiency are now under development and are being offered commercially, and systems of even higher efficiency are considered feasible.

History

The fourth quarter of the 19th century was one of great innovation in power machinery. Along with the spark-ignited gasoline engine, the compression-ignited diesel engine, and the steam turbine, engineers applied their skills to several hot-air engines. Charles Curtis received the first U.S. patent for a complete gas turbine on June 24, 1895. Aegidius Elling built the first gas turbine in 1903, which produced 11 hp.

The first commercial stationary gas turbine engineered for power generation was a 4000-kW machine built by the Brown Boverei Company in Switzerland in 1939.

Aviation provided the impetus for gas turbine development in the 1930s. In Germany, Hans von Ohain's first engine ran in March 1937. Frank Whittle's first engine ran in England in April 1937. The first airplane flight powered by a gas turbine jet engine was in Germany on August 27, 1939. The first British airplane powered by a gas turbine flew on May 15, 1941.

A Swiss railway locomotive using a gas turbine was first run in 1941. The first automobile powered by a gas turbine was a British Rover, which ran in 1950. And, in 1956, a gas turbine-powered Plymouth car drove over 3000 miles on a coast-to-coast exhibition trip in the United States.

Fuels and Firing

The first heat engines were external combustion steam engines. The combustion products never came in contact with the working fluid, so ash, corrosive impurities, and contaminants in the fuel or exhaust did not affect the internal operation of the engine. Later, internal combustion (piston) engines were developed. In these engines, a mixture of air and fuel burned in the space enclosed by the piston and cylinder walls, thereby heating the air. The air and combustion products formed the working fluid, and contacted internal engine parts.

Most gas turbines in use today are internal combustion engines and consequently require clean fuels to avoid corrosion and erosion of critical turbine components. Efforts were made to develop gas turbines rugged enough to burn residual or crude oil. However, due to the higher efficiencies obtainable by burning extremely clean fuel at higher temperatures, there is little current interest in using liquid fuel other than (clean) distillate oil in gas turbines. Interest in the use of residual oil is now centered on gasifying and cleaning these fuels prior to use.

A few externally heated gas turbines have been built for use with heavy oil, coal, nuclear reactor, radioisotope, and solar heat sources. However, none of these has become commercial. The added cost and pressure drop in the externally fired heater make externally fired gas turbines expensive. Because the working fluid temperature cannot be greater than that of the walls of the fired heater, externally fired gas turbines are substantially less efficient than modern internal combustion gas turbines with internally cooled blades.

The only internal combustion coal-fired gas turbine entering commercial service is the pressurized fluidized bed (PFB) combustion system. In the PFB, air discharged from the compressor of the turbine is used to fluidize a bed of limestone or dolomite in which coal is burned. The bed is maintained at modest temperature so that the ash in the coal does not form sticky agglomerates. Fortuitously, this temperature range also minimizes NO_x formation and allows capture of sulfur dioxide (SO_2) in the bed. Bed temperature is maintained in the desired range by immersed boiler tubes. Carryover fly ash is separated from gaseous combustion products by several stages of cyclone inertial separators and, in some cases, ceramic filters. The power turbine is modified to accommodate the combustion products, which after mechanical cleanup may still contain particles as large as 3 to 5 μm.

The most common gas turbine fuels today are natural gas and distillate oil. To avoid hot corrosion by alkali metal sulfates, the total sodium and potassium content of the fuel is typically limited to less than 5 ppm. Liquid fuels may also contain vanadium, which also causes corrosion. Fuels must be ash-free because particles larger than 3 to 5 μm rapidly erode blades and vanes. Experimental prototype gas turbines using pulverized coal pressurized combustors have not demonstrated adequate life. Hybrid systems — in which the moderate-temperature coal combustion products are mechanically cleaned and heated to higher temperature by use of a clean fuel such as natural gas or distillate oil — are the subject of ongoing development.

Efficiency

The term *efficiency* is applied not only to complete power generation machines but also to the individual compression, expansion, and combustion processes that make up the gas turbine operating cycle. Different definitions of efficiency apply in each case. In an **expansion process**, the **turbine efficiency** is the ratio of the actual power obtained to the maximum power that could have been obtained by expanding the gas reversibly and adiabatically between the same initial and final pressures.

Gas turbines typically involve high-speed gas flows, so appreciable differences exist between the static pressure and temperature and the total (or stagnation) pressure and temperature. Care must be taken in interpreting data to be sure that the pressure condition — static or stagnation — at each component interface is properly used.

Irreversible losses in one stage of an expansion process show up as heat (increased temperature) in later stages and add to the power delivered by such stages. Hence, a distinction exists between the polytropic efficiency (used to describe the efficiency of a process of differential pressure change) and the adiabatic (complete pressure change) efficiency. The efficiency of compressors and turbines based on their inlet and outlet pressures is called the isentropic or adiabatic efficiency. Unfortunately, both terms are reported in the literature, and confusion can exist regarding the meaning of the term *efficiency* .

Combustion efficiency in well-engineered and well-built internal combustion gas turbines is almost always close to 100%. The combustion losses appear as carbon monoxide, unburned hydrocarbons, and soot, which are typically below 100 ppm, with clean fuels.

The **gas turbine or engine efficiency** is the ratio of the net power produced to the energy in the fuel consumed. The principal gas turbine fuels are liquid and gaseous hydrocarbons (distillate oil and natural gas) which have high hydrogen content. Consequently, the term *engine efficiency* needs to be qualified as to whether it is based on the higher or the lower heat content of the fuel (the difference between the two being the latent heat of condensation of the water vapor in the products of combustion). Utility fuel transactions are traditionally based on higher heating values, and most engine publications presume the lower heating value of the fuel as the efficiency basis.

Engineers analyze gas turbine machines to evaluate improvements in component performance, in higher temperature and pressure ratio designs, and in innovative cycles. Ideal case cycle calculations generally assume the following:

- Air (with either constant or temperature-dependent specific heats) is the working fluid in both turbine and compressor (with equal mass flows);
- Air is the working fluid in both turbine and compressor but with the turbine mass flow greater by the amount of fuel used.

Components are modeled with or without frictional pressure drops, and heat transfer effectiveness may be ideal (unity) or actual, depending on the purpose of the analysis. Use of compressor air for cooling of high-temperature structure, nozzles, and blades are modeled in varying degrees of complexity. Two-dimensional temperature profiles or pattern factors exist. Component inlet and exit total pressure losses should be included in cycle analyses.

Gas Turbine Cycles

Gas turbine cycles are usually plotted on temperature-entropy (T-S) coordinates. Readers unfamiliar with entropy are referred to the chapter on thermodynamics. The T-S plot is useful in depicting cycles because in an adiabatic process — as is the case for turbines and compressors — the power produced or consumed is the product of the mass flow and the enthalpy change through the process. Thus, temperature difference, which is found on a T-S plot, is proportional to the power involved. Additionally, the heat exchange in a process involving zero power — such as a combustor or heat exchanger — is the product of the absolute temperature and the entropy change. On a T-S chart, the area under a process line for a combustor or heat exchanger is the heat exchanged.

The slope of a constant-pressure line on a T-S diagram is proportional to the absolute temperature. Consequently, lines of constant pressure become steeper, and diverge as the temperature increases. This illustrates that more work is obtained expanding a gas between fixed pressures at higher temperatures than at lower temperatures. Figure 8.2.1 shows a comparison of the process of an ideal and an actual simple cycle gas turbine on a T-S diagram. The increased compressor power consumption and the decreased turbine power generation in the actual cycle are shown to provide an understanding of the differences that component efficiencies make on machine performance.

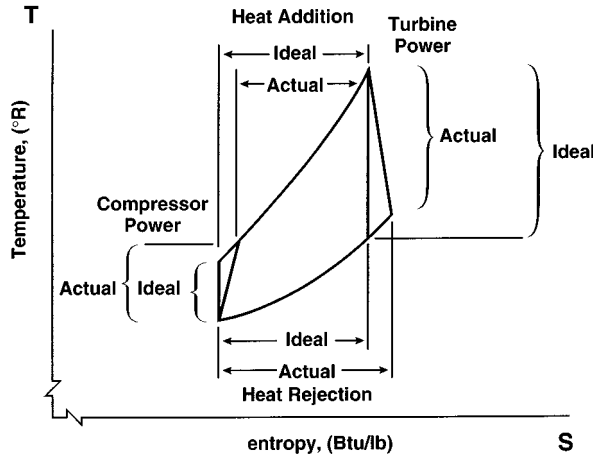

FIGURE 8.2.1 T-S diagram for a simple cycle illustrating the differences in compressor and turbine power for ideal (100% efficient) and actual components.

The incremental amount of power produced per differential pressure change in the gas is given by

$$d(\text{Power/mass flow}) = -RT\, dp/p$$

Two phenomena are illustrated by this equation. First, power is proportional to the absolute temperature of the gas. Second, power is proportional to the percent change in pressure. This latter point is important in understanding the effect of pressure losses in cycle components. In heat exchangers, the proper measure of power lost is the percent pressure drop.

Cycle Configurations

The basic Brayton cycle consists of a compressor, a combustor or burner, and an expander. This configuration is known as the simple cycle. In idealizing the actual cycle, combustion is replaced by constant-pressure heat addition, and the cycle is completed by the assumption that the exhaust to ambient pressure could be followed by a zero-pressure-loss cooling to inlet conditions.

A T-S diagram of the simple cycle gas turbine with an upper temperature limit set by metallurgical conditions is illustrated in Figure 8.2.2 for cycles of low, medium, and high pressure ratios. The heat addition is only by fuel combustion, simplified here to be without mass addition or change in specific heat of the working fluid.

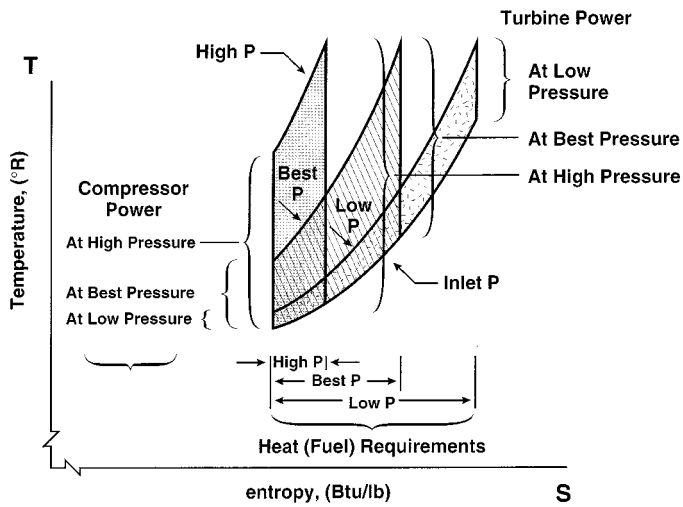

FIGURE 8.2.2 T-S diagram illustrating the power and heat (fuel) requirements at low, best, and high cycle pressures.

It is seen that the low-pressure-ratio cycle requires a large heat addition, which leads to a low efficiency, and the high-pressure-ratio cycle has turbine power output barely greater than the compressor power requirement, thereby leading to low net output and low efficiency. At intermediate pressure ratios, the turbine power output is substantially higher than the compressor power requirement, and the heat addition is modest in comparison with the difference between the turbine and compressor powers. There is an optimum pressure ratio for maximum efficiency, which is a function mainly of the maximum gas temperature in the machine, and to a lesser extent, by the component efficiencies, internal pressure losses, and the isentropic exponent. There is another optimum pressure ratio for maximum specific power (power per unit mass flow).

As the achievable turbine inlet temperature increases, the optimum pressure ratios (for both maximum efficiency and maximum specific power) also increase. The optimum pressure ratio for maximum specific power is at a lower pressure level than that for maximum efficiency for all cycles not employing a recuperator. For cycles with a recuperator, the reverse is true: maximum efficiency occurs at a lower

pressure ratio than maximum specific power. Heavy-duty utility and industrial gas turbines are typically designed to operate near the point of maximum specific power, which approximates lowest equipment cost, while aeroderivative gas turbines are designed to operate near the point of maximum efficiency, approximating highest thrust. Figure 8.2.3 shows a performance map (efficiency as a function of power per unit of air flow) for a simple cycle gas turbine for two turbine inlet temperatures. It is seen that at higher temperature, both the efficiency and specific power increase, as well as the optimum pressure ratios for both the maximum efficiency and maximum specific power conditions.

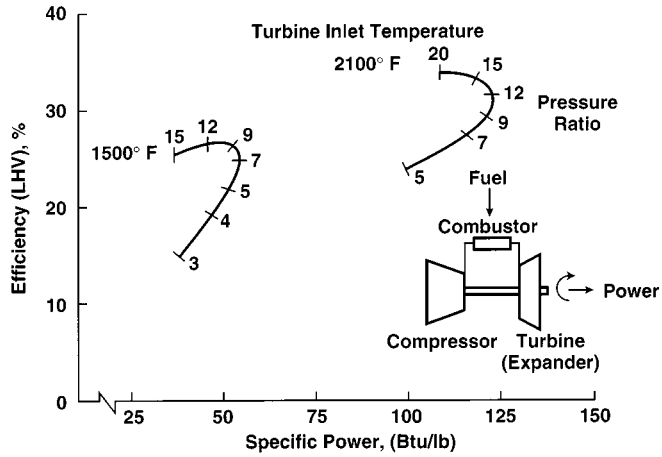

FIGURE 8.2.3 Performance map of a simple cycle gas turbine.

Aircraft gas turbines operate at temperatures above the limit of turbine materials by using blades and vanes with complex internal cooling passages. The added cost is economically justified because these machines can command high prices in the aircraft propulsion marketplace. Aeroderivative engines have higher pressure ratios, higher efficiencies, and lower exhaust temperatures than heavy-duty machines. The stationary power markets served by aeroderlvative gas turbines are principally pipeline compressor stations and oil/gas production wells. Aeroderivative gas turbines also are economically advantageous for intermediate-duty applications.

Components Used in Complex Cycles

Recuperators and **regenerators** recover heat from the turbine exhaust and use it to preheat the air from the compressor before it enters the combustor, thereby saving fuel. This heat transfer is shown in Figure 8.2.4. While recuperators and regenerators are quite similar thermodynamically, they are totally different in design. Recuperators are conventional heat exchangers in which hot and cold gases flow steadily on opposite sides of a solid (usually metal) wall.

Regenerators are periodic-flow devices. Fluid streams flow in opposite directions through passages in a wheel with heat storage walls. The wheel rotates, transferring heat from one stream to the other. Regenerators usually use a nest of very small parallel passages oriented axially on a wheel which rotates between hot and cold gas manifolds. Such regenerators are sometimes used in industrial processes for furnace heat recovery, where they are referred to as heat wheels. Because regenerators are usually more compact than recuperators, they are used in automotive gas turbines (under development). The difficulty in using regenerators on gas turbines intended for long life is that the two gas streams are at very different pressures. Consequently, the seals between the manifolds and the wheel must not leak excessively over the maintenance overhaul interval of the engine. If they do, the power loss due to seal leakage will compromise engine power and efficiency. Figure 8.2.5 shows a performance map for the regenerative

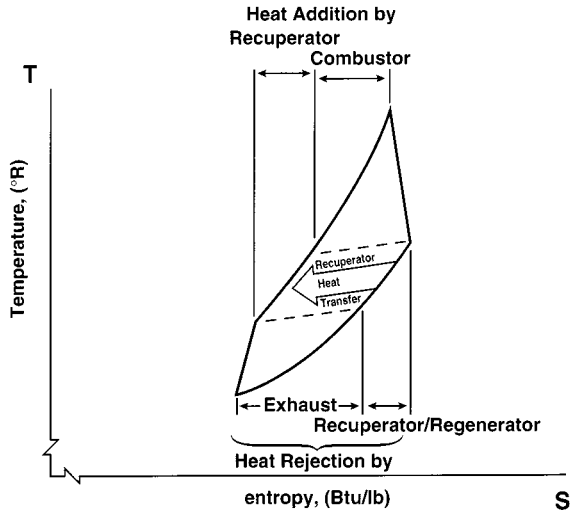

FIGURE 8.2.4 T-S diagram illustrating the heat transfer from the turbine exhaust to the compressor discharge accomplished by a recuperator/regenerator.

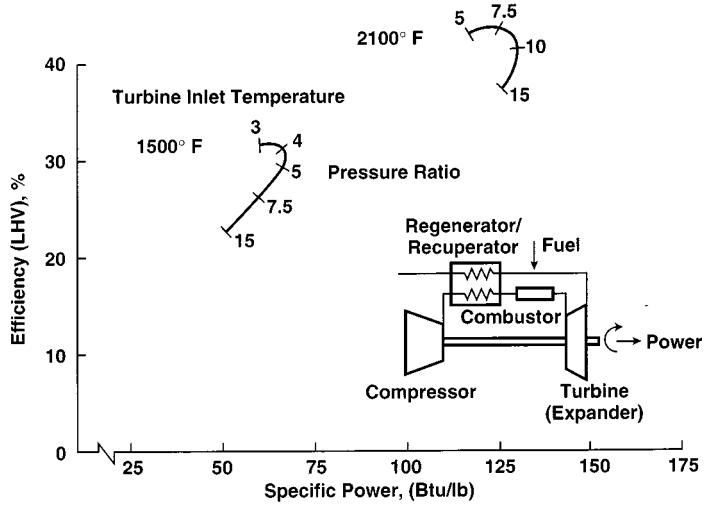

FIGURE 8.2.5 Performance map of a regenerative cycle gas turbine.

gas turbine cycle for two temperatures. It is seen that as the temperature increases, the efficiency, specific power, and optimum pressure ratio all increase.

Current research on the recovery of gas turbine exhaust heat includes examination of thermochemical recuperation, where exhaust heat is used to effect a chemical reaction (reforming) of the fuel with steam, thereby increasing the heating value of the fuel. Although this process is feasible, research is underway to determine if it is practical and economic.

Industrial process compressors frequently use **intercoolers** to reduce compressor power when the compressor has a high pressure ratio and operates for a large number of hours per year. When analyzing cycles with intercoolers, the added pressure drops in the compressor interstage entrance and exit diffuser and scroll and the pressure drop in the intercooler itself should be included.

In a similar manner, turbine reheat can be used to increase the power output of a large-pressure-ratio turbine. This is the thermodynamic principle in turbojet afterburner firing. Turbine reheat increases

power, but decreases efficiency unless the turbine exhaust heat is used for additional power generation, as is the case with a combined cycle, or is used with a recuperator to preheat combustor inlet air.

Intercoolers and reheat burners increase the temperature difference between the compressor and turbine discharges, thereby increasing the opportunity to use a recuperator to preheat the burner air with exhaust heat. An intercooled recuperated (ICR) machine is at present in development. The efficiency decrease at part load of an ICR gas turbine is much less than of conventional simple cycle machines.

Small gas turbines have uncooled turbine blades as a result of the difficulty in manufacturing extremely small cooling passages in small blades. This results in low efficiencies, making it difficult for such turbines to compete with high-volume production (low-cost) reciprocating (piston) engines. The low-pressure-ratio recuperated cycle has greater efficiency, although at higher cost. The recuperated cycle is finding favor in programs for small (under 300-kW) gas turbines used for stationary power. The recuperated cycle is efficient enough in comparison with piston engines (Otto cycles) to be of interest to automotive power plant engineers. Current designs of automotive gas turbines (AGT) have ceramic turbines and combustors and use ceramic regenerators made from a spirally wound corrugated structure with gas passages about a millimeter in diameter.

Because of their compact size, low emissions, and light weight, gas turbines are also being considered for hybrid engine-battery vehicles. Proponents are pursuing the low-pressure-ratio recuperated gas turbine as the way to obtain high efficiency and low emissions in a compact power plant.

An ingenious gas turbine cycle is the closed cycle in which the working fluid is sealed in the system. Heat is added to the fluid with an externally fired heater and extracted from the fluid through heat exchangers. The working fluid may be any gas, and the density of the gas may be varied — to vary the power delivered by the machine — by using a gas storage cylinder connected to the compressor discharge and inlet. The gas storage system is at an intermediate pressure so that it can discharge gas into the lowest pressure point in the cycle and receive gas from the highest pressure point in the cycle. About ten such units were built between 1938 and 1968; however, in spite of its sophistication, the added cost and low efficiency prevented this system from becoming economic.

The exhaust from a gas turbine is quite hot and can be used to raise steam, which can then be used to generate additional power with a steam turbine. Such a compound gas turbine-steam turbine system is referred to as a **combined cycle**. Figure 8.2.6 shows a schematic diagram of the equipment in a combined cycle. Because the exhaust of heavy-duty machines is hotter than that of aeroderivative machines, the gain in combined cycle system efficiency through use of the steam bottoming cycle described above is greater for heavy-duty machines than for aeroderivatives. Indeed, heavy-duty machines are designed with two criteria in mind: achieving lowest cost for peaking (based on the simple cycle configuration) and achieving highest efficiency in combined cycle configuration for baseload use. The optimum pressure ratios for these two system configurations are very close. Steam bottoming cycles used in combined cycles usually use steam at multiple pressure levels to increase efficiency.

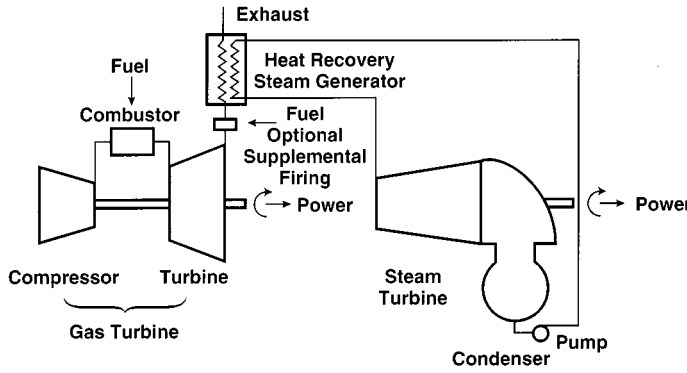

FIGURE 8.2.6 Combined (Brayton-Rankine) cycle.

Another system in which the power and efficiency of a gas turbine is increased through the use of steam is the **steam-injected gas turbine**. Figure 8.2.7 shows a schematic diagram of a steam-injected gas turbine cycle. Here the turbine exhaust flows into a heat recovery steam generator (HRSG) operating at a pressure somewhat higher than the compressor discharge pressure. The steam is introduced into the gas turbine at the combustor. The steam-air mixture then passes into the turbine, where the augmented mass flow increases the power produced by the turbine. Additional fuel is required by the combustor because the steam must be heated from the HRSG delivery temperature to the combustor discharge temperature. Typical turbines can accommodate only a limited additional mass flow — from 5 to 15%, depending on the design of the original gas turbine. Steam-injected gas turbines enable the host to use the steam for industrial purposes, space heating, or for the generation of additional power.

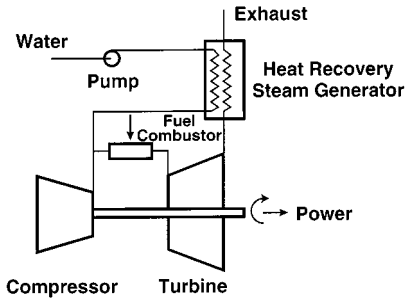

FIGURE 8.2.7 Steam-injected gas turbine.

A group of cycles under consideration for development involve the use of **adiabatic saturators** to provide steam at compressor discharge pressure to augment greatly the mass flow through the turbine, and consequently increase cycle power and efficiency. In the adiabatic saturator, water flows in a countercurrent path to the compressor discharge air in a mass transfer tower. Such equipment is often used in the chemical processing industries. The saturated air is preheated in a turbine exhaust heat recuperator. This cycle is called the **humid air turbine**, or HAT, cycle. The HAT cycle is particularly useful in using the low-temperature heat generated in coal-gasification-fueled gas turbine power plants. As the mass flow through the turbine is significantly augmented, engineers can no longer use the expansion turbine which was matched to the compressor in a conventional simple cycle gas turbine.

Figure 8.2.8 shows performance maps for the gas turbine cycles of major interest for a turbine inlet temperature typical of new products. Intercooling increases the specific power appreciably when compared with a simple cycle; however, such improvement requires an increase in pressure ratio. Recuperated cycles have considerably higher efficiency than similar cycles without recuperation. The effect of pressure ratio on the performance of recuperated cycles is opposite to that of similar cycles without recuperation. For recuperated cycles, the pressure ratio for maximum efficiency is considerably lower than for maximum specific power. Performance maps such as these are used in screening cycle alternatives for improved performance. Individual curves are generated for specific component performance values for use as a guide in developing new or improved machines.

Upper Temperature Limit

Classically, gas turbine engineers often spoke of a metallurgical limit in reference to maximum turbine inlet temperature. Later, turbine vane and blade cooling became standard on large machines. This situation creates a temperature difference between the combustion products flowing through the turbine and the turbine blade wall. Thus, because heat can be removed from the blades, the turbine can be operated with a combustion gas temperature higher than the metallurgical limit of the blade material. As a rule, the blades and vanes in new large gas turbines contain complex internal passages, through which up to 20% of compressor discharge air is directed. The cooling air first flows through internal convective cooling

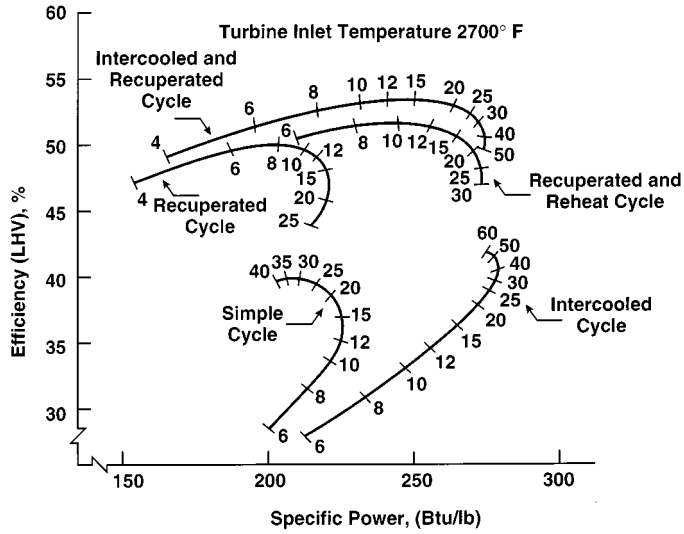

FIGURE 8.2.8 Specific power (Btu/lb).

passages, then through impingement passages, where the air is directed at the blade and vane walls, and finally through small holes in the blade, where it is used to provide a low-temperature film over the blade surface. This film cooling of the surface reduces heat transfer to the blade.

The design of blade and vane cooling passages is an extremely competitive endeavor because greater cooling enables use of higher combustion temperatures without exceeding the metallurgical limit of the blade material. However, a balance between air flow for cooling and air flow for power must be achieved; the cooling air flowing within a blade drops in pressure without producing any power within that stage (although it is available for power in later stages). In the newest gas turbines, blade cooling, the difference between turbine inlet gas temperature and blade metal temperature, is around 1000°F.

Some of the latest large gas turbines being introduced to the market in the 1997 to 2000 period are being offered for combined cycle application with closed-circuit **steam cooling** of selected hot section parts. Steam cooling reduces the need for air cooling, so that more of the compressor discharge air can be used for NO_x reduction in the combustor and for power generation. The heat transferred to the steam increases the efficiency of the bottoming cycle. The additional combustion products which flow through the high-pressure portions of the turbine generate substantially more power, thereby increasing both the power output and the efficiency of the machine. With more air for combustion, the fuel can be burned as a leaner mixture, with either less NO_x produced, or, as is preferred, with higher-temperature gases going to the turbine and the same NO_x (or a combination of these benefits).

Materials

The high-technology parts of a gas turbine are its hot section parts: blades, vanes, combustors and transition pieces. Gas turbine power, efficiency, and economics increase with the temperature of the gas flowing through the turbine blade passages. It is in the fabrication of these hot section parts that manufacturers are most competitive. Materials are selected to survive in serviceable condition for over 50,000 hr and associated numbers of thermal cycles. Ceramic coatings protect materials from oxidation and corrosion and provide thermal insulation, permitting higher gas temperatures.

Gas turbine alloys are frequently referred to as superalloys because of their extremely high strength at high temperatures. These superalloys are nickel based (such as IN 738), cobalt based (such as FSX-414), or with a nickel-iron base such as Inconel 718. Nickel resists oxidation and is creep resistant, but is subject to corrosive sulfidation. Alloy and manufacturing advancements have been led by the needs of military aircraft engines. Coating developments for corrosion resistance have been led by the needs

of stationary power for overhaul intervals as large as 50,000 hr. The developmental needs of automotive gas turbines have led to significant advances in strength and reliability of high-temperature ceramic components, including radial inflow turbines. Ceramic materials, principally silicon nitride, are expected to enter service soon in small gas turbines.

Combustion

Gas turbine combustors appear to be simple in design, yet they solve several difficult engineering challenges. Until relatively recently, gas turbine combustors employed a (turbulent) diffusion flame design approach, which created the most compact flame. European heavy-duty gas turbine manufacturers — with substantial interest in burning heavy fuel oils — preferred large, off-engine combustors, often called silo combustors because of their appearance, in order to obtain lower flame velocities and longer residence times. American heavy-duty gas turbine manufacturers use compact on-engine combustors and design for gaseous and clean (distillate) liquid fuels. Aeropropulsion gas turbines require the smallest possible frontal area and use only clean liquid fuels; hence, they use on-engine combustors.

Recently, stationary engines have been required to reduce NO_x emissions to the greatest extent possible, and combustors on stationary gas turbines first modified their diffusion flame combustors and employed water and steam injection to quench flame hot spots. Most recently, designs changed to the lean-premixed process. With the improved blade cooling, materials, and coatings now in use, the material limits on turbine inlet temperature and the NO_x emission limits on combustor temperature appear to be converging on a combustion-temperature asymptote around 2700°F (1482°C). This may be increased if catalytic combustors prove practical.

Mechanical Product Features

In view of the need to achieve all the performance features described above, one must keep in mind that a gas turbine is a high-speed dynamic machine with numerous machine design, materials, and fabrication features to consider. Major issues include the following: critical shaft speed considerations, bearing rotational stability, rotor balancing, thrust bearing design, bearing power loss, oil lubrication system, oil selection, air filter design and minimization of inlet and exhaust diffuser pressure drops, instrumentation, controls, diagnostic systems, scheduled service and inspection, overhaul, and repair. All of these topics must be addressed to produce a cost-effective, reliable, long-lived, practical gas turbine product that will satisfy users while also returning to investors sufficient profit for them to continue to offer better power generation products of still higher performance.

Defining Terms

Adiabatic saturator: A combined heat-and-mass-exchanger whereby a hot gas and a volatile liquid pass through a series of passages such that the liquid is heated and evaporates into the gas stream.

Combined cycle: An arrangement of a gas turbine and a stream turbine whereby the heat in the exhaust from the gas turbine is used to generate steam in a heat recovery boiler which then flows through a steam turbine, thereby generating additional power from the gas turbine fuel.

Combustion efficiency: Ratio of rate of heat delivered in a device which burns fuel to the rate of energy supplied in the fuel.

Expansion process: Process of power generation whereby a gas passes through a machine while going from a condition of high pressure to one of low pressure, usually the machine produces power.

Gas turbine or engine efficiency: The ratio of the net power delivered (turboexpander power minus compressor and auxiliary power) to the rate of energy supplied to the gas turbine or engine in the form of fuel, or, in certain cases such as solar power, heat.

Humid air turbine: A gas turbine in which the flow through the expander is augmented by large amounts of steam generated by use of an adiabatic saturator.

Intercooler: A heat exchanger used to cool the flow between sections of a compressor such that the high pressure section acts on a stream of reduced volumetric flow rate, thereby requiring less overall power to compress the stream to the final pressure.

Recuperator: A heat exchanger in which the hot and cold streams pass on opposite sides of a wall through which heat is conducted.

Regenerator: A heat exchanger in which the hot and cold streams alternately heat and cool a wall whose temperature rises and falls, thereby transferring heat between the streams.

Steam cooling: A process in which steam is used as the heat transfer fluid to cool a hot component.

Steam-injected gas turbine: A system in which the gas turbine flow is augmented by steam, thereby generating additional power.

Turbine efficiency: Ratio of the power delivered in an expansion process employing a turbine as the expander to the maximum power which could be produced by expanding the gas in a reversible adiabatic (isentropic) process from its initial pressure and temperature to its final pressure to the actual power.

Cycle efficiency:

$$\eta = \frac{\dot{m}_t \Delta h_t - \dot{m}_c \Delta h_c}{\dot{m}_f HV}$$

where HV = heating value of fuel.
For specific heat independent of temperature and small mass flow of fuel in comparison to air:

$$\eta = \frac{\Delta T_t - \Delta T_c}{\Delta T_b}$$

Isentropic efficiency (finite pressure ratio):

$$\eta_t = \Delta T \text{ actual} / \Delta T \text{ isentropic}$$

$$\eta_t = \frac{1 - T_e/T_i}{1 - r^{(\gamma-1)/\gamma}}$$

or

$$\eta_t = \frac{1 - r^{(n-1)/n}}{1 - r^{(\gamma-1)/\gamma}}$$

and

$$\eta_c = \Delta T \text{ isentropic} / \Delta T \text{ actual}$$

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{T_e/T_i - 1}$$

or

$$\eta_c = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(\eta-1)/\eta} - 1}$$

Polytropic efficiency (differential pressure ratio):

$$\eta_t = \frac{(n-1)/n}{(\gamma-1)/\gamma}$$

and

$$\eta_c = \frac{(\gamma-1)/\gamma}{(n-1)/n}$$

Relationships between isentropic and polytropic efficencies:

$$\eta_{s,c} = \frac{r^{(\gamma-1)/\gamma} - 1}{r^{(\gamma-1)/\gamma \eta_{pc}} - 1}$$

$$\eta_{s,t} = \frac{1 - r^{(\gamma-1)/\gamma \eta_{p,t}}}{1 - r^{(\gamma-1)/\gamma}}$$

$$\eta_{p,c} = \frac{\ln r^{(\gamma-1)/\gamma}}{\ln\left[\dfrac{r^{(\gamma-1)/\gamma} - 1}{\eta_{s,c}} + 1\right]}$$

$$\eta_{p,t} = \frac{\ln\left[1 - \eta_{s,t}\left(1 - r^{(\gamma-1)/\gamma}\right)\right]}{\ln r^{(\gamma-1)/\gamma}}$$

8.3 Internal Combustion Engines

David E. Klett and Elsayed M. Afify

Introduction

This section discusses the two most common reciprocating internal combustion (IC) engine types in current use; the **spark ignition** (SI) and the **compression ignition** (CI or diesel) **engine**. Both the Stirling engine (technically, an external combustion engine) and the gas turbine engine are covered in other sections of this chapter. Space limitations do not permit detailed coverage of the very broad field of IC engines. For a more detailed treatment of SI and CI engines and for information on variations, such as the Wankel rotary engine and the Miller cycle engine (a variation on the reciprocating four-stroke SI engine introduced in production by Mazda in 1993), the reader is referred to the several excellent textbooks on the subject, technical papers, and other sources that are included in the list of references and the Further Information section.

Basic SI and CI engines have not fundamentally changed since the early 1900s with the possible exception of the introduction of the Wankel rotary SI engine in the 1960s (Norbye, 1971). However, major advances in the areas of materials, manufacturing processes, electronic controls, and computer-aided design have led to significant improvements in dependability, longevity, thermal efficiency, and emissions during the past decade. Electronic controls, in particular, have played a major role in efficiency gains in SI automotive engines through improved control of the fuel injection and ignition systems that control the combustion process. Electronic control of diesel fuel injection systems is also becoming more common and is producing improvements in diesel emissions and fuel economy.

This section presents the fundamental theoretical background of IC engine function and performance, including **four-stroke** and **two-stroke** SI and CI **engines**. Sections on combustion, emissions, fuels, and intake pressurization (**turbocharging** and **supercharging**) are also included.

Engine Types and Basic Operation

IC engines may be classified by a wide variety of characteristics, the primary ones being SI vs. CI, four-stroke vs. two-stroke, and reciprocating vs. rotary. Other possible categories of classification include intake type (naturally aspirated vs. turbocharged or supercharged), number of cylinders, cylinder arrangement (in-line, vee, opposed), cooling method (air vs. water), fueling system (injected vs. carbureted), valve gear arrangement (overhead cam vs. pushrod), type of **scavenging** for two-stroke engines (cross, loop, or uniflow), and type of injection for diesel engines (direct vs. indirect).

Four-Stroke SI Engine

Figure 8.3.1 is a cross-section schematic of a four-stroke SI engine. The SI engine relies on a spark plug to ignite a volatile air-fuel mixture as the piston approaches **top dead center** (**TDC**) on the compression stroke. This mixture may be supplied from a carburetor, a single throttle-body fuel injector, or by individual fuel injectors mounted in the intake port of each cylinder. One combustion cycle involves two revolutions of the crankshaft and thus four strokes of the piston, referred to as the intake, compression, power, and exhaust strokes. Intake and exhaust valves control the flow of mixture and exhaust gases into and out of the cylinder, and an ignition system supplies a spark-inducing high voltage to the spark plug at the proper time in the cycle to initiate combustion. On the intake stroke, the intake valve opens and the descending piston draws a fresh combustible charge into the cylinder. During the compression stroke, the intake valve closes and the fuel-air mixture is compressed by the upward piston movement. The mixture is ignited by the spark plug, typically somewhat before TDC. The rapid **premixed homogeneous combustion** process causes a sharp increase in cylinder temperature and pressure that forces the piston down for the power stroke. Near **bottom dead center** (BDC) the exhaust valve opens and the cylinder pressure drops rapidly to near atmospheric. The piston then returns to TDC, expelling the

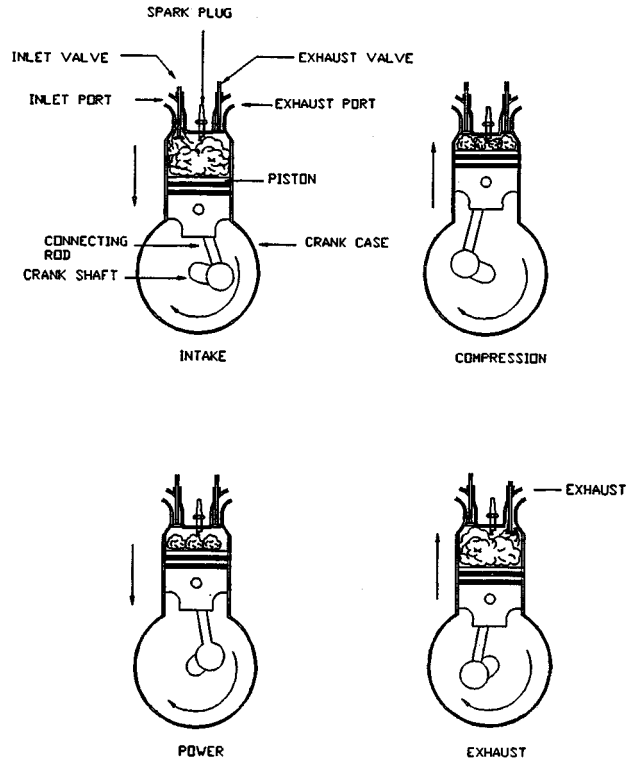

FIGURE 8.3.1 Schematic diagram of four-stroke SI engine.

exhaust products. At TDC, the exhaust valve closes and the intake valve opens to repeat the cycle again. Figure 8.3.2 is a cutaway drawing of a modern high-performance automotive SI engine. This is a fuel-injected normally aspirated aluminum alloy V-8 engine of 4.6 L displacement with dual overhead cams for each cylinder bank. Peak power output is 228 kw at 5800 rpm.

Two-Stroke SI Engine

The two-stroke SI engine completes a combustion cycle for every revolution of the crankshaft by essentially overlapping the power and exhaust functions in one downward stroke and the intake and compression processes in one upward stroke. A single-cylinder, crankcase-scavenged, two-stroke SI engine is illustrated schematically in Figure 8.3.3. The operation is as follows. On the upward stroke, the piston first covers the transfer port and then the exhaust port. Beyond this point the fresh charge is compressed and ignited near TDC. During the upward stroke, the negative pressure created in the crankcase below the piston draws in a fresh charge of fuel-air mixture through a one-way valve. On the downward power stroke, the mixture in the crankcase is pressurized. The piston uncovers the exhaust port and the high-pressure exhaust gases exit. Near BDC the transfer port is uncovered and the pressurized mixture flows from the crankcase into the cylinder and the cycle repeats. Since the crankcase is part of the induction system, it does not contain oil, and lubrication is accomplished by mixing oil with the fuel. With the cross-flow scavenging configuration illustrated in Figure 8.3.3, there will be a certain degree of mixing of the fresh charge with the combustion products remaining in the cylinder and some loss of fresh charge out the exhaust port.

Since two-stroke engines produce twice the power impulses of four-stroke engines for the same rpm, a two-stroke engine has a higher **power density** and is thus smaller and lighter than a four-stroke engine of equal output. The disadvantages of the two-stroke engine have historically been lower fuel efficiency and higher exhaust emissions because of the overlapping of the intake and exhaust processes and the

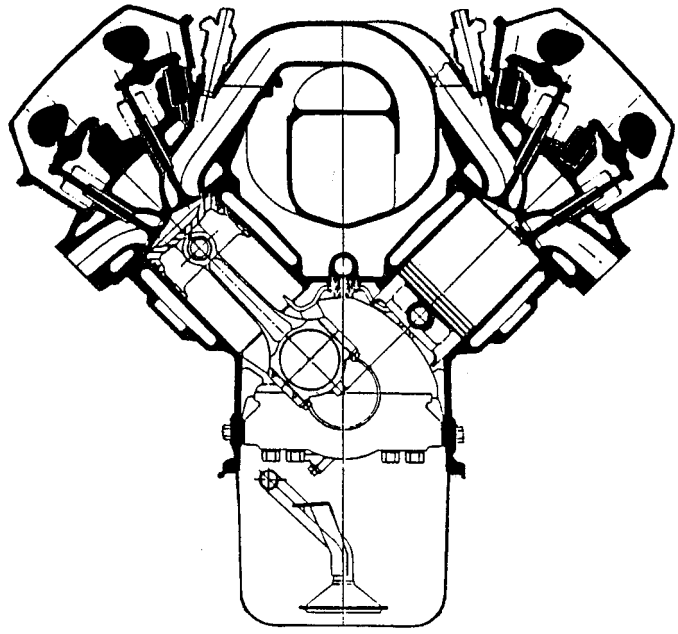

FIGURE 8.3.2 Ford 4.6-L aluminum V-8 SI engine. (Courtesy of Ford Motor Company.)

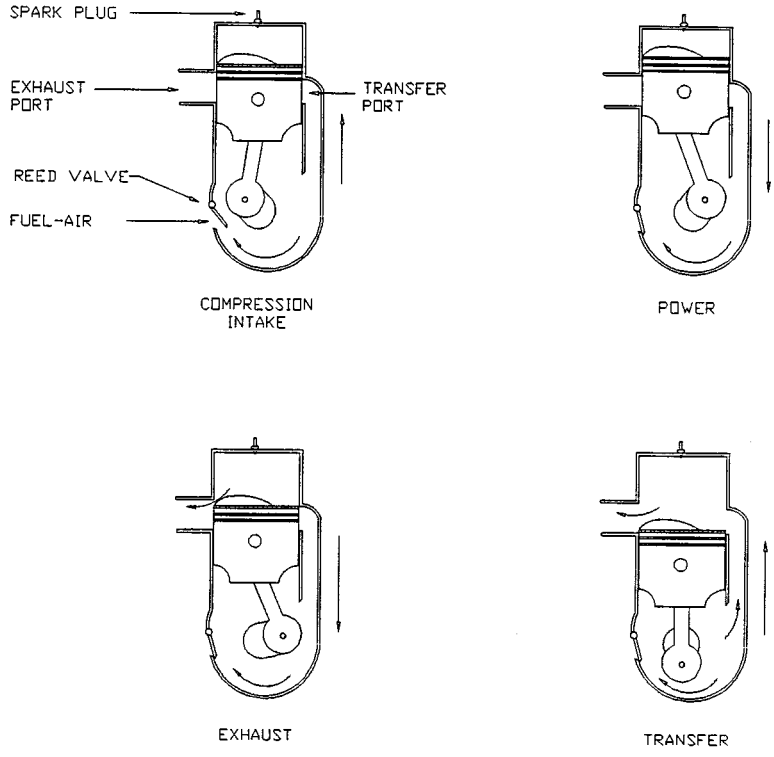

FIGURE 8.3.3 Schematic drawing of two-stroke SI engine.

loss of some fresh intake mixture with the exhaust products. For this reason, two-stroke SI engines have largely been confined to small-displacement applications, such as motorcycles, outboard marine engines, and small equipment. Several manufacturers have addressed these shortcomings in recent years and have achieved significant improvements in two-stroke engine fuel economy and emissions (Blair, 1988). The Orbital OCP (Orbital Combustion Process) engine, illustrated in Figure 8.3.4, is a modern two-stroke engine that utilizes direct injection of fuel into the cylinder in conjunction with a high-turbulence combustion chamber design and an electronically controlled exhaust port scavenging control valve to achieve very favorable fuel economy and significantly reduced levels of NO_x and hydrocarbon emissions. This engine, in three and six cylinder versions, is currently being used in automotive and marine applications.

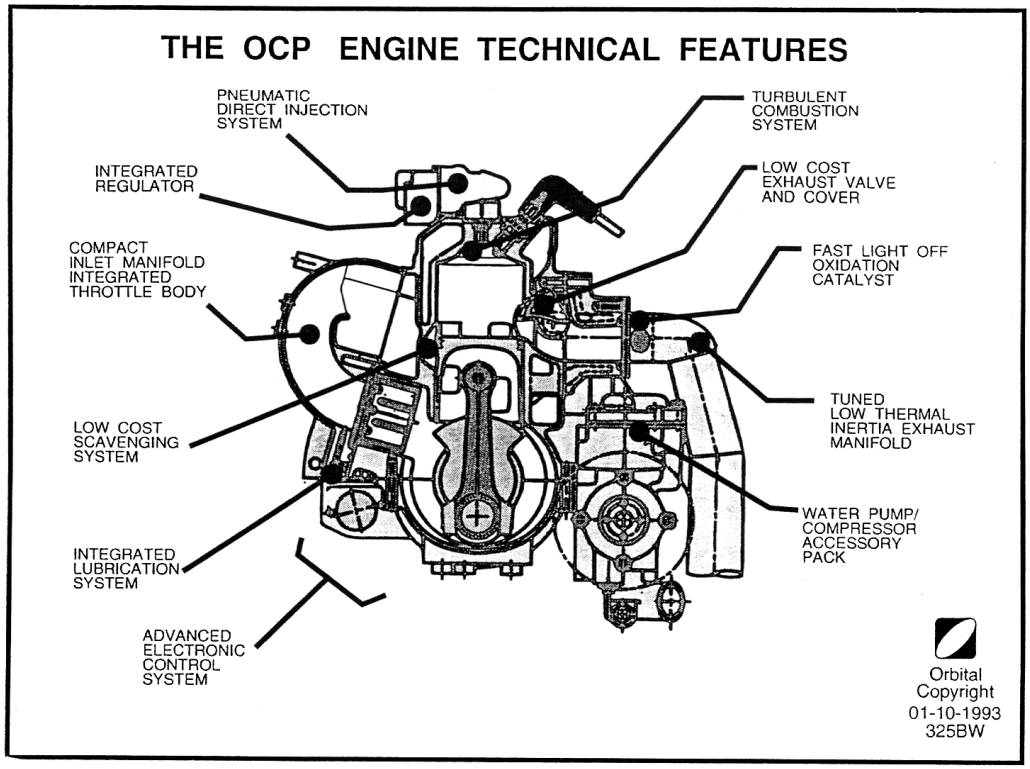

FIGURE 8.3.4 Orbital OCP two-stroke SI engine. (Courtesy of Orbital Engine Company.)

Compression Ignition Engine

The basic valve and piston motions are the same for the CI, or diesel, engine as discussed above for the SI engine. The CI engine relies on the high temperature and pressure of the cylinder air resulting from the compression process to cause **autoignition** of the fuel, which is injected directly into the combustion chamber of **direct injection (DI)** engines or into the prechamber of **indirect injection (IDI)** engines, when the piston approaches TDC on the compression stroke. The compression ratios are typically much higher for CI than for SI engines to achieve the high air temperatures required for autoignition, and the fuels used must have favorable autoignition qualities.

The time period between the start of fuel injection and the occurrence of autoignition is called the **ignition delay period**. Long ignition delay periods allow more time for fuel vaporization and fuel-air mixing, resulting in objectionable diesel knock when this larger premixed charge ignites. Combustion chambers and fuel injection systems must be designed to avoid extended ignition delay periods. Diesel

engines may be classified as DI or IDI. In DI engines, the combustion chamber consists of a bowl formed in the top of the piston and the fuel is injected into this volume. The injector tip generally has from four to eight holes to form multiple spray cones. Two variations are illustrated in Figure 8.3.5. The quiescent chamber engine utilizes a large-diameter shallow bowl shape that produces low **swirl** and low turbulence of the air during compression. Fuel is injected at high pressure through a multihole nozzle, and mixing of the fuel and air relies primarily on the energy of the injected fuel to cause air entrainment in the spray cone and diffusion of vaporized fuel into the air. This system is suited to large slow-speed engines that are operated with significant excess air.

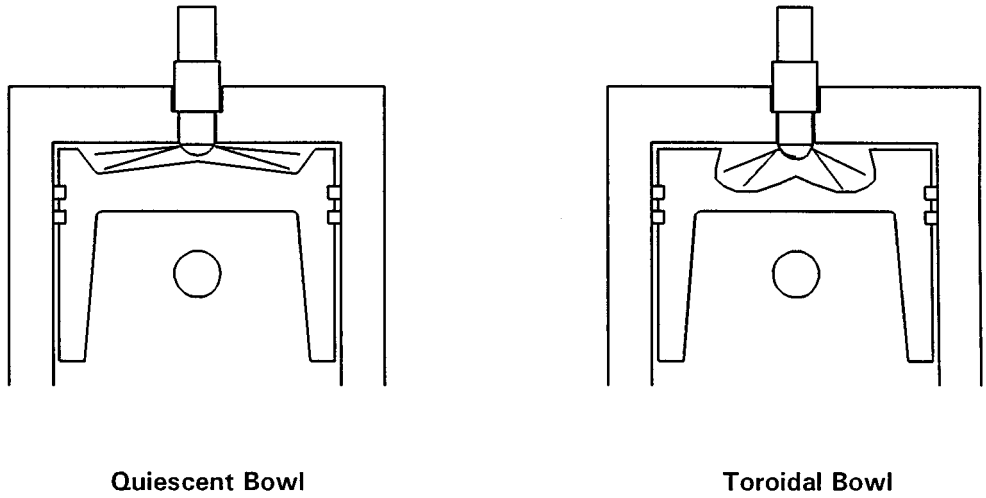

FIGURE 8.3.5 Examples of DI diesel combustion chamber design.

The toroidal bowl combustion chamber is used in conjunction with intake ports and/or valve shrouds designed to produce air swirl to enhance fuel-air mixing. The **swirl ratio** is defined by swirl ratio = swirl speed (rpm)/engine speed (rpm). The swirl velocity component is normal to the fuel spray direction and tends to promote mixing in the regions between the individual spray cones. This system makes better use of the available air and is utilized extensively in moderate-speed engines such as over-the-road truck engines. DI does not lend itself well to high-speed operation, as the time available for proper mixing and combustion is less. Diesel engines for passenger car applications are generally designed for higher-speed operation to produce higher specific output, and typically utilize IDI combustion systems, two of which are illustrated in Figure 8.3.6.

IDI systems make use of small prechambers incorporated in the cylinder head to promote rapid mixing of fuel and air and shorten the ignition delay period. Swirl chambers are designed to produce a strong vortex in the prechamber during compression. The fuel is sprayed into the chamber through a single-hole nozzle and the high vorticity promotes rapid mixing and short ignition delay periods. Precombustion chambers do not attempt to generate an orderly vortex motion within the chamber, but instead rely on a high level of turbulence, created by the rush of air into the chamber during compression, to promote mixing. Both types of prechambers generally include a lining of low-conductivity material (ceramic) to increase the surface temperature to promote further fuel evaporation. Prechambers can be used in small-displacement diesel engines to achieve operating speeds up to 5000 rpm. Disadvantages of the IDI system include poor cold-start characteristics due to high heat-transfer rates from the compressed air to the chamber wall that result from the high velocities and turbulence levels in the chamber. **Glow plugs** are often installed in each prechamber to heat the air to improve cold starting. Higher compression ratios are also used for IDI engines to further improve cold starting. The compression ratios, typically 18 to 24, are higher than the optimum for fuel efficiency (due to decreased mechanical efficiency), and IDI

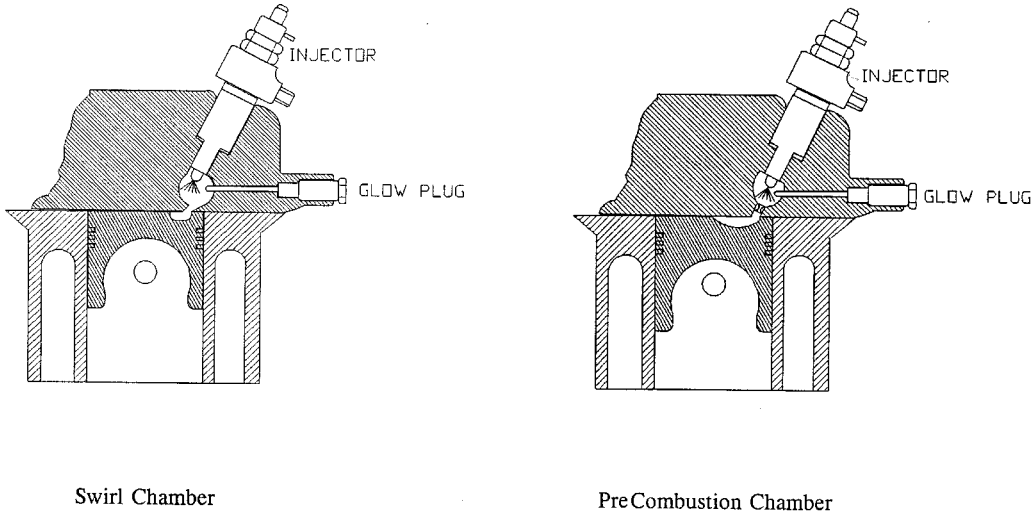

FIGURE 8.3.6 Two examples of IDI combustion chambers.

engines are typically less efficient than larger, slower, DI engines. The use of IDI is generally restricted to high-speed automotive engines, with displacements in the range of 0.3 to 0.8 liter per cylinder, and some degree of fuel economy is sacrificed in the interest of improved driveability.

CI engines are produced in both two-stroke and four-stroke versions. Since the fuel is injected directly into the combustion chamber of CI engines just prior to TDC, two-stroke CI engines do not suffer the same emission and efficiency shortcomings as do two-stroke SI engines. Hence, they are available in much larger displacements for high-power-requirement applications such as locomotive and ship propulsion and electric power generation systems. Two-stroke CI engines are generally of the DI type as the use of IDI in a two-stroke engine would lead to aggravated cold-start problems.

Air Standard Power Cycles

The actual operation of IC engines is idealized at a very basic level by the air standard power cycles (ideal thermodynamic models for converting heat into work on a continuous basis). The following simplifying assumptions are common to the air standard cycles: (1) the working substance is air, (2) the air is assumed to behave as an ideal gas with constant specific heats, (3) heat is added to the cycle from an external source, and (4) expansion and compression processes not involving heat transfer occur isentropically. The air standard cycles, while grossly oversimplified in terms of the complex processes occurring within actual engines, are nevertheless useful in understanding some fundamental principles of SI and CI engines. The simplified models also lend insight into important design parameters, e.g., **compression ratio**, that govern theoretical maximum cycle thermal efficiencies.

Constant-Volume Heat Addition — Ideal Otto Cycle

The theory of operation of the SI engine is idealized by the Otto cycle which assumes that heat is added to the system at constant volume. Constant-volume heat addition is approximated in the SI engine by virtue of the combustion process taking place rapidly when the piston is near TDC. A *P-V* diagram for the Otto cycle is illustrated in Figure 8.3.7. The cycle consists of the following processes: 1 → 2 isentropic compression, 2 → 3 constant-volume heat addition, 3 → 4 isentropic expansion, and 4 → 1 constant-volume heat rejection. The constant-volume heat rejection process is approximated in SI engines by the exhaust valve opening near BDC and the rapid blow down of exhaust gases.

Thermal efficiency for a power cycle is defined as the ratio of work output to heat input per cycle,

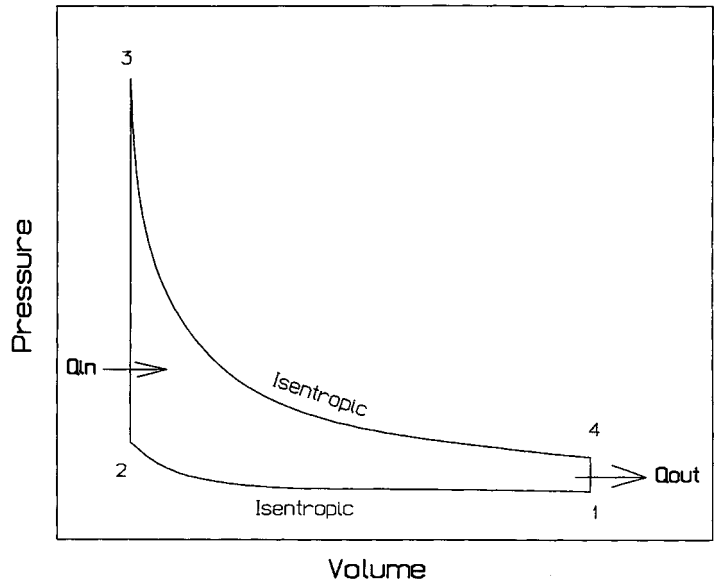

FIGURE 8.3.7 Schematic pressure-volume diagram for the ideal Otto cycle.

$$\eta = \frac{W_{out}}{Q_{in}} \tag{8.3.1}$$

For the Otto cycle, the basic efficiency expression can be manipulated into the form

$$\eta = 1 - \frac{1}{r^{\gamma - 1}} \tag{8.3.2}$$

where γ is the ratio of specific heats ($\gamma = C_p/C_v$) and r is the compression ratio, or ratio of the maximum to minimum cycle volumes ($r = V_1/V_2$). In actual IC engines, the minimum cycle volume is referred to as the **clearance volume** and the maximum cycle volume is the **cylinder volume**. The ideal Otto cycle efficiency for air, with $\gamma = 1.4$, is shown plotted in Figure 8.3.8. The theoretical efficiency of the constant volume heat addition cycle increases rapidly with compression ratio, up to about $r = 8$. Further increases in compression ratio bring moderate gains in efficiency. Compression ratios in practical SI engines are limited because of autoignition (knock) and high NO_x emission problems that accompany high compression ratios. Production SI automotive engines typically have compression ratios in the range 8 to 10, whereas high-performance normally aspirated racing engines may have compression ratios as high as 14, but they require the use of special fuels to avoid autoignition.

Constant-Pressure Heat Addition — Ideal Diesel Cycle

The air standard diesel cycle is the idealized cycle underlying the operation of CI or diesel engines. The diesel cycle, illustrated by the *P-V* diagram in Figure 8.3.9, consists of the following processes: 1 → 2 isentropic compression from the maximum to the minimum cycle volume, 2 → 3 constant-pressure heat addition during an accompanying increase in volume to V_3, 3 → 4 isentropic expansion to the maximum cycle volume, and 4 → 1 constant-volume heat rejection.

Actual diesel engines approximate constant-volume heat addition by injecting fuel for a finite duration which continues to burn and release heat at a rate that tends to maintain the pressure in the cylinder over a period of time during the expansion stroke. The efficiency of the ideal diesel cycle is given by

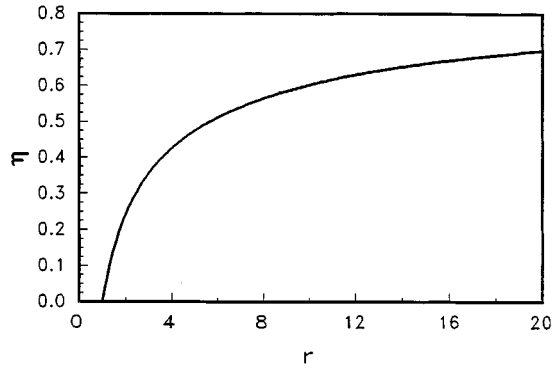

FIGURE 8.3.8 Efficiency of the ideal Otto cycle.

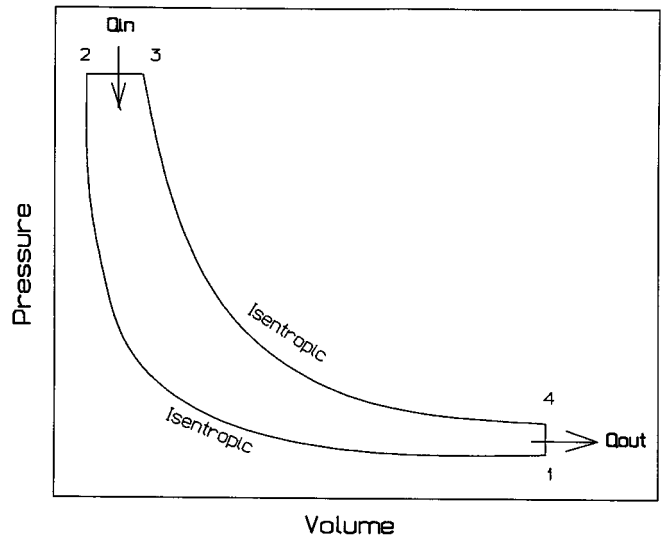

FIGURE 8.3.9 Schematic pressure-volume diagram of ideal diesel cycle.

$$\eta = 1 - \frac{1}{r^{\gamma-1}}\left[\frac{r_c^{\gamma} - 1}{\gamma\left(r_c - 1\right)}\right] \tag{8.3.3}$$

The efficiency of the ideal diesel cycle depends not only on the compression ratio, r, but also on the **cut-off ratio**, $r_c = V_3/V_2$, the ratio of the volume when heat addition ends to the volume when it begins. Equation (8.3.3) is shown plotted in Figure 8.3.10 for several values of r_c and for $\gamma = 1.4$. An r_c value of 1 is equivalent to constant-volume heat addition, i.e., the Otto cycle. The efficiency of the ideal Diesel cycle is less than the efficiency of the ideal Otto cycle for any given compression ratio and any value of the cut-off ratio greater than 1. The fact that CI engines, by design, operate at much higher compression ratios than SI engines (generally between 12 and 24) accounts for their typically higher operating efficiencies relative to SI engines.

Actual Cycles

IC engines do not operate on closed thermodynamic cycles, such as the air standard power cycles, but rather on open mechanical cycles, and heat addition occurs neither at constant volume or constant

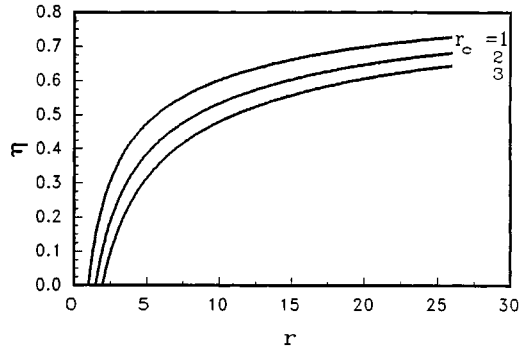

FIGURE 8.3.10 Efficiency of the ideal diesel cycle.

pressure. Figure 8.3.11 is a schematic representation of an **indicator diagram** (pressure-volume history) of a four-stroke IC engine; it could be either SI or CI. The pressure changes during the intake and exhaust strokes are exaggerated in the diagram. The **indicated work** performed per cycle can be calculated by taking the integral of *PdV* for the complete cycle. The **indicated mean effective pressure**, **imep**, is defined as the ratio of the net indicated work output to the **displacement volume**:

$$\text{imep} = \frac{\text{indicated work output per cycle}}{\text{displacement volume}} \tag{8.3.4}$$

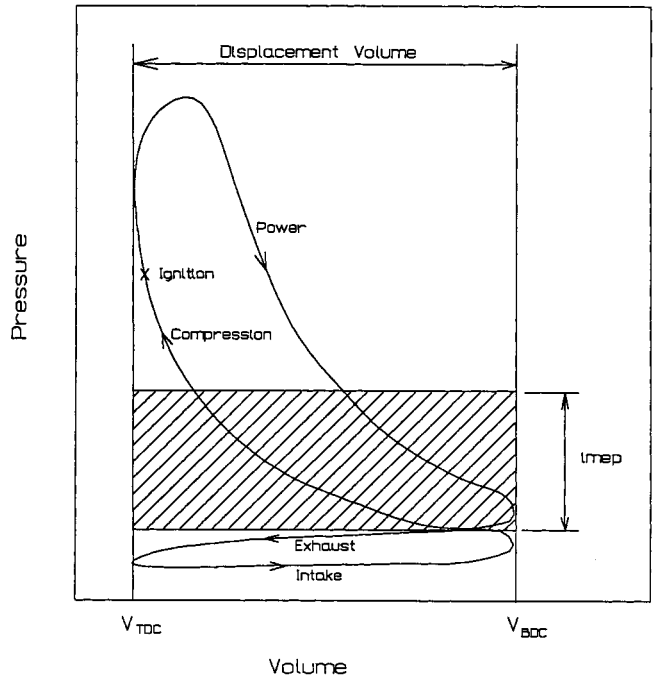

FIGURE 8.3.11 Schematic indicator diagram.

The shaded area in Figure 8.3.11 thus represents the net indicated work output per cycle. During intake and exhaust, the negative work performed represents pumping losses and acts to decrease the net work output of the engine. The magnitude of the pumping losses depends on the flow characteristics of the intake and exhaust systems including the valves, ports, manifolds, piping, mufflers, etc. The more

restrictive these passages, the higher will be the pumping losses. SI engines control power output by throttling the intake air. Thus, under partial-load conditions, the pressure drop resulting from the air throttling represents a significant increase in pumping loss with a corresponding decrease in operating efficiency. SI engines are therefore less efficient at partial-load operation than at full load. The power level of CI engines, on the other hand, is controlled by varying the amount of fuel injected, as opposed to throttling the intake air, making them significantly more efficient than SI engines under partial-load conditions.

Brake work (or power) is the actual work (or power) produced at the output shaft of an engine, as measured by a dynamometer. The brake work will be less than the indicated work due to friction losses and any parasitic power requirements for oil pumps, water pumps, etc. The **brake mean effective pressure**, **bmep**, is defined as

$$\text{bmep} = \frac{\text{brake work output per cycle}}{\text{displacement volume}} \tag{8.3.5}$$

The mechanical efficiency can then be defined as

$$\eta_m = \frac{\text{brake work (power)}}{\text{indicated work (power)}} = \frac{\text{bmep}}{\text{imep}} \tag{8.3.6}$$

Engine thermal efficiency can be determined from the ratio of power output to rate of fuel energy input, or

$$\eta_t = \frac{\text{Power}}{m_f Q_c} \tag{8.3.7}$$

where m_f is the rate of fuel consumption per unit time and Q_c is the heat of combustion per unit mass of fuel. The thermal efficiency in Equation (8.3.7) could be either indicated or brake depending on the nature of the power used in the calculation. Uncertainty associated with variations of energy content of fuels may present a practical difficulty with determining engine thermal efficiency. In lieu of thermal efficiency, **brake specific fuel consumption** (**bsfc**), is often used as an efficiency index.

$$\text{bsfc} = \frac{\text{fuel consumption rate (kg/hr)}}{\text{brake power (kW)}} \tag{8.3.8}$$

The efficiency of engines operating on the same fuel may be directly compared by their bsfc.

Volumetric efficiency, η_v, is an important performance parameter for four-stroke engines defined as

$$\eta_v = \frac{m_{\text{actual}}}{m_d} \tag{8.3.9}$$

where m_{actual} is the mass of intake mixture per cycle at inlet conditions (pressure and temperature near the inlet port) and m_d is the mass of mixture contained in the displacement volume at inlet conditions. For SI engines the mixture mass includes both air and fuel; for CI engines only air is present during intake. With the intake mixture density determined at inlet conditions, η_v accounts for flow losses associated with the intake ports, valves, and cylinder. Sometimes, for convenience, the mixture density is taken at ambient conditions. In this case, η_v is called the overall volumetric efficiency and includes the flow performance of the entire intake system. Since a certain minimum amount of air is required for complete combustion of a given amount of fuel, it follows that the maximum power output of an engine

is directly proportional to its air-flow capacity. Thus, while not affecting in any way the thermal efficiency of the engine, the volumetric efficiency directly affects the maximum power output for a given displacement, and thus can affect the efficiency of the overall system in which the engine is installed because of the effect on system size and weight. Volumetric efficiency is affected primarily by intake and exhaust valve geometry, valve lift and timing, intake port and manifold design, mixing of intake charge with residual exhaust gases, engine speed, ratio of inlet pressure to exhaust back pressure, and heat transfer to the intake mixture from warmer flow passages and combustion chamber surfaces. For further information on the fundamentals of IC engine design and operation see Taylor (1985), Ferguson (1986), Heywood (1988), and Stone (1993).

Combustion in IC Engines

Combustion in Spark Ignition Engines

Background. In SI engines, combustion of the fuel-air mixture is initiated by a spark generated between the electrodes of a spark plug. The intake and compression strokes are designed to prepare the mixture for combustion by completely vaporizing the fuel and heating the mixture to just below its autoignition temperature. This is one reason, in addition to controlling emissions, for the current practice of limiting the maximum compression ratio of SI engines to about 10:1. Near the end of compression, the mixture is well conditioned for combustion and the spark is discharged to initiate the combustion process. For best fuel economy, the combustion process must be completed as close as possible to TDC. This requires that the spark timing be controlled for varying operating speed and load conditions of the engine. Fuel metering and control, according to the engine load requirements, and with minimum variation from cylinder to cylinder and cycle to cycle, is essential for good fuel economy, power output, and emission control of the engine.

Both carburetors and fuel injection systems are used for fuel-metering control. Because of the superior control capabilities of fuel injection systems, they are nearly universally used today in production automotive applications. Carburetors are used for applications with less-stringent emission requirements, e.g., small engines for lawn and garden equipment. Figure 8.3.12 illustrates the effect of **fuel-air ratio** on the indicated performance of an SI engine. The **equivalence ratio** (γ) is defined by the ratio Fuel-Air_{actual}/Fuel-$Air_{stoichiometric}$. Rich mixtures have fuel-air ratios greater than stoichiometric ($\gamma > 1$) and lean mixtures have fuel-air ratios less than stoichiometric ($\gamma < 1$). Optimum fuel economy, coinciding with maximum thermal efficiency, is obtained at part throttle with a lean mixture as a result of the fact that the heat release from lean mixtures suffers minimal losses from dissociation and variation of specific heat effects when compared with stoichiometric and rich fuel-air ratios. Maximum power is obtained at full throttle with a slightly rich mixture, an indication of the full utilization of the air inside the cylinders. Idling, with a nearly closed throttle, requires a rich mixture because of the high percentage of exhaust gas residuals that remains in the cylinders. The fuel-air mixture requirement under transient operation, such as acceleration, requires a rich mixture to compensate for the reduced evaporation caused by the sudden opening of the throttle. Cold starting also requires a rich mixture to ensure the vaporization of sufficient amounts of the highly volatile components in the fuel to achieve proper ignition.

Normal Combustion Process. The combustion processes in SI engines can be divided into two categories, normal and abnormal. The normal combustion process occurs in three stages: initiation of combustion, flame propagation, and termination of combustion. Combustion normally starts across the spark plug gap when the spark is discharged. The fuel molecules in and around the spark discharge zone are ignited and a small amount of energy is released. The important criterion for the initial reaction to be self-sustaining is that the rate of heat release from the initial combustion be larger than the rate of heat transfer to the surroundings. The factors that play an important role in making the initial reaction self-sustaining, and thereby establishing a flame kernel, are the ignition energy level, the spark plug gap, the fuel-air ratio, the initial turbulence, and the condition of the spark plug electrodes.

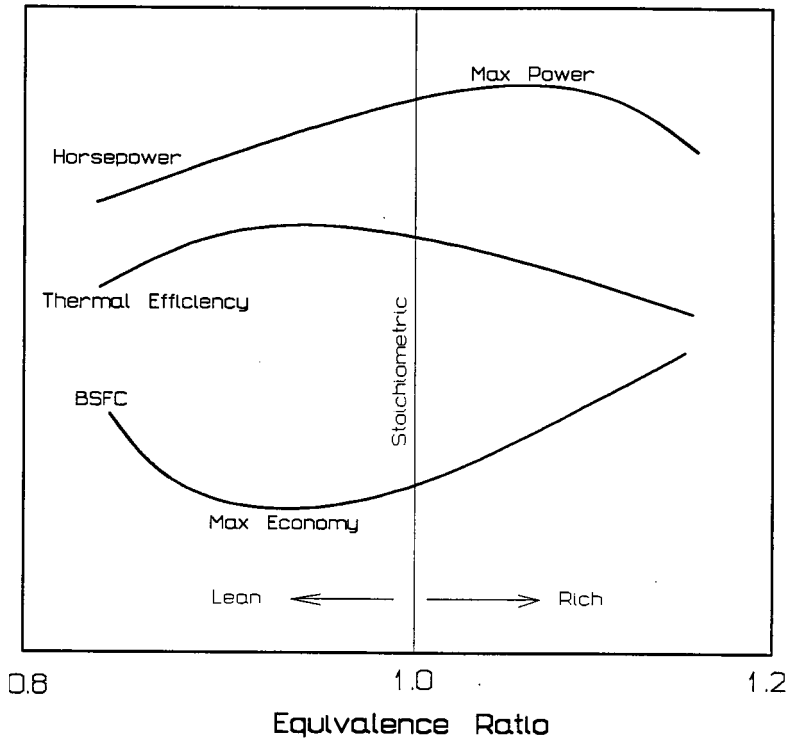

FIGURE 8.3.12 Effect of fuel-air mixture on indicated performance of an SI engine.

After a flame kernel is established, a thin spherical flame front advances from the spark plug region progressively into the unburned mixture zone. Flame propagation is supported and accelerated by two processes. First, the combined effect of the heat transfer from the high-temperature flame region and the bombardment by the active radicals from the flame front into the adjacent unburned zone raises the temperature and accelerates the rate of reactivity of the unburned mixture region directly adjacent to the flame front. This helps condition and prepare this zone for combustion. Second, the increase in the temperature and pressure of the burned gases behind the flame front will cause it to expand and progressively create thermal compression of the remaining unburned mixture ahead of the flame front. It is expected that the flame speed will be low at the start of combustion, reach a maximum at about half the flame travel, and decrease near the end of combustion. Overall, the flame speed is strongly influenced by the degree of turbulence in the combustion chamber, the shape of the combustion chamber, the mixture strength, the type of fuel, and the engine speed.

When the flame front approaches the walls of the combustion chamber, the high rate of heat transfer to the walls slows down the flame propagation and finally the combustion process terminates close to the walls because of surface quenching. This leaves a thin layer of unburned fuel close to the combustion chamber walls which shows up in the exhaust as unburned hydrocarbons.

Abnormal Combustion. Abnormal combustion may occur in SI engines associated with two combustion phenomena: **knock** and **surface ignition**. Knock occurs near the end of the combustion process if the end portion of the unburned mixture, which is being progressively subjected to thermal compression, autoignites prematurely before the flame front reaches it. As a result of the sudden energy release, a violent pressure wave propagates back and forth across the combustion chamber, causing the walls or other parts of the engine to vibrate, producing a sharp metallic noise called knock. If knock persists for a period of time, the high rate of heat transfer caused by the traveling high pressure and temperature wave may overheat the spark plug electrode or ignite carbon deposits that may be present in the

combustion chamber, causing uncontrolled combustion and preignition. As a result, loss of power and serious engine damage may occur.

Knock is sensitive to factors that increase the temperature and pressure of the end portion of the unburned mixture, as well as to fuel composition and other time factors. Factors that increase the probability of knock include (1) increasing the temperature of the mixture by increasing the charge intake temperature, increasing the compression ratio, or turbo/supercharging; (2) Increasing the density of the mixture by turbo/supercharging or increasing the load; (3) advancing the spark timing; (4) increasing the time of exposure of the end portion of the unburned mixture to autoignition conditions by increasing the length of flame travel or decreasing the engine speed and turbulence; and (5) using low-octane fuel and/or maximum power fuel-air ratios. Engine design factors that affect knock in SI engines include the shape of the combustion chamber and the location of the spark plug and inlet and exhaust valves relative to the location of the end portion of the unburned mixture.

Surface ignition is the ignition of the unburned mixture by any source in the combustion chamber other than the normal spark. Such sources could include overheated exhaust valves or spark plug electrodes, glowing carbon deposits, or other hot spots. Surface ignition will create secondary flame fronts which cause high rates of pressure rise resulting in a low-pitched, thudding noise accompanied by engine roughness. Severe surface ignition, especially when it occurs before spark ignition, may cause serious structural and/or component damage to the engine.

Combustion in Compression Ignition Engines

Unlike the SI engine, in which the charge is prepared for combustion as a homogeneous mixture during the intake and compression strokes, fuel preparation for combustion in CI engines occurs in a very short period of time called the ignition delay period. During this period, the fuel injected into the high-temperature air near the end of the compression stroke undergoes two phases of transformation. A physical delay period, during which the fuel is vaporized, mixed with the air, and raised in temperature, is followed by a chemical delay period during which fuel cracking and decomposition occur which leads to autoignition and combustion of the fuel.

The combustion process is **heterogeneous** and involves two modes, usually identified as premixed combustion and diffusion combustion. Premixed combustion occurs early in the process when the fuel which has evaporated and mixed with air during the ignition delay period ignites. This mode is characterized by uncontrolled combustion and is the source of combustion noise since it is accompanied by a high rate of heat release which produces a high rate of pressure rise. When the premixed fuel-air mixture is depleted, diffusion combustion takes over, characterized by a lower rate of heat release and producing controlled combustion during the remainder of the process. Figure 8.3.13 depicts the different stages of the combustion process in CI engines.

The ignition delay period plays a key role in controlling the time duration of the two modes of combustion. Prolonging the ignition delay period, either through engine design factors or variations in operating conditions, will generate a larger portion of premixed fuel-air mixture and will thus tend to increase the premixed combustion mode duration and decrease the diffusion mode duration. This may lead to higher peak cylinder pressure and temperature which may improve thermal efficiency and reduce CO and **unburned hydrocarbon (UHC)** emissions at the expense of increased emissions of oxides of nitrogen ($\mathbf{NO_x}$). Large increases in the ignition delay period will cause high rates of pressure rise during the premixed combustion and may lead to objectionable diesel knock. Reducing the ignition delay period causes the premixed combustion duration to decrease while increasing the diffusion combustion duration. A large reduction in ignition delay may lead to loss of power, decrease in thermal efficiency, and possible deterioration of exhaust emissions. Several factors related to the fuel-air mixture temperature and density, engine speed, combustion chamber turbulence, injection pressure, rate of injection, and fuel composition influence the duration of the ignition delay period.

Knock in CI Engines. As the combustion process in CI engines is triggered by autoignition of the fuel injected during the ignition delay period, factors that prolong the ignition delay period will increase the

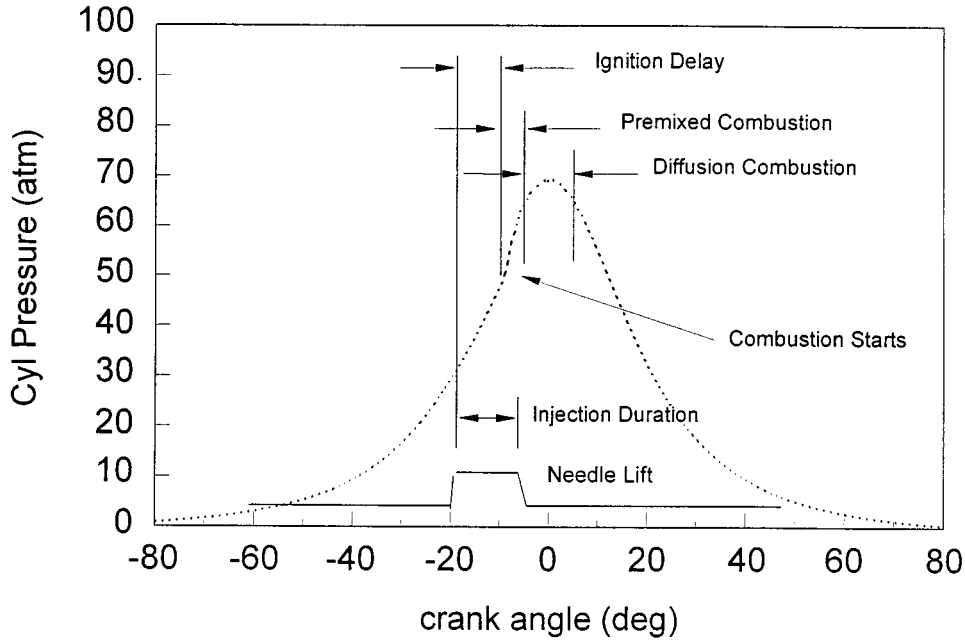

FIGURE 8.3.13 Combustion process in a CI engine.

premixed combustion duration causing very high rates of energy release and thus high rates of pressure rise. As a result, diesel knock may occur. The phenomenon is similar to knock in SI engines except that it occurs at the beginning of the combustion process rather than near the end, as observed in SI combustion. Factors that reduce the ignition delay period will reduce the possibility of knock in diesel engines. Among them are increasing the compression ratio, supercharging, increasing combustion chamber turbulence, increasing injection pressure, and using high-**cetane-number** (**CN**) fuel. For a more detailed discussion of the combustion process in IC engines, see Henein (1972), Lenz (1992), and Keating (1993).

Exhaust Emissions

Harmful Constituents

The products of combustion from IC engines contain several constituents that are considered hazardous to human health, including CO, UHCs NO_x, and **particulates** (from diesel engines). These emission products are discussed briefly below followed by a description of the principal schemes for their reduction.

Carbon Monoxide. CO is a colorless, odorless, and tasteless gas that is highly toxic to humans. Breathing air with a small volumetric concentration (0.3%) of CO in an enclosed space can cause death in a short period of time. CO results from the incomplete combustion of hydrocarbon fuels. One of the main sources of CO production in SI engines is the incomplete combustion of the rich fuel mixture that is present during idling and maximum power steady state conditions and during such transient conditions as cold starting, warm-up, and acceleration. Fuel maldistribution, poor condition of the ignition system, very lean combustion, and slow CO reaction kinetics also contribute to increased CO production in SI engines. CO production is not as significant in CI engines since these engines are always operated with significant excess air.

Unburned Hydrocarbons. When UHCs combine with NO_x (see below) in the presence of sunlight, ozone and photochemical oxidants form that can adversely affect human health. Certain UHCs are also

considered to be carcinogenic. The principal cause of UHC in SI engines is incomplete combustion of the fuel-air charge, resulting in part from flame quenching of the combustion process at the combustion chamber walls, and engine misfiring. Additional sources in four-stroke engines may include fuel mixture trapped in crevices of the top ring land of the piston and outgassed fuel during the expansion (power) stroke that was absorbed into the lubricating oil film during intake. In two-stroke SI engines, the scavenging process often results in a portion of the fresh mixture exiting the exhaust port before it closes, resulting in large UHC emissions.

The presence of UHC in CI engines is related to the heterogeneous nature of the fuel-air mixture. Under certain conditions, fuel-air mixtures that lie outside the flammability limits at both the lean and rich extremes can exist in portions of the combustion chamber and escape combustion, thus contributing significantly to UHC in the exhaust. Fuel injected near the end of the combustion process, and fuel remaining in the nozzle **sac volume** at the end of injection, both contribute to UHC emission in CI engines. Engine variables that affect UHC emissions include the fuel-air ratio, intake air temperature, and cooling water temperature.

Oxides of Nitrogen. Nitric oxide (NO) is formed from the combination of nitrogen and oxygen present in the intake air under the high-temperature conditions that result from the combustion process. As the gas temperature drops during the expansion stroke, the reaction is frozen, and levels of NO persist in the exhaust products far in excess of the equilibrium level at the exhaust temperature. In the presence of additional oxygen in the air, some NO transforms to nitrogen dioxide (NO_2), a toxic gas. The NO and NO_2 combined are referred to as oxides of nitrogen or NO_x. The production of NO_x is in general aggravated by conditions that increase the peak combustion temperature. In SI engines the most important variables that affect NO_x production are the air/fuel ratio, spark timing, intake air temperature, and amount of residual combustion products remaining in the cylinder after exhaust. In CI engines, ignition delay, which affects the degree of premixed combustion, plays a key role in NO_x formation. A larger premixed combustion fraction will produce higher combustion temperatures and higher levels of NO_x.

Particulates. Particulates are a troublesome constituent in the exhaust from CI engines. Particulates are defined by the US Environmental Protection Agency (EPA) as any exhaust substance (other than water) that can be trapped on a filter at a temperature of 325 K or below. Particulates trapped on a filter may be classified as soot plus an organic fraction of hydrocarbons and their partial oxidation products. Soot consists of agglomerates of solid uncombusted carbon particles. Particulates are of concern because their small size permits inhalation and entrapment in the lung walls, making them potential lung carcinogens.

Soot is formed in CI engines under conditions of heavy load when the gas temperature is high and the concentration of oxygen is low. Smoke production is affected by such parameters as fuel CN, rate of fuel injection, inlet air temperature, and the presence of secondary injection.

Control of Emissions from IC Engines

Figure 8.3.14 depicts the relative concentrations of CO, NO_x, and UHC in the exhaust products of an SI engine as a function of the fuel-air mixture. Lean mixture combustion, which promotes good thermal efficiency, also results in low UHC and CO production but causes high levels of NO_x emission. Increasing the fuel/air ratio to reduce NO_x results in increased CO and UHC emission. Approaches to reduce total emissions fall under two categories; the first concentrates on engine design and fuel modifications and the second involves treatment of exhaust gases after leaving the engine. In SI engines, the first approach focuses on addressing engine variables and design modifications which improve in-cylinder mixing and combustion in an effort to reduce CO and UHC emissions. To reduce NO_x, attention is focused on factors that reduce peak combustion temperature and reduce the oxygen available in the flame front. Design and operating parameters that have been implemented or modified for decreased emissions include compression ratio reduction, increased coolant temperature, modification of the combustion chamber shape to minimize surface-to-volume ratio and increase turbulence, improvement of intake manifold design for better charge distribution, use of fuel injection instead of carburetors for better mixture control,

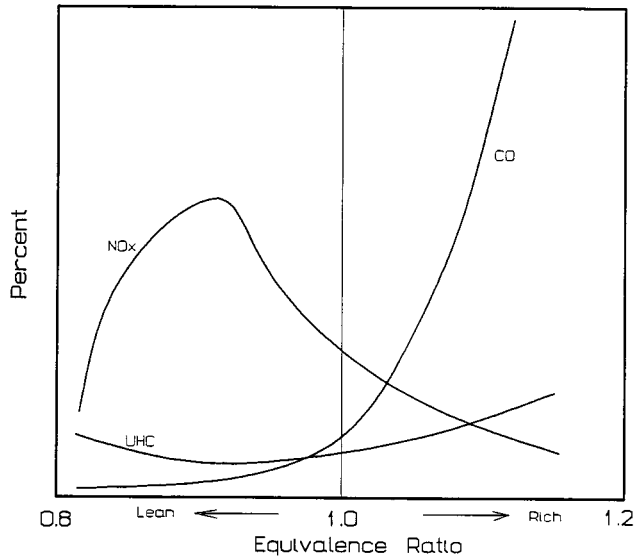

FIGURE 8.3.14 Emission levels from an SI engine vs. fuel-air mixture.

use of exhaust gas recirculation to reduce NO_x by lowering combustion temperatures, positive crankcase ventilation to reduce UHC, and increased aromatic content in gasoline.

Engine modifications that have been implemented to reduce emissions from CI engines include modifications to the combustion chamber shape to match the air swirl pattern and fuel spray pattern for better mixing and complete combustion, use of exhaust gas recirculation to limit NO_x production, use of higher injection pressure for better atomization to reduce soot and UHC, and the use of precise injection timing with electronic control.

In the second approach, several devices have been developed for after treatment of exhaust products. A thermal reactor may be used to oxidize UHC and CO. These typically consist of a well-insulated volume placed close to the exhaust manifold, with internal baffles to increase the gas residence time and an air pump to supply fresh oxygen for the oxidation reactions. Thermal reactors are ineffective for NO_x reduction and thus have limited application.

Catalytic converters utilize a catalyst, typically a noble metal such as platinum, rhodium, or palladium, deposited on a ceramic substrate to promote reactions at lower temperatures. Two types are in use, oxidation converters and reduction converters. Oxidation catalytic converters use the excess air available in lean mixtures (or supplied from an external air pump) to oxidize CO and UHC emissions. Reduction catalytic converters operate with low levels of oxygen to cause reduction of NO_x. Sometimes, dual catalytic converters are employed to treat all three pollutants with a reducing converter, to reduce NOx, placed upstream of an oxidation converter for treating CO and UHC. This arrangement requires that the engine be operated with a rich mixture which decreases fuel economy.

Three-way catalytic converters are a recent development that permits treatment of NO_x, CO, and UHC in a single device, thus reducing size and weight of the exhaust system. Proper operation of a three-way catalyst requires very nearly stoichiometric combustion. If the combustion is too lean, NO_x is not adequately reduced, and if it is too rich, UHC and CO are not adequately oxidized. There is a narrow band for equivalence ratio from about 0.999 to 1.007 within which conversion efficiency is 80% or better for all three pollutants (Kummer, 1980). Maintaining engine operation within this narrow mixture band requires a closed-loop fuel-metering system that utilizes an oxygen sensor placed in the exhaust system to monitor excess oxygen and control the fuel injection to maintain near stoichiometric combustion.

Reduction catalytic converters cannot be used with CI engines to reduce NO_x since they normally run lean with significant amounts of excess oxygen in the exhaust. Thus, engine design factors must be relied on to keep NO_x as low as possible. Soot emission may be reduced by after treatment using a

device called a trap oxidizer. A trap oxidizer filters particulate matter from the exhaust stream and oxidizes it, usually with the aid of a catalyst for reducing the oxidation temperature. They have been used on small, high-speed automotive diesel engines, but their application to larger, slower-speed engines is limited because of the higher level of particulate production and the lower exhaust temperature. For additional information on emissions see Henein (1972), Obert (1973), and *SAE Surface Vehicle Emissions Standards Manual* (1993).

Fuels for SI and CI Engines

Background

The primary distinguishing factor between SI and CI engines is the fundamental difference in the combustion process. SI engines rely on homogeneous, premixed combustion, while CI engines are designed for heterogeneous combustion with a premixed combustion period followed by a diffusion combustion period. The differences in the combustion process call for quite different qualities in the fuels to achieve optimum performance.

By far the most common fuel for SI engines is gasoline, although other fuels can be used in special circumstances including alcohol, natural gas, and propane. Even such low-grade fuels as wood gas and coal gas have been used to fuel SI engines during wartime when conventional fuels were in short supply. Diesel fuel is the predominant fuel for CI engines, but they too can be designed to operate on a variety of other fuels, such as natural gas, bio-gas, and even coal slurries. This discussion is confined to gasoline and diesel fuel, both of which are distilled from crude oil.

Crude oil is composed of several thousand different hydrocarbon compounds, which upon heating are vaporized at different temperatures. In the distillation process, different "fractions" of the original crude are separated according to the temperatures at which they vaporize. The more volatile fraction, naphtha, is followed in order of increasing temperature of vaporization by fractions called distillate, gas oil, reduced crude, and residual oil. These fractions may be further subdivided into light, middle, and heavy classifications. Light virgin naphtha can be used directly as gasoline, although it has relatively poor antiknock quality. The heavier fractions can be chemically processed through coking and catalytic cracking to produce additional gasoline. Diesel fuel is derived from the light to heavy virgin gas oil fraction and from further chemical processing of reduced crude.

Gasoline

Gasoline fuels are mixtures of hydrocarbon compounds with boiling points in the range of 32 to 215°C. The two most important properties of gasoline for SI engine performance are volatility and octane rating. Adequate volatility is required to ensure complete vaporization, as required for homogeneous combustion, and to avoid cold-start problems. If the volatility is too high, however, vapor locking in the fuel delivery system may become a problem. Volatility may be specified by the distillation curve (the distillation temperatures at which various percentages of the original sample have evaporated). Higher-volatility fuels will be characterized by lower temperatures for given fixed percentages of evaporated sample, or conversely, by higher percentages evaporated at or below a given temperature. Producers generally vary the volatility of gasoline to suit the season, increasing the volatility in winter to improve cold-start characteristics and decreasing it in summer to reduce vapor locking.

The octane rating of a fuel is a measure of its resistance to autoignition or knocking; higher-octane fuels are less prone to autoignition. The octane rating system assigns the value of 100 to iso-octane (C_8H_{18}, a fuel that is highly resistant to knock) and the value 0 to *n*-heptane (C_7H_{16}, a fuel that is prone to knock). Two standardized methods are employed to determine the octane rating of fuel test samples, the research method and the motor method; see ASTM Standards Part 47 — Test Methods for Rating Motor, Diesel and Aviation Fuels (ASTM, 1995). Both methods involve testing the fuel in a special variable-compression-ratio engine (cooperative fuels research or CFR engine). The test engine is operated on the fuel sample and the compression ratio is gradually increased to obtain a standard knock intensity reading from a knock meter. The octane rating is obtained from the volumetric percentage of iso-octane

in a blend of iso-octane and *n*-heptane that produces the same knock intensity at the same compression ratio. The principal differences between the research method and the motor method are the higher operating speed, higher mixture temperature, and greater spark advance employed in the motor method. Ratings obtained by the research method are referred to as the **research octane number** (RON), while those obtained with the motor method are called the motor octane number (MON). MON ratings are lower than RON ratings because of the more stringent conditions, i.e., higher thermal loading of the fuel. The octane rating commonly advertised on gasoline pumps is the **antiknock index**, $(R + M)/2$, which is the average of the values obtained by the two methods. The typical range of antiknock index for automotive gasolines currently available at the pump is 87 to 93. In general, higher compression SI engines require higher-octane fuels to avoid autoignition and to realize full engine performance potential from engines equipped with electronic control systems incorporating a knock sensor.

Straight-run gasoline (naphtha) has a poor octane rating on the order of 40 to 50 RON. Higher-octane fuels are created at the refinery by blending with higher-octane components produced through alkylation wherein light olefin gases are reacted with isobutane in the presence of a catalyst. Iso-octane, for example, is formed by reacting isobutane with butene. Aromatics with double carbon bonds shared between more than one ring, such as naphthalene and anthracene, serve to increase octane rating because the molecules are particularly difficult to break.

Additives are also used to increase octane ratings. In the past, a common octane booster added to automotive fuels was lead alkyls, either tetraethyl or tetramethyl lead. For environmental reasons, lead has been removed from automotive fuels in most countries. It is, however, still used in aviation fuel. Low-lead fuel has a concentration of about 0.5 g/L which boosts octane rating by about five points. The use of leaded fuel in an engine equipped with a catalytic converter to reduce exhaust emissions will rapidly deactivate the catalyst (typically a noble metal such as platinum or rhodium), quickly destroying the utility of the catalytic converter. Octane-boosting additives that are in current use include the oxygenators methanol, ethanol, and methyl tertiary butyl ether (MTBE).

RON values of special-purpose high-octane fuels for racing and aviation purposes can exceed 100 and are arrived at through an extrapolation procedure based on the knock-limited indicated mean effective pressure (klimep). The klimep is determined by increasing the engine intake pressure until knock occurs. The ratio of the klimep of the test fuel to that for iso-octane is used to extrapolate the octane rating above 100.

Diesel Fuels

Diesel fuels are blends of hydrocarbon compounds with boiling points in the range of 180 to 360°C. Properties that are of primary importance for CI fuels include the density, viscosity, cloud point, and ignition quality (CN). Diesel fuel exhibits a much wider range of variation in properties than does gasoline. The density of diesel fuels tends to vary according to the percentages of various fractions used in the blend. Fractions with higher distillation temperatures tend to increase the density. Variations in density result in variations in volumetric energy content and hence fuel economy, since fuel is sold by volume measure. Higher-density fuel will also result in increased soot emission. Viscosity is important to proper fuel pump lubrication. Low-viscosity fuel will tend to cause premature wear in injection pumps. Too high viscosity, on the other hand, may create flow problems in the fuel delivery system. Cloud point is the temperature at which a cloud of wax crystals begins to form in the fuel. This property is critical for cold-temperature operation since wax crystals will clog the filtration system. ASTM does not specify maximum cloud point temperatures, but rather recommends that cloud points be no more than 6°C above the tenth percentile minimum ambient temperature for the region for which the fuel is intended; see ASTM D 975 (ASTM 1995).

CN provides a measure of the autoignition quality of the fuel and is the most important property for CI engine fuels. The CN of a fuel sample is obtained through the use of a CI CFR engine in a manner analogous to the determination of octane rating. The test method for CN determination is specified in standard ASTM D 613. *n*-Cetane (same as hexadecane, $C_{16}H_{34}$) has good autoignition characteristics and is assigned the cetane value of 100. The bottom of the cetane scale was originally defined in terms

of α-methyl naphthalene ($C_{11}H_{10}$) which has poor autoignition characteristics and was assigned the value 0. In 1962, for reasons of availability and storability, the poor-ignition-quality standard fuel used to establish the low end of the cetane scale was changed to heptamethylnonane (HMN), with an assigned CN of 15. The CN of a fuel sample is determined from the relative volumetric percentages of cetane and HMN in a mixture that exhibits the same ignition delay characteristics as the test sample using the relation

$$\text{CN} = \%\ n\text{-cetane} + 0.15\,(\%\ \text{HMN}) \tag{8.3.10}$$

ASTM standard D 976 (ASTM, 1995) provides the following empirical correlation for calculating the **cetane index** of straight petroleum distillate fuels (no additives) as an approximation to the measured CN:

$$\text{Cetane Index} = 454.74 - 1641.416D + 774.74D^2 - 0.554B + 97.803\,(\log B)^2 \tag{8.3.11}$$

where D = density at 15°C (g/mL) and B = mid-boiling temperature (°C).

ASTM standard D 975 (ASTM, 1995) establishes three classification grades for diesel fuels (No. 1-D, No. 2-D, and No. 4-D) and specifies minimum property standards for these grades. No. 1-D is a volatile distillate fuel for engines that must operate with frequent changes in speed and load. No. 2-D is a lower-volatility distillate fuel for industrial and heavy mobile service engines. No. 4-D is a heavy fuel oil for low- and medium-speed engines. Nos. 1-D and 2-D are principally transportation fuels, while No. 4-D is for stationary applications. The ASTM minimum CN for No. 1-D and No. 2-D is 40, and for No. 4-D the minimum is 30. Typical CNs for transportation fuels lie in the range 40 to 55. Use of a low-cetane fuel aggravates diesel knock because of the longer ignition delay period which creates a higher fraction of premixed combustion.

Antiknock quality (octane number) and ignition quality (CN) are opposing properties of distillate fuels. The CN increases with decreasing octane rating of various fuels. Gasoline, with good antiknock quality, has a CN of approximately 10, while a diesel fuel with a CN of 50 will have an octane number of about 20. Thus, gasoline is not a suitable fuel for CI engines because of its poor autoignition quality, and diesel fuel is inappropriate for use in SI engines as a result of its poor antiknock quality. For additional information on fuels for IC engines see Owen and Coley (1995) and the *SAE Fuels and Lubricants Standards Manual* (1993).

Intake Pressurization — Supercharging and Turbocharging

Backround

Pressurizing the intake air (or mixture) by means of a compressor may be used to boost the specific power output of both SI and CI engines. Supercharging generally refers to the use of compressors that are mechanically driven from the engine crankshaft, while turbocharging refers to compressors powered by a turbine which extracts energy from the exhaust stream. Increasing the intake pressure increases the density and hence the mass flow rate of the intake mixture, allowing an increase in the fueling rate, thereby producing additional power. The mere process of increasing the cylinder pressure results in increased work output per cycle, as illustrated in the *P-V* diagram in Figure 8.3.15 which compares supercharged and naturally aspirated, air standard Otto cycles having the same compression ratio. The work done for the compressed intake cycle (Area 1,2,3,4,1 and Area 5,6,7,1,5) is greater than that for the naturally aspirated cycle (Area 1′,2′,3′,4′,1′) due to the boost of the intake pressure. Positive-displacement superchargers are capable of producing higher boost pressures than turbochargers, which are nearly always centrifugal-type fans. From a practical standpoint, the maximum useful boost pressure from either system is limited by the onset of autoignition in SI engines, and by the permissible mechanical and thermal stresses in CI engines.

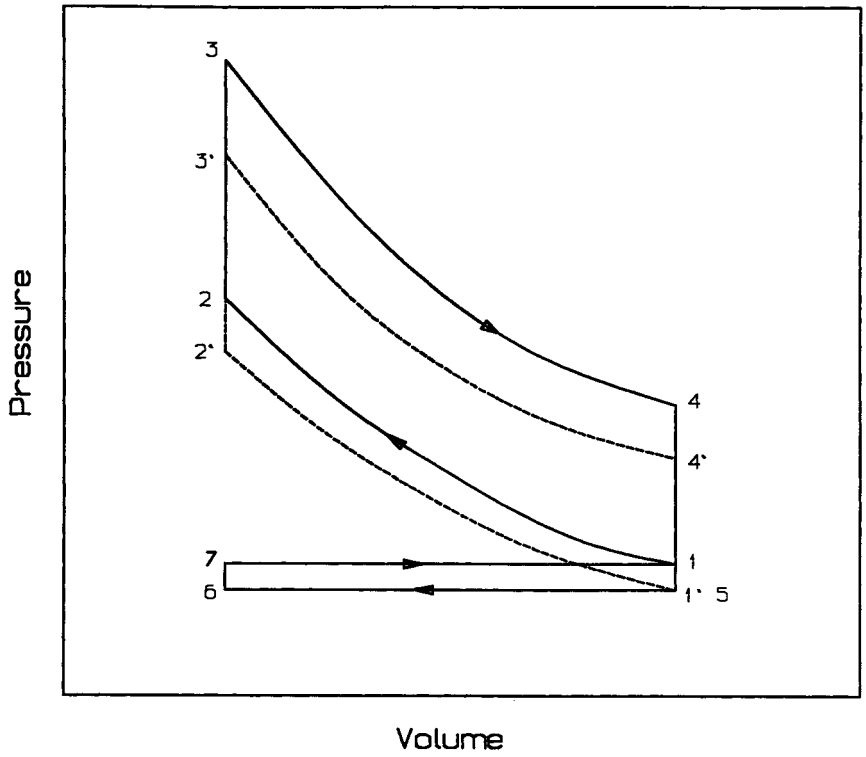

FIGURE 8.3.15 Comparison of supercharged and naturally aspirated Otto cycle.

Supercharging

The principal applications of supercharging of SI engines are in high-output drag-racing engines and in large aircraft piston engines to provide high specific output at takeoff and to improve power output at high altitudes. For diesel applications, supercharging is used mainly in marine and land-transportation applications. It is common to use either supercharging or turbocharging to improve the scavenging process in two-stroke diesel engines. Figure 8.3.16 is a schematic of an engine with a mechanically driven supercharger. Superchargers may be belt, chain, or gear driven from the engine crankshaft.

Two types of superchargers are in use: the positive displacement type (Roots blower) and the centrifugal type. Roots blowers may be classified as: (1) straight double lobe, (2) straight triple lobe, and (3) helix triple lobe (twisted 60%). The helix-triple-lobe-type runs quieter than the others and is generally recommended, especially for diesel engines operating under high torque at various speed conditions. The centrifugal-type, because of its high capacity and small weight and size, is best suited for applications where power and volumetric efficiency improvement are required at high engine speed, e.g., with aircraft engines. A centrifugal blower will also survive a backfire more readily than a Roots blower in SI applications. Since superchargers are directly driven from the engine output shaft, there is no inherent lag in the rate of pressure increase with engine speed, as is typically the case with turbochargers.

Turbocharging

Turbochargers utilize a centrifugal compressor that is directly connected to a turbine which extracts energy from the exhaust gases of the engine and converts it to the shaft work necessary to drive the compressor. Turbocharging is widely used to increase power output in automotive and truck applications of four-stroke SI and CI engines and to improve scavenging of two-stroke CI engines.

There are three methods of turbocharging: the constant-pressure, the pulse, and the pulse converter methods. In the constant-pressure method, as illustrated in Figure 8.3.17, the exhaust pressure is main-

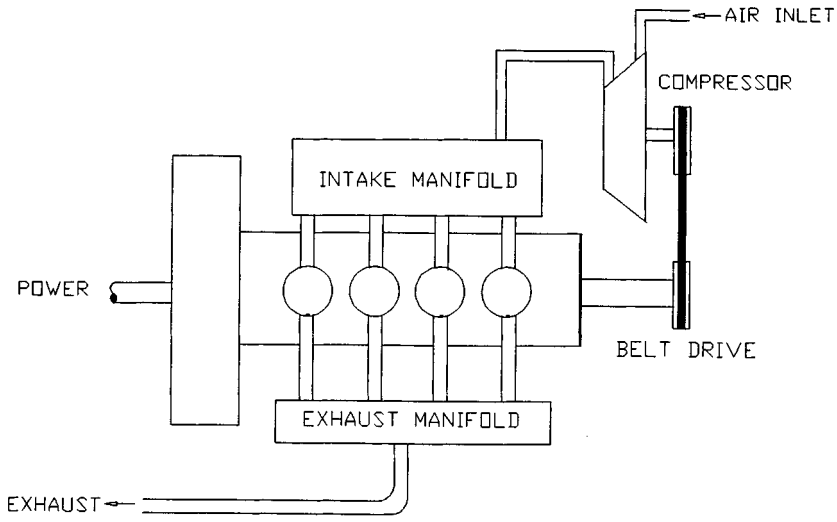

FIGURE 8.3.16 Schematic diagram of supercharged engine.

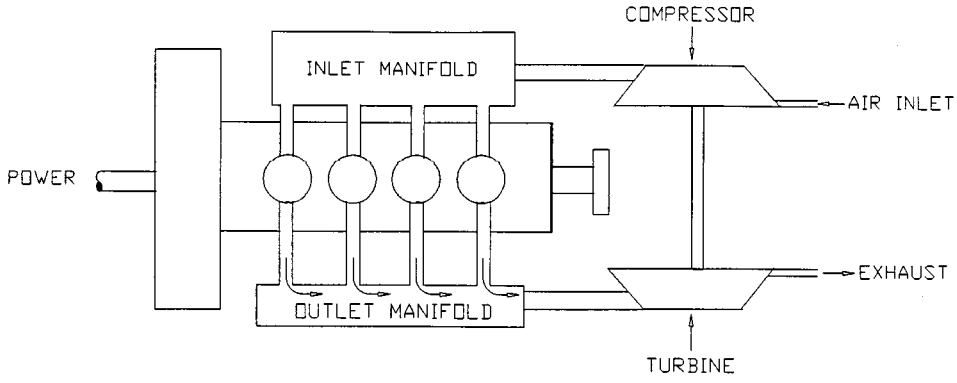

FIGURE 8.3.17 Schematic diagram of a constant-pressure turbocharger.

tained at a nearly constant level above atmospheric. To accomplish this, the exhaust manifold must be large enough to damp out the pressure fluctuations caused by the unsteady flow characteristic of the engine exhaust process. In this method, the turbine operates efficiently under steady-flow conditions; however, some engine power is lost because of the increased backpressure in the exhaust manifold.

The pulse turbocharger, as illustrated in Figure 8.3.18, utilizes the kinetic energy generated by the exhaust blow-down process in each cylinder. This is accomplished by using small exhaust lines grouped together in a common manifold to receive the exhaust from the cylinders which are blowing down sequentially. In this method, the pressure at the turbine inlet tends to fluctuate, which is not conducive to good turbine efficiency. This is offset to a large degree, however, by improved engine performance as a result of the lower exhaust backpressure relative to the constant-pressure method. The pulse converter method represents a compromise between the previous two techniques. In principle, this is accomplished by converting the kinetic energy in the blow-down process into a pressure rise at the turbine by utilizing one or more diffusers. Details of the different methods of turbocharging may be found in Watson and Janota (1982).

Recent advances in turbocharging technology have focused mainly on (1) improvement of the turbine transient response (turbo-lag), (2) improvement of the torque-speed characteristics of the engine, and (3) increasing the power output by increasing the boost pressure and using charge cooling (intercooling).

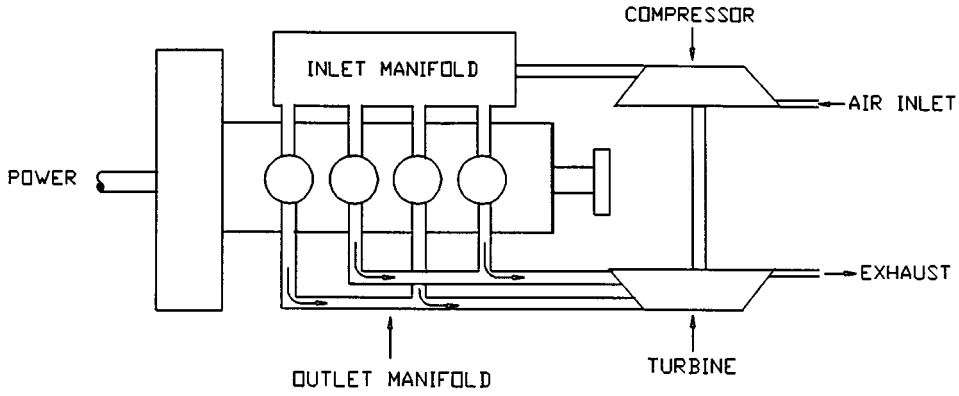

FIGURE 8.3.18 Schematic diagram of a pulse turbocharger.

The use of ceramic materials in fabricating turbine rotors improves the turbine transient response since they are lighter in weight and have less rotational inertia. Ceramic rotors also have greater thermal operating range because of their lower thermal expansion. The use of variable-geometry turbochargers can improve the low-speed torque characteristics of the engine and help reduce the transient response time. This is due to the ability of the variable-geometry turbocharger to change its internal geometry to accommodate low flow rates at low engine speeds and higher-volume flow rates at high engine speeds. However, since the geometry of the turbine rotor remains unchanged while the internal geometry varies, the turbine efficiency will be reduced for all internal geometries other than the optimum design geometry. In response to increased demand for diesel engines with high boost pressure and with size constraints, advances in the aerothermodynamics of axial/radial flow and of two-stage turbochargers, and also in the design of compressor and turbine blades, have allowed high boost pressure at improved overall turbocharger efficiency.

Charge cooling by means of a heat exchanger (intercooler) between the compressor and the intake ports is effective in reducing NO_x emissions and improving the power output of turbocharged diesel engines and in reducing the probability of knock in SI engines. There are two types of charge cooling in use, air-to-air and air-to-water. Air-to-water cooling is used in marine applications, where a source of cool water is available, while air-to-air intercoolers are used for automotive and truck applications.

Defining Terms

Antiknock index: The average of the two octane numbers obtained by the research method and the motor method.

Autoignition: The ability of a fuel-air mixture to spontaneously ignite under conditions of high temperature and pressure.

Bottom dead center (BDC): Piston located at its lowest position in the cylinder. Cylinder volume is maximum at BDC.

Brake mean effective pressure (bmep): Ratio of brake work output per cycle to the displacement volume.

Brake specific fuel consumption (bsfc): The ratio of fuel consumption rate in kg/hr to the engine output in kw.

Brake work: Work produced at the output shaft of an IC engine as measured by a dynamometer.

Cetane index: An approximation to the measured cetane number determined from an empirical relationship specified in ASTM D 976.

Cetane number: A measure of the autoignition quality of a fuel important for proper performance of CI engines determined experimentally through use of a CI CFR test engine.

Clearance volume: Combustion chamber volume remaining above the piston at TDC.

Compression ignition (CI) engine: Air alone is compressed in the cylinder and fuel is injected near TDC. Combustion results from autoignition of the fuel-air mixture due to the high temperature of the air.

Compression ratio: The ratio of the cylinder volume at BDC to the volume at TDC.

Cut-off ratio: Ratio of cylinder volume at the end of heat addition to the volume at the start of heat addition in the ideal diesel cycle.

Cylinder volume: Volume above piston at BDC. Equals displacement volume plus clearance volume.

Direct injection (DI): Method of fuel injection in low- and medium-speed CI engines wherein fuel is injected into the main combustion chamber which is formed by a bowl in the top of the piston.

Displacement volume: Difference in cylinder volume between TDC and BDC.

Equivalence ratio: Actual fuel-air ratio divided by stoichiometric fuel-air ratio.

Four-stroke engine: Entire cycle completed in two revolutions of the crankshaft and four strokes of the piston.

Fuel-air ratio: Ratio of mass of fuel to mass of air in the cylinder prior to combustion.

Glow plug: Electric heater installed in prechamber of an IDI diesel engine to aid cold starting.

Heterogeneous combustion: Refers to the mixture of liquid fuel droplets and evaporated fuel vapor and air mixture that is present in CI engine combustion chambers prior to ignition.

Ignition delay period: Period between start of injection and onset of autoignition in a CI engine.

Indicated mean effective pressure (imep): Ratio of net indicated work output of an IC engine to the displacement volume.

Indicated work: Work output of an IC engine cycle determined by an area calculation from an indicator diagram.

Indicator diagram: Pressure-volume trace for an IC engine cycle. Area enclosed by diagram represents work.

Indirect injection (IDI): Method of fuel injection used in high-speed CI engines wherein the fuel is injected into a precombustion chamber to promote fuel-air mixing and reduce ignition delay.

Knock: In SI engines: the noise that accompanies autoignition of the end portion of the uncombusted mixture prior to the arrival of the flame front. In CI engines: The noise that accompanies autoignition of large premixed fractions that are generated during prolonged ignition delay periods. Knock is detrimental to either type of engine.

NO_x: Harmful oxides of nitrogen (NO and NO_2) appearing in the exhaust products of IC engines.

Octane number: Antiknock rating for fuels important for prevention of autoignition in SI engines.

Particulates: Any exhaust substance, other than water, that can be collected on a filter. Harmful exhaust product from CI engines.

Power density: Power produced per unit of engine mass.

Premixed homogeneous combustion: Fuel and air are mixed in an appropriate combustible ratio prior to ignition process. This is the combustion mode for SI engines and for the initial combustion phase in CI engines.

Sac volume: Volume of nozzles below the needle of a diesel fuel injector that provides a source of UHC emissions in CI engines.

Scavenging: The process of expelling exhaust gases and filling the cylinder with fresh charge in two-stroke engines. This is often accomplished in SI engines by pressurizing the fresh mixture in the crankcase volume beneath the piston and in CI engines by using a supercharger or turbocharger.

Spark ignition (SI) engine: Homogeneous charge of air-fuel mixture is compressed and ignited by a spark.

Stroke: Length of piston movement from TDC to BDC, equal to twice the crankshaft throw.

Supercharging: Pressurizing the intake of an IC engine using a compressor that is mechanically driven from the crankshaft.

Surface ignition: A source of autoignition in SI engines caused by surface hot spots.

Swirl: Circular in-cylinder air motion designed into CI engines to promote fuel-air mixing.

Swirl ratio: Ratio of rotational speed of in-cylinder air (rpm) to engine speed (rpm).

Top dead center (TDC): Piston located at its uppermost position in the cylinder. Cylinder volume (above the piston) is minimum at TDC.

Turbocharging: Pressurizing the intake of an IC engine with a compressor that is driven by a turbine which extracts energy from the exhaust gas stream.

Two-stroke engine: Entire cycle completed in one revolution of the crankshaft and two strokes of the piston.

Unburned hydrocarbons (UHC): Harmful emission product from IC engines consisting of hydrocarbon compounds that remain uncombusted.

Volumetric efficiency: Ratio of the actual mass of air intake per cycle to the displacement volume mass determined at inlet temperature and pressure.

8.4 Hydraulic Turbines

Roger E. A. Arndt

Introduction

A hydraulic turbine is a mechanical device that converts the potential energy associated with a difference in water elevation **(head)** into useful work. Modern hydraulic turbines are the result of many years of gradual development. Economic incentives have resulted in the development of very large units (exceeding 800 mW in capacity) with efficiencies that are sometimes in excess of 95%.

The emphasis on the design and manufacture of very large turbines is shifting to the production of smaller units, especially in developed nations, where much of the potential for developing large-baseload plants has been realized. At the same time, the escalation in the cost of energy has made many smaller sites economically feasible and has greatly expanded the market for smaller turbines. The increased value of energy also justifies the cost of refurbishment and increasing the capacity of older facilities. Thus, a new market area is developing for updating older turbines with modern replacement **runners** having higher efficiency and greater capacity.

General Description

Typical Hydropower Installation

As shown schematically in Figure 8.4.1, the hydraulic components of a hydropower installation consist of an intake, penstock, guide vanes or distributor, turbine, and **draft tube**. Trash racks are commonly provided to prevent ingestion of debris into the turbine. Intakes usually require some type of shape transition to match the passageway to the turbine and also incorporate a gate or some other means of stopping the flow in case of an emergency or for turbine maintenance. Some types of turbines are set in an open flume; others are attached to a closed-conduit penstock.

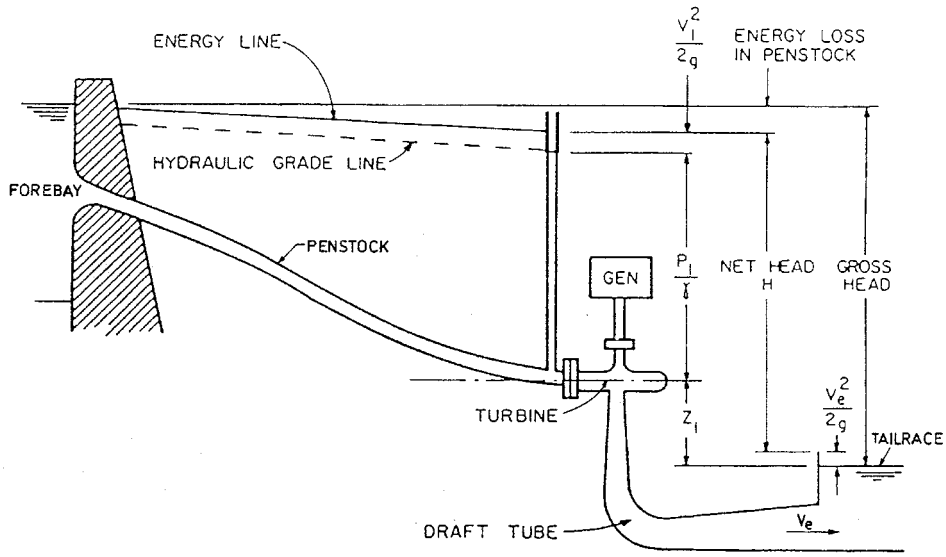

FIGURE 8.4.1 Schematic of a hydropower installation.

Turbine Classification

There are two types of turbines, denoted as impulse and reaction. In an impulse turbine, the available head is converted to kinetic energy before entering the **runner**; the power available is extracted from the flow at approximately atmospheric pressure. In a reaction turbine, the runner is completely submerged and both the pressure and the velocity decrease from inlet to outlet. The velocity head in the inlet to the turbine runner is typically less than 50% of the total head available.

Impulse Turbines. Modern impulse units are generally of the Pelton type and are restricted to relatively high-head applications (Figure 8.4.2). One or more jets of water impinge on a wheel containing many curved buckets. The jet stream is directed inward, sideways, and outward, thereby producing a force on the bucket, which in turn results in a torque on the shaft. All kinetic energy leaving the runner is "lost." A draft tube is generally not used since the runner operates under approximately atmospheric pressure and the head represented by the elevation of the unit above tailwater cannot be utilized.* Since this is a high-head device, this loss in available head is relatively unimportant. As will be shown later, the Pelton wheel is a low-**specific-speed** device. Specific speed can be increased by the addition of extra nozzles, the specific speed increasing by the square root of the number of nozzles. Specific speed can also be increased by a change in the manner of inflow and outflow. Special designs such as the Turgo or cross-flow turbines are examples of relatively high specific speed impulse units (Arndt, 1991).

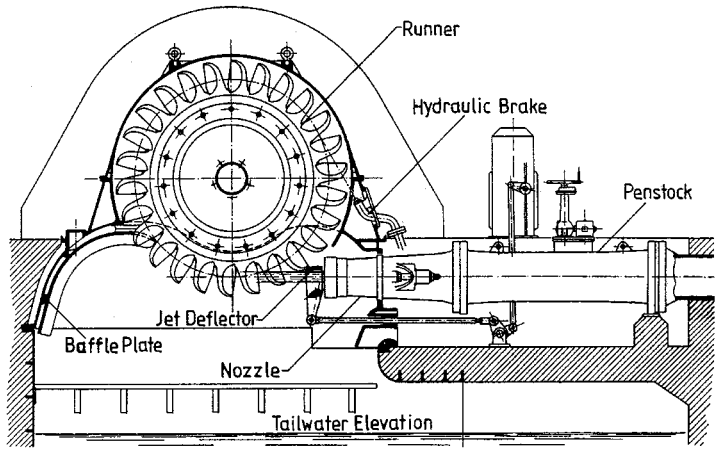

FIGURE 8.4.2 Cross section of a single wheel, single jet Pelton turbine. This is the third-highest-head pelton turbine in the world, H = 1447 m, n = 500 rpm, P = 35.2 MW, $N_s \sim 0.038$. (Courtesy of Vevey Charmilles Engineering Works, Adapted from J. Raabe, *Hydro Power: The Design, Use, and Function of Hydromechanical, Hydraulic, and Electrical Equipment*, VDI Verlag, Dusseldorf, Germany.)

Most Pelton wheels are mounted on a horizontal axis, although newer vertical-axis units have been developed. Because of physical constraints on orderly outflow from the unit, the maximum number of nozzles is generally limited to six or fewer. While the power of a reaction turbine is controlled by the **wicket gates**, the power of the Pelton wheel is controlled by varying the nozzle discharge by means of an automatically adjusted needle, as illustrated in Figure 8.4.2. Jet deflectors, or auxiliary nozzles are provided for emergency unloading of the wheel. Additional power can be obtained by connecting two wheels to a single generator or by using multiple nozzles. Since the needle valve can throttle the flow while maintaining essentially constant jet velocity, the relative velocities at entrance and exit remain unchanged, producing nearly constant efficiency over a wide range of power output.

* In principle, a draft tube could be used, which requires the runner to operate in air under reduced pressure. Attempts at operating an impulse turbine with a draft tube have not met with much success.

Reaction Turbines. Reaction turbines are classified according to the variation in flow direction through the runner. In radial- and mixed-flow runners, the flow exits at a radius different than from the radius at the inlet. If the flow enters the runner with only radial and tangential components, it is a radial-flow machine. The flow enters a mixed-flow runner with both radial and axial components. Francis turbines are of the radial- and mixed-flow types, depending on the design specific speed. A Francis turbine is illustrated in Figure 8.4.3.

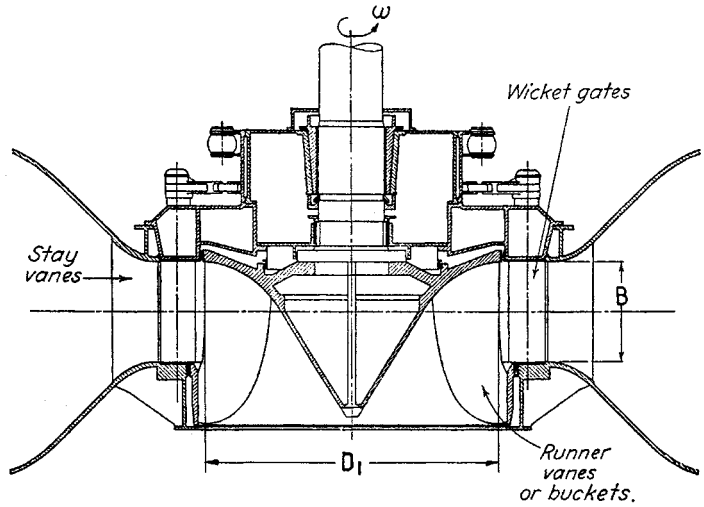

FIGURE 8.4.3 Francis turbine, $N_s \sim 0.66$. (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

Axial-flow propeller turbines are generally either of the fixed-blade or Kaplan (adjustable-blade) variety. The "classical" propeller turbine, illustrated in Figure 8.4.4, is a vertical-axis machine with a scroll case and a radial wicket gate configuration that is very similar to the flow inlet for a Francis turbine. The flow enters radially inward and makes a right-angle turn before entering the runner in an axial direction. The Kaplan turbine has both adjustable runner blades and adjustable wicket gates. The control system is designed so that the variation in blade angle is coupled with the wicket gate setting in a manner which achieves best overall efficiency over a wide range of flow rates.

Some modern designs take full advantage of the axial-flow runner; these include the tube, bulb, and Straflo types illustrated in Figure 8.4.5. The flow enters and exits the turbine with minor changes in direction. A wide variation in civil works design is also permissible. The tubular-type can be fixed propeller, semi-Kaplan, or fully adjustable. An externally mounted generator is driven by a shaft which extends through the flow passage either upstream or downstream of the runner. The bulb turbine was originally designed as a high-output, low-head unit. In large units, the generator is housed within the bulb and is driven by a variable-pitch propeller at the trailing end of the bulb. Pit turbines are similar in principle to bulb turbines, except that the generator is not enclosed in a fully submerged compartment (the bulb). Instead, the generator is in a compartment that extends above water level. This improves access to the generator for maintenance.

Principles of Operation

Power Available, Efficiency

The power that can be developed by a turbine is a function of both the head and flow available:

$$P = \eta \rho g Q H \tag{8.4.1}$$

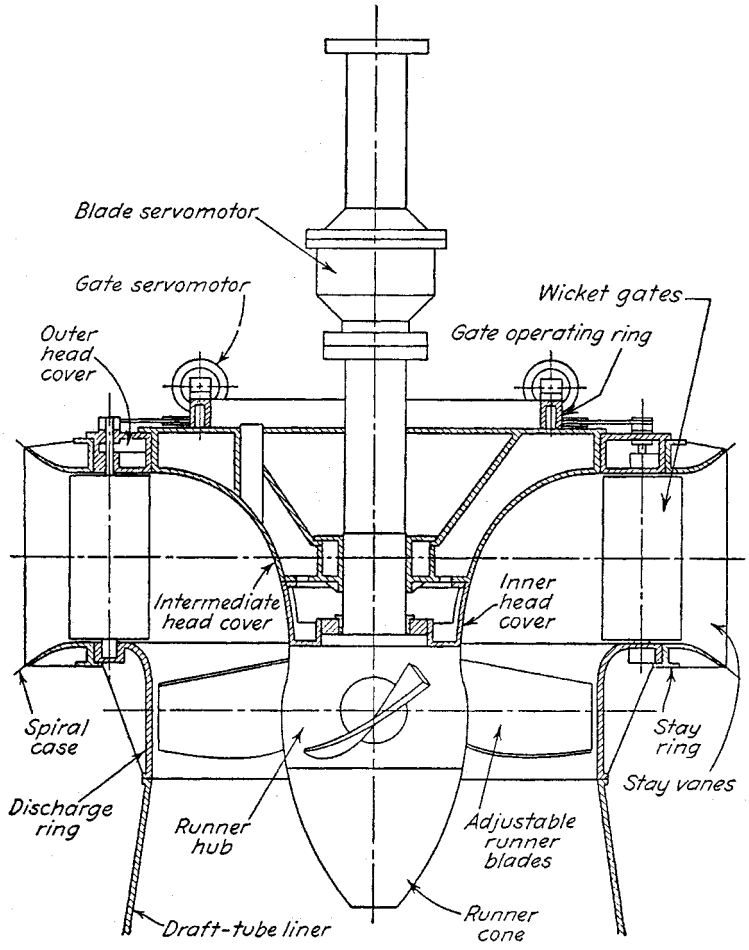

FIGURE 8.4.4 Smith-Kaplan axial flow turbine with adjustable-pitch runner blades $N_s \sim 2.0$. (From J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

where η is the turbine efficiency, ρ is the density off water (kg/m^3), g is the acceleration due to gravity (m/sec^2), Q is the flow rate (m^3/sec), and H is the *net head* in meters. Net head is defined as the difference between the total head at the inlet to the turbine and the total head at the tailrace as illustrated in Figure 8.4.1. Different definitions of net head are used in practice, which depend on the value of the exit velocity head, $V_e^2/2g$, used in the calculation. The International Electrotechnical Test Code uses the velocity head at the draft tube exit.

The efficiency depends on the actual head and flow utilized by the turbine runner, flow losses in the draft tube, and the frictional resistance of mechanical components.

Similitude and Scaling Formulae

Under a given head, a turbine can operate at various combinations of speed and flow depending on the inlet settings. For reaction turbines, the flow into the turbine is controlled by the wicket gate angle, α. The flow is typically controlled by the nozzle opening in impulse units. Turbine performance can be described in terms of nondimensional variables:

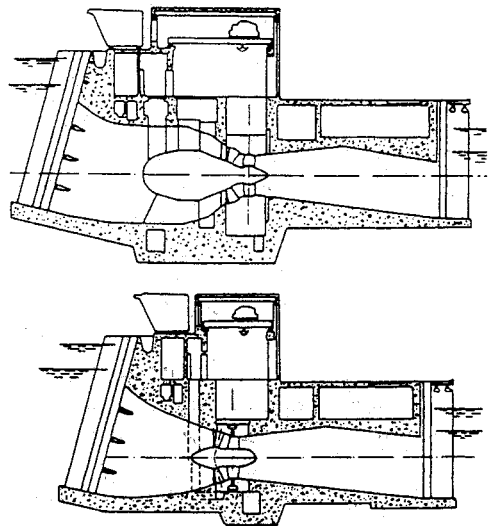

FIGURE 8.4.5 Comparison between bulb (upper) and Straflow (lower) turbines. (Courtesy of U.S. Department of Energy.)

$$\psi = \frac{2gH}{\omega^2 D^2} \tag{8.4.2}$$

$$\phi = \frac{Q}{\sqrt{2gH}D^2} \tag{8.4.3}$$

where ω is the rotational speed of the turbine in radians per second and D is the diameter of the turbine.

The hydraulic efficiency of the runner alone is given by

$$\eta_h = \frac{\phi}{\sqrt{\psi}}\left(C_1 \cos\alpha_1 - C_2 \cos\alpha_2\right) \tag{8.4.4}$$

where C_1 and C_2 are constants that depend on the specific turbine configuration and α_1 and α_2 are the inlet and outlet angles that the absolute velocity vectors make with the tangential direction. The value of $\cos\alpha_2$ is approximately zero at peak efficiency. The terms ϕ, ψ, α_1, and α_2 are interrelated. By using model test data, isocontours of efficiency can be mapped in the ϕ-ψ plane. This is typically referred to as a hill diagram as shown in Figure 8.4.6.

The specific speed is defined as

$$N_s \equiv \frac{\omega\sqrt{Q}}{(2gH)^{3/4}} = \sqrt{\frac{\phi}{\psi}} \tag{8.4.5}$$

A given specific speed describes a specific combination of operating conditions that ensures similar flow patterns and same efficiency in geometrically similar machines regardless of size and rotational speed of the machine. It is customary to define the design specific speed in terms of the value at the design head and flow where peak efficiency occurs. The value of specific speed so defined permits a classification of different turbine types.

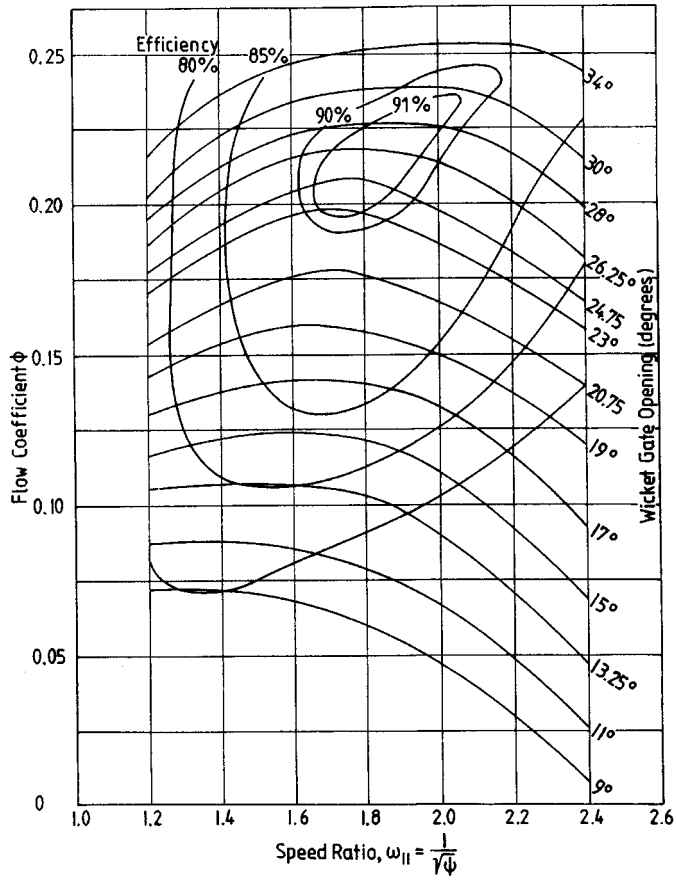

FIGURE 8.4.6 Typical hill diagram. (Adapted from T.L. Wall, Draft tube surging times two: the twin vortex problem, in *Hydro Rev.* 13(1): 60–69, 1994. With permission.)

The specific speed defined herein is dimensionless. Many other forms of specific speed exist which are dimensional and have different numerical values depending on the system of units used (Arndt, 1991).* The similarity arguments used to arrive at the concept of specific speed indicate that a given machine of diameter D operating under a head H will discharge a flow Q and produce a torque T and power P at a rotational speed ω given by

$$Q = \phi D^2 \sqrt{2gH} \tag{8.4.6}$$

$$T = T_{11} \rho D^3 2gH \tag{8.4.7}$$

$$P = P_{11} \rho D^2 (2gH)^{3/2} \tag{8.4.8}$$

$$\omega = \frac{2u_1}{D} = \omega_{11} = \frac{\sqrt{2gH}}{D} \qquad \left[\omega_{11} = \frac{1}{\sqrt{\psi}}\right] \tag{8.4.9}$$

* The literature also contains two other minor variations of the dimensionless form. One differs by a factor of $1/\pi^{1/2}$ and the other by $2^{3/4}$.

with

$$P_{11} = T_{11}\omega_{11} \tag{8.4.10}$$

where T_{11}, P_{11}, and ω_{11} are also nondimensional.* In theory, these coefficients are fixed for a machine operating at a fixed value of specific speed, independent of the size of the machine. Equations 8.4.6 through 8.4.10 can be used to predict the performance of a large machine using the measured characteristics of a smaller machine or model.

Factors Involved in Selecting a Turbine

Performance Characteristics

Impulse and reaction turbines are the two basic types of turbines. They tend to operate at peak efficiency over different ranges of specific speed. This is due to geometric and operational differences.

Impulse Turbines. Of the head available at the nozzle inlet, a small portion is lost to friction in the nozzle and to friction on the buckets. The rest is available to drive the wheel. The actual utilization of this head depends on the velocity head of the flow leaving the turbine and the setting above tailwater. Optimum conditions, corresponding to maximum utilization of the head available, dictate that the flow leaves at essentially zero velocity. Under ideal conditions, this occurs when the peripheral speed of the wheel is one half the jet velocity. In practice, optimum power occurs at a speed coefficient, ω_{11}, somewhat less than 1.0. This is illustrated in Figure 8.4.7. Since the maximum efficiency occurs at fixed speed for fixed H, V_j must remain constant under varying flow conditions. Thus, the flow rate Q is regulated with an adjustable nozzle. However, maximum efficiency occurs at slightly lower values of ω_{11} under partial power settings. Present nozzle technology is such that the discharge can be regulated over a wide range at high efficiency.

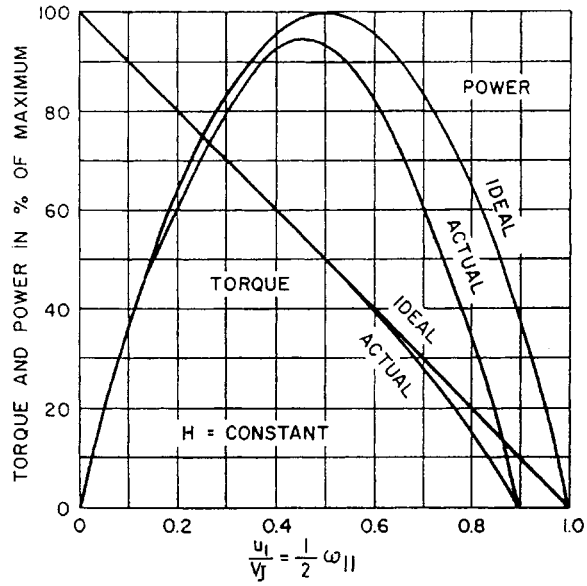

FIGURE 8.4.7 Ideal and actual variable-speed performance for an impulse turbine. (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

* The reader is cautioned that many texts, especially in the American literature, contain dimensional forms of T_{11}, P_{11}, and ω_{11}.

A given head and penstock configuration establishes the optimum jet velocity and diameter. The size of the wheel determines the speed of the machine. The design specific speed is approximately

$$N_s = 0.77\frac{d_j}{D} \quad \text{(Pelton turbines)} \tag{8.4.11}$$

Practical values of d_j/D for Pelton wheels to ensure good efficiency are in the range 0.04 to 0.1, corresponding to N_s values in the range 0.03 to 0.08. Higher specific speeds are possible with multiple-nozzle designs. The increase is proportional to the square root of the number of nozzles. In considering an impulse unit, one must remember that efficiency is based on net head; the net head for an impulse unit is generally less than the net head for a reaction turbine at the same *gross head* because of the lack of a draft tube.

Reaction Turbines. The main difference between impulse and reaction turbines is the fact that a pressure drop takes place in the rotating passages of the reaction turbine. This implies that the entire flow passage from the turbine inlet to the discharge at the tailwater must be completely filled. A major factor in the overall design of modern reaction turbines is the draft tube. It is usually desirable to reduce the overall equipment and civil construction costs by using high-specific speed runners. Under these circumstances the draft tube is extremely critical both flow-stability and efficiency viewpoints.* At higher specific speed, a substantial percentage of the available total energy is in the form of kinetic energy leaving the runner. To recover this efficiently, considerable emphasis should be placed on the draft tube design.

The practical specific speed range for reaction turbines is much broader than for impulse wheels. This is due to the wider range of variables which control the basic operation of the turbine. The pivoted guide vanes allow for control of the magnitude and direction of the inlet flow. Because there is a fixed relationship among blade angle, inlet velocity, and peripheral speed for shock-free entry, this requirement cannot be completely satisfied at partial flow without the ability to vary blade angle. This is the distinction between the efficiency of fixed-propeller and Francis-types at partial loads and the fully adjustable Kaplan design.

Referring to Equation 8.4.4, optimum hydraulic efficiency of the runner would occur when α_2 is equal to 90°. However, the overall efficiency of the turbine is dependent on the optimum performance of the draft tube as well, which occurs with a little swirl in the flow. Thus, the best overall efficiency occurs with $\alpha_2 \approx 75°$ for high-specific speed turbines.

The determination of optimum specific speed in a reaction turbine is more complicated than for an impulse unit since there are more variables. For a radial-flow machine, an approximate expression is

$$N_s = 1.64\left[C_v \sin\alpha_1 \frac{B}{D_1}\right]^{1/2} \omega_{11} \quad \text{(Francis turbines)} \tag{8.4.12}$$

where C_v is the fraction of net head that is in the form of inlet velocity head and B is the height of the inlet flow passage (Figure 8.4.3). Value of N_s for Francis units is normally found to be in the range 0.3 to 2.5.

Standardized axial-flow machines are available in the smaller sizes. These units are made up of standard components, such as shafts and blades. For such cases,

$$N_s \sim \frac{\sqrt{\tan\beta}}{n_B^{3/4}} \quad \text{(propeller turbines)} \tag{8.4.13}$$

* This should be kept in mind when retrofitting an older, low-specific-speed turbine with a new runner of higher capacity.

where β is the blade pitch angle and n_B is the number of blades. The advantage of controllable pitch is also obvious from this formula, the best specific speed simply being a function of pitch angle.

It should be further noted that ω_{11} is approximately constant for Francis units and N_s is proportional to $(B/D_1)^{1/2}$. It can be also shown that velocity component based on the peripheral speed at the throat, ω_{11e}, is proportional to N_s. In the case of axial-flow machinery, ω_{11} is also proportional to N_s. For minimum cost, peripheral speed should be as high as possible, consistent with cavitation-free performance. Under these circumstances, N_s would vary inversely with the square root of head:

$$N_s = \frac{C}{\sqrt{H}} \quad (H \text{ is in meters}) \tag{8.4.14}$$

where the range of C is 21 to 30 for fixed propeller units, 21 to 32 for Kaplan units, and 16 to 25 for Francis units.

Performance Comparison. The physical characteristics of various runner configurations are summarized in Figure 8.4.8. It is obvious that the configuration changes with speed and head. Impulse turbines are efficient over a relatively narrow range of specific speed, whereas Francis and propeller turbines have a wider useful range. An important consideration is whether or not a turbine is required to operate over a wide range of load. Pelton wheels tend to operate efficiently over a wide range of power loading because of their nozzle design. In the case of reaction machines that have fixed geometry, such as Francis and propeller turbines, efficiency can vary widely with load. However, Kaplan and Deriaz* turbines can maintain high efficiency over a wide range of operating conditions. The decision of whether to select a simple configuration with a relatively "peaky" efficiency curve or go to the added expense of installing a more complex machine with a broad efficiency curve will depend on the expected operation of the plant and other economic factors.

Note in Figure 8.4.8 that there is an overlap in the range of application of various types of equipment. This means that either type of unit can be designed for good efficiency in this range, but other factors, such as generator speed and cavitation, may dictate the final selection.

Speed Regulation

The speed regulation of a turbine is an important and complicated problem. The magnitude of the problem varies with size, type of machine and installation, type of electrical load, and whether or not the plant is tied into an electrical grid. Note that runaway or no-load speed can be higher than design speed by factors as high as 2.6. This is an important design consideration for all rotating parts, including the generator.

The speed of a turbine has to be controlled to a value that matches the generator characteristics and the grid frequency:

$$n = \frac{120 f}{N_p} \tag{8.4.15}$$

where n is turbine speed in rpm, f is the required grid frequency in Hz, and N_p is the number of poles in the generator. Typically, N_p is in multiples of 4. There is a tendency to select higher speed generators to minimize weight and cost. However, consideration has to be given to speed regulation.

It is beyond the scope of this section to discuss the question of speed regulation in detail. Regulation of speed is normally accomplished through flow control. Adequate control requires sufficient rotational inertia of the rotating parts. When load is rejected, power is absorbed, accelerating the flywheel; and when load is applied, some additional power is available from deceleration of the flywheel. Response

* An adjustable blade mixed-flow turbine (Arndt, 1991).

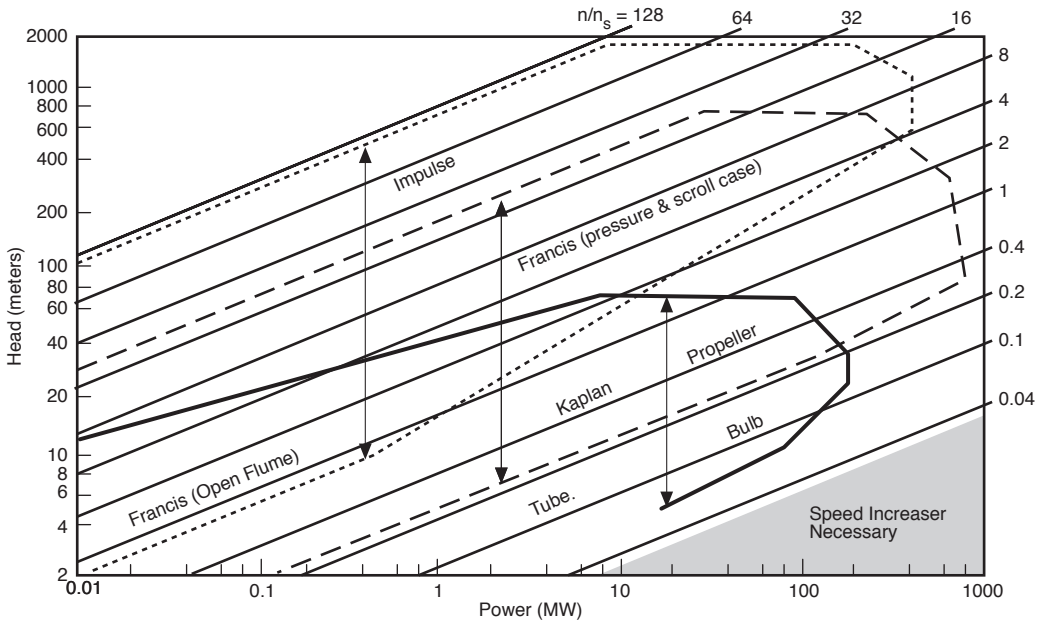

FIGURE 8.4.8 Application chart for various turbine types (n/n_S is the ratio of turbine speed in rpm, n, to specific speed defined in the metric system, $n_S = nP^{1/2}/H^{3/4}$ with P in kilowatts). (From Arndt, R.E.A., in *Hydropower Engineering Handbook*, J.S. Gulliver and R.E.A. Arndt, Eds., McGraw-Hill, New York, 1991, 4.1–4.67. With permission.)

time of the governor must be carefully selected, since rapid closing can lead to excessive pressures in the penstock.

A Francis turbine is controlled by opening and closing the wicket gates, which vary the flow of water according to the load. The actuator components of a governor are required to overcome the hydraulic and frictional forces and to maintain the wicket gates in fixed position under steady load. For this reason, most governors have hydraulic actuators. On the other hand, impulse turbines are more easily controlled, because the jet can be deflected or an auxiliary jet can by bypass flow from the power-producing jet without changing the flow rate in the penstock. This permits long delay times for adjusting the flow rate to the new flywheel; and when load is applied power conditions. The spear or needle valve controlling the flow rate can close quite slowly, say, in 30 to 60 sec, thereby minimizing pressure rise in the penstock.

Several types of governors are available, which vary with the work capacity desired and/or the degree of sophistication of control. These vary from pure mechanical to mechanical-hydraulic and electrohydraulic. Electrohydraulic units are sophisticated pieces of equipment and would not be suitable for remote regions. The precision of governing necessary will depend on whether the electrical generator is synchronous or asynchronous (induction type). There are advantages to the induction type of generator. It is less complex and therefore less expensive, but has typically slightly lower efficiency. Its frequency is controlled by the frequency of the grid it is feeding into, thereby eliminating need of an expensive the conventional governor. It cannot operate independently but can only feed into a network and does so with lagging power factor which may or may not be a disadvantage, depending on the nature of the load. Long transmission lines, for example, have a high capacitance and in this case the lagging power factor may be an advantage.

Speed regulation is a function of the flywheel effect of the rotating components and the inertia of the water column of the system. The start-up time of the rotating system is given by

$$t_s = \frac{I\omega^2}{P} \tag{8.4.16}$$

where I = moment of inertia of the generator and turbine, kg · m^2 (Bureau of Reclamation, 1966).

The start-up time of the water column is given by

$$t_p = \frac{\sum LV}{gH} \tag{8.4.17}$$

where L = length of water column
V = velocity in each component of the water column

For good speed regulation, it is desirable to keep $t_s/t_p > 4$. Lower values can also be used, although special precautions are necessary in the control equipment. Higher ratios of t_s/t_p can be obtained by increasing I or decreasing t_p. Increasing I implies a larger generator, which also results in higher costs. The start-up time of the water column can be reduced by reducing the length of the flow system, by using lower velocities, or by adding **surge tanks**, which essentially reduce the effective length of the conduit. A detailed analysis should be made for each installation, since for a given length, head, and discharge the flow area must be increased to reduce t_p, which leads to associated higher construction costs.

Cavitation and Turbine Setting

Another factor that must be considered prior to equipment selection is the evaluation of the turbine with respect to tailwater elevations. Hydraulic turbines are subject to pitting due to cavitation (Arndt, 1981, 1991). For a given head, smaller, lower-cost, high-speed runner must be set lower (i.e, closer to tailwater or even below tailwater) than a larger, higher-cost, low-speed turbine runner. Also, atmospheric pressure or elevation above sea level is a factor, as are tailwater elevation ion variations and operating requirements. This is a complex concept which can only be accurately resolved by model tests. The runner design will have different cavitation characteristics. Therefore, the anticipated turbine location or setting with respect to tailwater elevations is an important consideration in turbine selection.

Cavitation is not normally a problem with impulse wheels. However, by the very nature of their operation, cavitation is an important factor in reaction turbine installations. The susceptibility for cavitation to occur is a function of the installation and the turbine design. This can be expressed conveniently in terms of Thoma's sigma defined as

$$\sigma_T = \frac{H_a - H_v - z}{H} \tag{8.4.18}$$

where H_a is the atmospheric pressure head, H_V is the vapor pressure need (generally negligible), and z is the elevation of a turbine reference plane above the tailwater (see Figure 8.4.1). Draft tube losses and the exit velocity head have been neglected.

σ_T must be above a certain value to avoid cavitation problems. The critical value of σ_T is a function of specific speed (Arndt, 1991). The Bureau of Reclamation (1966) suggests that cavitation problems can be avoided when

$$\sigma_T > 0.26 N_s^{1.64} \tag{8.4.19}$$

Equation 8.4.19 does not guarantee total elimination of cavitation, only that cavitation is within acceptable limits. Cavitation can be totally avoided only if the value σ_T at an installation is much greater than the limiting value given in Equation 8.4.19. The value of σ_T for a given installation is known as

the plant sigmas, σ_p. Equation 8.4.19 should only be considered as a guide in selecting σ_p, which is normally determined by a model test in the manufacturer's laboratory. For a turbine operating under a given head, the only variable controlling σ_p is the turbine setting z. The required value of σ_p then controls the allowable setting above tailwater:

$$z_{\text{allow}} = H_a - H_v - \sigma_p H \tag{8.4.20}$$

It must be borne in mind that H_a varies with elevation. As a rule of thumb, H_a decreases from the sea-level value of 10.3 m by 1.1 m for every 1000 m above sea level.

Defining Terms

Draft tube: The outlet conduit from a turbine which normally acts as a diffuser. This is normally considered to be an integral part of the unit.

Forebay: The hydraulic structure used to withdraw water from a reservoir or river. This can be positioned a considerable distance upstream from the turbine inlet.

Head: The specific energy per unit weight of water. *Gross head* is the difference in water surface elevation between the forebay and tailrace. *Net head* is the difference between *total head* (the sum of velocity head $V^2/2g$, pressure head $p/\rho g$, and elevation head z at the inlet and outlet of a turbine. Some European texts use specific energy per unit mass, e.g., specific kinetic energy is $V^2/2$.

Runner: The rotating component of a turbine in which energy conversion takes place.

Specific speed: A universal number for a given machine design.

Spiral case: The inlet to a reaction turbine.

Surge tank: A hydraulic structure used to diminish overpressures in high-head facilities due to water hammer resulting from the sudden stoppage of a turbine

Wicket gates: Pivoted, streamlined guide vanes that control the flow of water to the turbine.

8.5 Stirling Engines

William B. Stine

Introduction

The Stirling engine was patented in 1816 by Rev. Robert Stirling, a Scottish minister (Figure 8.5.1). Early Stirling engines were coal-burning, low-pressure air engines built to compete with saturated steam engines for providing auxiliary power for manufacturing and mining. In 1987, John Ericsson built an enormous marine Stirling engine with four 4.2-m-diameter pistons. Beginning in the 1930s, the Stirling engine was brought to a high state of technology development by Philips Research Laboratory in Eindhoven, The Netherlands with the goal of producing small, quiet electrical generator sets to be used with high-power-consuming vacuum tube electronic devices. Recently, interest in Stirling engines has resurfaced, with solar electric power generation (Stine and Diver, 1994) and hybrid automotive applications in the forefront.

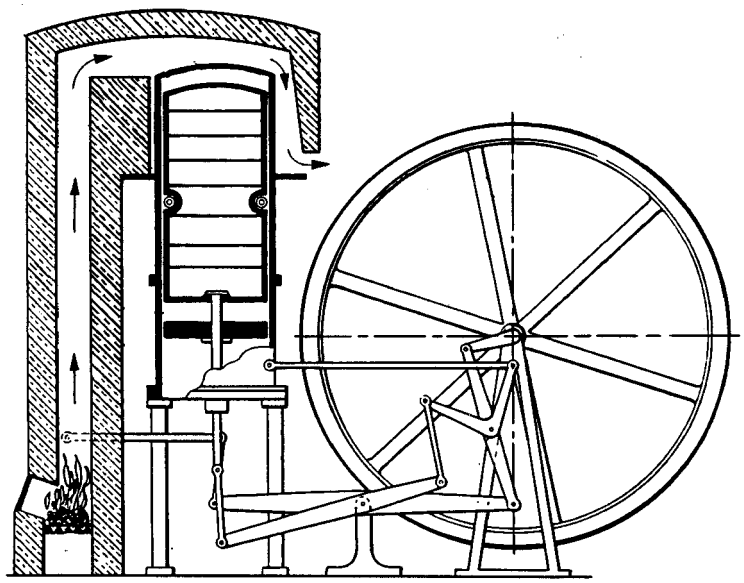

FIGURE 8.5.1 The original patent Stirling engine of Rev. Robert Stirling.

In theory, the **Stirling cycle** engine can be the most efficient device for converting heat into mechanical work with high efficiencies requiring high-temperatures. In fact, with regeneration, the efficiency of the Stirling cycle equals that of the Carnot cycle, the most efficient of all ideal thermodynamic cycles. (See West, 1986 for further discussion of the thermodynamics of Stirling cycle machines.)

Since their invention, prototype Stirling engines have been developed for automotive purposes; they have also been designed and tested for service in trucks, buses, and boats (Walker, 1973). The Stirling engine has been proposed as a propulsion engine in yachts, passenger ships, and road vehicles such as city buses (Meijer, 1992). The Stirling engine has also been developed as an underwater power unit for submarines, and the feasibility of using the Stirling for high-power space-borne systems has been explored by NASA (West, 1986). The Stirling engine is considered ideal for solar heating, and the first solar application of record was by John Ericsson, the famous British-American inventor, in 1872 (Stine and Diver, 1994).

Stirling engines are generally externally heated engines. Therefore, most sources of heat can be used to drive them, including combustion of just about anything, radioisotopes, solar energy, and exothermic

chemical reactions. High-performance Stirling engines operate at the thermal limits of the materials used for their construction. Typical temperatures range fiom 650 to 800°C (1200 to 1470°F), resulting in engine conversion efficiencies of around 30 to 40%. Engine speeds of 2000 to 4000 rpm are common

Thermodynamic Implementation of the Stirling Cycle

In the ideal Stirling cycle, a **working gas** is alternately heated and cooled as it is compressed and expanded. Gases such as helium and hydrogen, which permit rapid heat transfer and do not change phase, are typically used in the high-performance Stirling engines. The ideal Stirling cycle combines four processes, two constant-temperature heat-exchange processes and two constant-volume heat-exchange processes. Because more work is done by expanding high-temperature, high-pressure gas than is required to compress low-temperature, low-pressure gas, the Stirling cycle produces net work, which can drive an electric alternator or other mechanical devices.

Working Gases

In the Stirling cycle, the working gas is alternately heated and cooled in constant-temperature and constant-volume processes. The traditional gas for Stirling engines has been air at atmospheric pressure. At this pressure, air has a reasonably high density and therefore can be used directly in the cycle with loss of working gas through seals a minor problem. However, internal component temperatures are limited because of the oxygen in air which can degrade materials rapidly.

Because of their high heat-transfer capabilities, hydrogen and helium are used for high-speed, high-performance Stirling engines. To compensate for the low density of these gases, the mean pressure of the working gas is raised by charging the gas spaces in the engine to high pressures. Compression and expansion vary above and below this **charge pressure**. Hydrogen, thermodynamically a better choice, generally results in more-efficient engines than does helium (Walker, 1980). Helium, on the other hand, has fewer material-compatibility problems and is safer to work with. To maximize power, high-performance engines typically operate at high pressure, in the range of 5 to 20 MPa (725 to 2900 psi). Operation at these high gas pressures makes sealing difficult, and seals between the high-pressure region of the engine and those parts at ambient pressure have been problematic in some engines. New designs to reduce or eliminate this problem are currently being developed.

Heat Exchange

The working gas is heated and cooled by heat exchangers that add heat from an external source, or reject heat to the surroundings. Further, in most engines, an internal heat storage unit stores and rejects heat during each cycle.

The **heater** of a Stirling engine is usually made of many small-bore tubes that are heated externally with the working gas passing through the inside. External heat transfer by direct impingement of combustion products or direct adsorption of solar irradiation is common. A trade-off between high heat-transfer rate using many small-bore tubes with resulting pumping losses, and fewer large-bore tubes and lower pumping losses drives the design. A third criterion is that the volume of gas trapped within these heat exchangers should be minimal to enhance engine performance. In an attempt to provide more uniform and constant-temperature heat transfer to the heater tubes, **reflux** heaters are being developed (Stine and Diver, 1994). Typically, by using sodium as the heat-transfer medium, liquid is evaporated at the heat source and is then condensed on the outside surfaces of the engine heater tubes.

The **cooler** is usually a tube-and-shell heat exchanger. Working gas is passed through the tubes, and cooling water is circulated around the outside. The cooling water is then cooled in an external heat exchanger. Because all of the heat rejected from the power cycle comes from the cooler, the Stirling engine is considered ideal for cogeneration applications.

Most Stirling engines incorporate an efficiency-enhancing **regenerator** that captures heat from the working gas during constant-volume cooling and replaces it when the gas is heated at constant volume. Heating and cooling of the regenerator occurs at over 60 times a second during high-speed engine operation. In the ideal cycle, all of the heat-transferred during the constant volume heating and cooling

processes occurs in the regenerator, permitting the external heat addition and rejection to be efficient constant-temperature heat-transfer processes. Regenerators are typically chambers packed with fine-mesh screen wire or porous metal structures. There is enough thermal mass in the packing material to store all of the heat necessary to raise the temperature of the working gas from its low to its high temperature. The amount of heat stored by the regenerator is generally many times greater than the amount added by the heater.

Power Control

Rapid control of the output power of a Stirling engine is highly desirable for some applications such as automotive and solar electric applications. In most Stirling engine designs, rapid power control is implemented by varying the density (i.e., the mean pressure) of the working gas by bleeding gas from the cycle when less power is desired. To return to a higher power level, high-pressure gas must be reintroduced into the cycle. To accomplish this quickly and without loss of working gas, a complex system of valves, a temporary storage tank, and a compressor are used.

A novel method of controlling the power output is to change the length of stroke of the power piston. This can be accomplished using a variable-angle swash plate drive as described below. Stirling Thermal Motors, Inc., uses this method on their STM 4-120 Stirling engine (Figure 8.5.2).

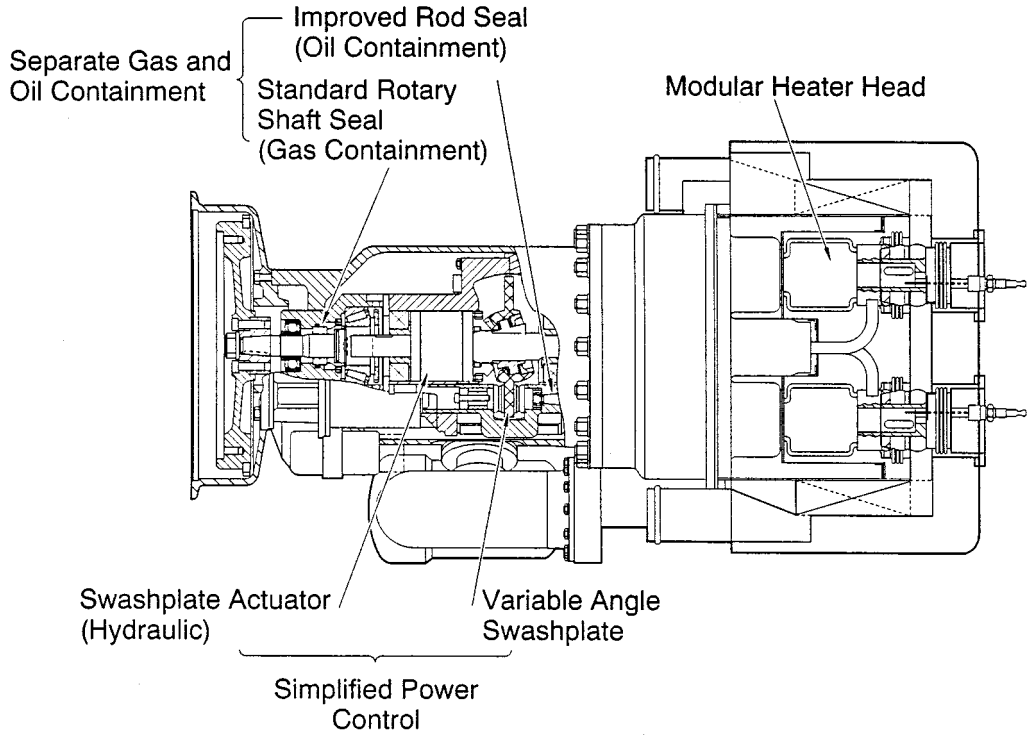

FIGURE 8.5.2 Stirling Thermal Motors 4-120 variable swash plate Rinia configuration engine. (Courtesy Stirling Thermal Motors, Ann Arbor, Michigan.)

Mechanical Implementation of the Stirling Cycle

Piston/Displacer Configurations

To implement the Stirling cycle, different combinations of machine components have been designed to provide for the constant-volume movement of the working gas between the high- and low-temperature regions of the engine, and compression and expansion during the constant-temperature heating and

cooling. The compression and expansion part of the cycle generally take place in a cylinder with a piston. Movement of the working gas back and forth through the heater, regenerator, and cooler at constant volume is often implemented by a **displacer**. A displacer in this sense is a hollow plug that, when moved to the cold region, displaces the working gas from the cold region causing it to flow to the hot region and vice versa. Only a small pressure difference exists between either end of the displacer, and, therefore, sealing requirements and the force required to move it are minimal.

Three different design configurations are generally used (Figure 8.5.3). Called the alpha-, beta-, and gamma-configurations. Each has its distinct mechanical design characteristics, but the thermodynamic cycle is the same. The **alpha-configuration** uses two pistons on either side of the heater, regenerator, and the cooler. These pistons first move uniformly in the same direction to provide constant-volume processes to heat or cool the gas. When all of the gas has been moved into one cylinder, one piston remains fixed and the other moves to compress or expand the gas. Compression work is done by the **cold piston** and expansion work done on the **hot piston** The alpha-configuration does not use a displacer. The Stirling Power Systems V-160 engine (Figure 8.5.4) is an example of this configuration.

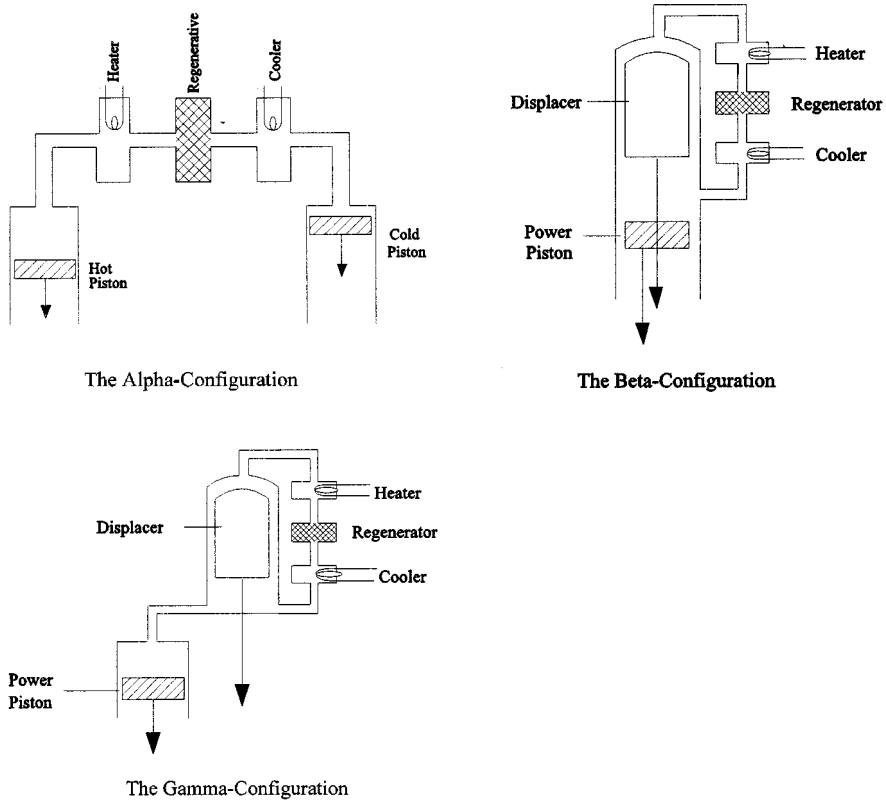

FIGURE 8.5.3 Three fundamental mechanical configurations for Stirling Engines.

A variation on using two separate pistons to implement the alpha-configuration is to use the front and back side of a single piston called a **double-acting piston**. The volume at the front side of one piston is connected, through the heater, regenerator, and cooler, to the volume at the back side of another piston. With four such double-acting pistons, each 90° out of phase with the next, the result is a four-cylinder alpha-configuration engine. This design is called the *Rinia* or *Siemens configuration* and the United Stirling 4-95 (Figure 8.5.5) and the Stirling Thermal Motors STM 4-120 (Figure 8.5.2) are current examples.

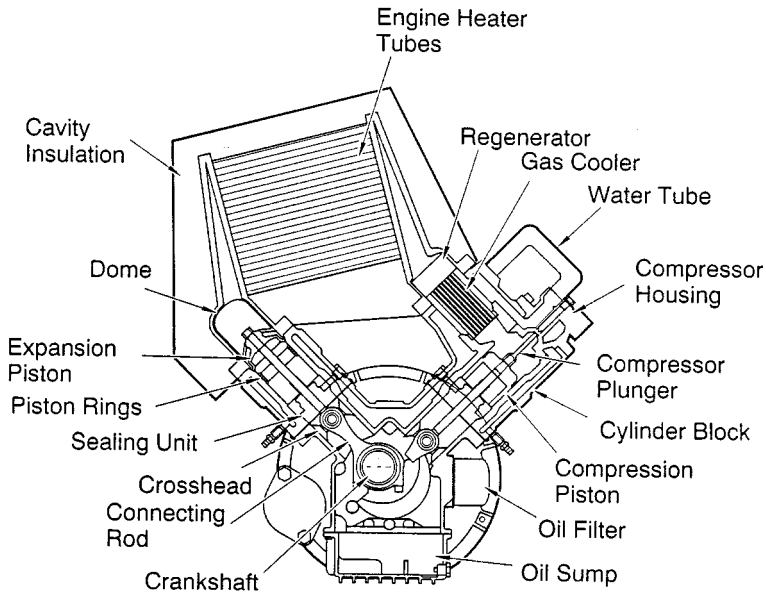

FIGURE 8.5.4 Stirling Power Systems/Solo Kleinmotoren V-160 alpha-configuration Stirling engine.

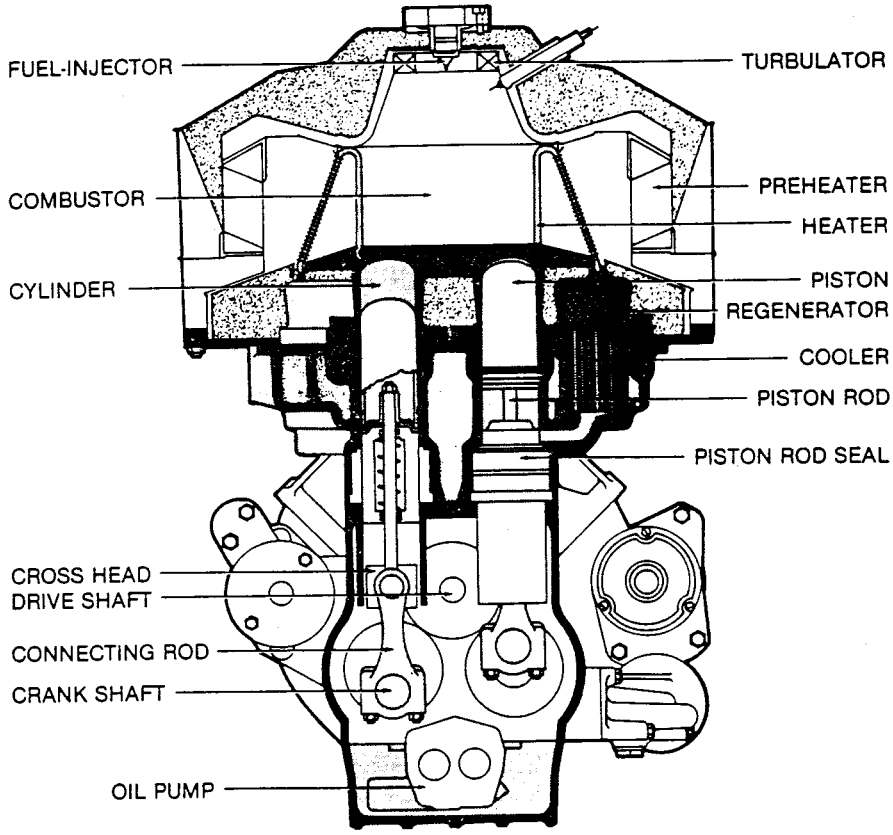

FIGURE 8.5.5 The 4-95 high-performance Siemens configuration Rinia engine by United Stirling (Malmo, Sweden).

The **beta-configuration** is a design incorporating a displacer and a power piston in the same cylinder. The displacer shuttles gas between the hot end and the cold end of the cylinder through the heater, regenerator, and cooler. The power piston, usually located at the cool end of the cylinder, compresses the working gas when the gas is in the cool end and expands the working gas when the gas has been moved to the hot end. The original patent engine by Robert Stirling and most free-piston Stirling engines discussed below are of the beta-configuration.

The third configuration, using separate cylinders for the displacer and the power piston, is called the **gamma-configuration**. Here, the displacer shuttles gas between the hot end and the cold end of a cylinder through the heater, regenerator, and cooler, just as with the beta-configuration. However, the power piston is in a separate cylinder, pneumatically connected to the displacer cylinder.

Piston/Displacer Drives

Most Stirling engine designs dynamically approximate the Stirling cycle by moving the piston and displacer with **simple harmonic motion**, either through a crankshaft, or bouncing as a spring/mass second-order mechanical system. For both, a performance penalty comes from the inability of simple harmonic motion to perfectly follow the desired thermodynamic processes. A more desirable dynamic from the cycle point of view, called overdriven or **bang-bang motion**, has been implemented in some designs, most notably the **Ringbom configuration** and engines designed by Ivo Kolin (West, 1986).

Kinematic Engines. Stirling engine designs are usually categorized as either kinematic or free-piston. The power piston of a **kinematic Stirling engine** is mechanically connected to a rotating output shaft. In typical configurations, the power piston is connected to the crankshaft with a connecting rod. In order to eliminate side forces against the cylinder wall, a **cross-head** is often incorporated, where the connecting rod connects to the cross-head, which is laterally restrained so that it can only move linearly in the same direction as the piston. The power piston is connected to the cross-head and therefore experiences no lateral forces. The critical sealing between the high-pressure and low-pressure regions of the engine can now be created using a simple **linear seal** on the shaft between the cross-head and the piston. This design also keeps lubricated bearing surfaces in the low-pressure region of the engine, reducing the possibility of fouling heat-exchange surfaces in the high-pressure region of the engine. If there is a separate displacer piston as in the beta- and gamma configurations, it is also mechanically connected to the output shaft.

A variation on crankshaft/cross-head drives is the **swash plate** or **wobble-plate drive**, used with success in some Stirling engine designs. Here, a drive surface affixed to the drive shaft at an angle, pushes fixed piston **push rods** up and down as the slanted surface rotates beneath. The length of stroke for the piston depends on the angle of the plate relative to the axis of rotation. The STM 4-120 engine (Figure 8.5.2) currently being commercialized by Stirling Thermal Motors incorporates a **variable-angle swash plate drive** that permits variation in the length of stroke of the pistons.

Free-Piston Engine/Converters. An innovative way of accomplishing the Stirling cycle is employed in the free-piston engine. In this configuration, the power piston is not mechanically connected to an output shaft. It bounces alternately between the space containing the working gas and a spring (usually a gas spring). In many designs, the displacer is also free to bounce on **gas springs** or mechanical springs (Figure 8.5.6). This configuration is called the Beale free-piston Stirling engine after its inventor, William Beale. Piston stroke, frequency, and the timing between the two pistons are established by the dynamics of the spring/mass system coupled with the variations in cycle pressure. To extract power, a magnet can be attached to the power piston and electric power generated as it moves past stationary coils. These Stirling engine/alternator units are called **free-piston Stirling converters**. Other schemes for extracting power from free-piston engines, such as driving a hydraulic pump, have also been considered.

Free-piston Stirling engines have only two moving parts, and therefore the potential advantages of simplicity, low cost, and ultra-reliability. Because electricity is generated internally, there are no dynamic seals between the high-pressure region of the engine and ambient, and no oil lubrication is required. This design promises long lifetimes with minimal maintenance. A number of companies are currently

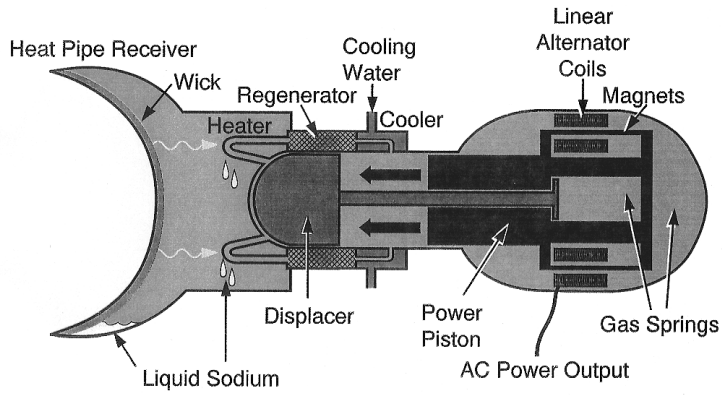

FIGURE 8.5.6 Basic components of a Beale free-piston Stirling converter incorporating a sodium heat pipe receiver for heating with concentrated solar energy.

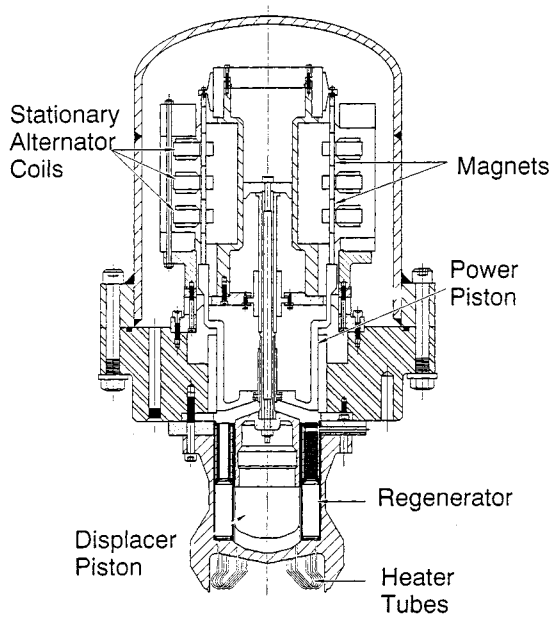

FIGURE 8.5.7 The Sunpower 9-kWe free-piston beta-configuration Stirling engine.

developing free-piston engines including Sunpower, Inc. (Figure 8.5.7), and Stirling Technology Company.

Seals and Bearings

Many proposed applications for Stirling engine systems require long-life designs. To make systems economical, a system lifetime of at least 20 years with minimum maintenance is generally required. Desired engine lifetimes for electric power production are 40,000 to 60,000 hr — approximately ten times longer than that of a typical automotive internal combustion engine. Major overhaul of engines, including replacement of seals and bearings, may be necessary within the 40,000- to 60,000-hr lifetime, which adds to the operating cost. A major challenge, therefore, in the design of Stirling engines is to reduce the potential for wear in critical components or to create novel ways for them to perform their tasks.

Piston seals differ from those used in internal combustion engines in a number of ways. Sealing of the power piston is critical since **blow-by loss** of the hydrogen or helium working gas must be captured and recompressed, or replaced from a high-pressure cylinder. Displacer sealing is less critical and only necessary to force most of the working gas through the heater, regenerator, and cooler. Oil for friction reduction or sealing cannot be used because of the danger of it getting into the working gas and fouling the heat-exchange surfaces. This leads to two choices for sealing of pistons, using **polymer sealing rings** or **gas bearings** (simply close tolerance fitting between piston and wall).

Free-piston engines with gas springs have special internal sealing problems. Small leakage can change the force-position characteristics of the "spring" and rapidly upset the phase and displacement dynamics designed into the engine. In order to prevent this, *centering ports* are used to ensure that the piston stays at a certain location; however, these represent a loss of potential work from the engine.

Materials

Materials used in Stirling engines are generally normal steels with a few exceptions. Materials that can withstand continuous operation at the cycle high temperature are required for the heater, regenerator, and the hot side of the displacement volume. Because most engines operate at high pressure, thick walls are often required. In the hot regions of the engine, this can lead to *thermal creep* due to successive heating and cooling. In the cool regions, large spaces for mechanical linkages can require heavy, thick walls to contain the gas pressure. Use of composite structure technology or reducing the size of the pressurized space can eliminate these problems.

Future of the Stirling Engine

The principal advantages of the Stirling engine, external heating and high efficiency, make this the engine of the future, replacing many applications currently using internal combustion engines and providing access to the sun as an inexpensive source of energy (Figure 8.5.6). For hybrid-electric automotive applications, the Stirling engine is not only almost twice as efficient as modern spark-ignition engines, but because of the continuous combustion process, it burns fuel more cleanly and is not sensitive to the quality or type of fuel. Because of the simplicity of its design, the Stirling engine can be manufactured as an inexpensive power source for electricity generation using biomass and other fuels available in developing nations.

Most importantly, the Stirling engine will provide access to inexpensive solar energy. Because it can receive its heat from a resource 93 million miles away using concentrating solar collectors, and because its manufacture is quite similar to the gasoline or diesel engine, and because economies of scale are certain when producing thousands of units per year, the Stirling engine is considered to be the least expensive alternative for solar energy electric generation applications in the range from 1 kWe to 100 MWe.

Defining Terms

Alpha-configuration: Design of a Stirling engine where two pistons moving out of phase, and cause the working gas between them to go through the four processes of the Stirling cycle.

Beale free-piston Stirling engine: Stirling engine configuration where the power piston and displacer in a single cylinder are free to bounce back and forth along a single axis, causing the enclosed working gas to go through the four processes of the Stirling cycle. Restoration forces are provided by the varying pressure of the working gas, springs (gas or mechanical), and the external load which can be a linear alternator or a fluid pump.

Beta-configuration: Design of a Stirling engine where the displacer and power piston are located in the same cylinder and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Blow-by: The gas that leaks past a seal, especially a piston-to-cylinder seal.

Charge pressure: Initial pressure of the working gas.

Cooler: Heat exchanger that removes heat from the working fluid and transfers it out of the cycle.

Cross-head: A linear sliding bearing surface connected to a crankshaft by a connecting rod. It is purpose is to provide linear reciprocating motion along a single line of action.

Displacer: Closed volume 'plug' that forces the working fluid to move from one region of the engine to another by displacing it.

Double-acting piston: A piston in an enclosed cylinder where pressure can be varied on both sides of the piston, resulting a total amount of work being the sum of that done on or by both sides.

Dynamic seals: Seals that permit transfer of motion without permitting gas or oil leakage. These can be either *linear seals* permitting a shaft to move between two regions (i.e., the piston rod seals in a Stirling engine), or *rotating seals* that permit rotating motion to be transmitted from one region to another (i.e., the output shaft of a Stirling engine).

Free-piston Stirling converters: A name given to a hermetically sealed free-piston Stirling engine incorporating an internal alternator or pump.

Gamma-configuration: A design of a Stirling engine where the displacer and power piston are located in separate, connected cylinders and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Gas bearing: A method of implementing the sliding seal between a piston and cylinder as opposed to using piston rings. Uses a precision-fitting piston that depends on the small clearance and long path for sealing and on the viscosity of the gas for lubrication.

Gas spring: A piston that compresses gas in a closed cylinder where the restoration force is linearly proportional to the piston displacement. This is a concept used in the design of free-piston Stirling engines.

Heater: A heat exchanger which adds heat to the working fluid from an external source.

Kinematic stirling engine: Stirling engine design that employ physical connections between the power piston, displacer, and a mechanical output shaft.

Linear seal: see **dynamic seals**.

Overdriven (bang-bang) motion: Linear motion varying with time as a square-wave function. An alternative to simple harmonic motion and considered a better motion for the displacer of a Stirling engine but difficult to implement.

Phase angle: The angle difference between displacer and power piston harmonic motion with a complete cycle representing 360°. In most Stirling engines, the harmonic motion of the power piston follows (lags) the motion of the displacer by approximately 90°.

Push rod: A thin rod connected to the back of the piston that transfers linear motion through a dynamic linear seal, between the low- and high-pressure regions of an engine.

Reflux: A constant-temperature heat-exchange process where a liquid is evaporated by heat addition and then condensed as a result of cooling.

Regenerator: A heat-transfer device that stores heat from the working gas during part of a thermodynamic cycle and returns it during another part of the cycle. In the Stirling cycle the regenerator stores heat from one constant-volume process and returns it in the other constant-volume process.

Ringbom configuration: A Stirling engine configuration where the power piston is kinematically connected to a power shaft, and the displacer is a free piston that is powered by the difference in pressure between the internal gas and atmospheric pressure.

Simple harmonic motion: Linear motion varying with time as a sine function. Approximated by a piston connected to a crankshaft or a bouncing of a spring mass system.

Stirling cycle: A thermodynamic power cycle with two constant-volume heat addition and rejection processes and two constant-temperature heat-addition and rejection processes.

Swash plate drive: A disk on a shaft, where the plane of the disk is tilted away from the axis of rotation of the shaft. Piston push rods that move parallel to the axis of rotation but are displaced from the axis of rotation, slide on the surface of the rotating swash plate and therefore move up and down.

Variable-angle swash plate drive: A swash plate drive where the tilt angle between the drive shaft and the plate can be varied, resulting in a change in the displacement of the push rods.

Wobble plate drive: Another name for a swash plate drive.

Working gas: Gas within the engine that exhibits pressure and temperature change as it is heated or cooled and/or compressed or expanded.

8.6 Advanced Fossil Fuel Power Systems

Anthony F. Armor

Introduction

The generation of electric power from fossil fuels has undergone significant and, in some cases, dramatic changes over the last 20 years or so. Technology improvements in fossil fuel combustion have been largely driven by environmental issues, by the need to conserve fossil fuel resources, and by the economics of the competitive marketplace. The importance of fossil fuel-fired electric generation to the world is undeniable — more than 70% of all power in the U.S. is fossil fuel based, and worldwide the percentage is higher and growing. Today, most power plants worldwide burn coal, but increasingly generating companies are turning to natural gas, as the cost of gas-fired generation and the long-term supply of gas appear favorable. This section reviews the current status and likely future deployment of competing generation technologies based on fossil fuels.

It is likely, particularly in the developed world, that gas turbine-based plants will dominate the new generation market in the immediate future. The most advanced combustion turbines (CTs) now achieve more than 40% **lower heating value** (LHV) efficiency in simple cycle mode and greater than 50% efficiency in **combined cycle** (CC) mode. In addition, combustion turbine/combined cycle (CT/CC) plants offer siting flexibility, swift construction schedules, and capital costs between $400/kW and $800/kW. These advantages, coupled with adequate natural gas supplies and the assurance, in the longer term, of **coal gasification** backup, make this technology currently the prime choice for green field and repowered plants in the United States and in Europe.

But for the developing world, particularly China and India, there is good reason why the direct coal-fired power plant may still be the primary choice for many generation companies. Fuel is plentiful and inexpensive, and sulfur dioxide scrubbers have proved to be more reliable and effective than early plants indicated. In fact, as high as 99% SO_2 removal efficiency is now possible.

Combustion of coal can occur in three basic forms, direct combustion of pulverized coals (PC), combustion of coal in a suspended bed of coal and inert matter, and coal gasification. The pulverized coal (PC) plant, the most common form of coal combustion, has the capability for much improved efficiency even with full **flue gas desulfurization** (FGD), because materials technology has now advanced to the point where higher steam pressures and temperatures are possible. In the United States, Europe, Japan, and Russia, the advanced superficial PC plant is moving ahead commercially.

Worldwide, the application of atmospheric and pressurized fluidized bed combustion (FBC) plants has increased, and such plants offer reductions in both SO_2 and NO_x while permitting the efficient combustion of vast deposits of low-rank fuels such as lignites. In the United States, there are now over 150 large operating units for power generation, and throughout Europe, China, and the former Soviet Union countries small FBC units have been extensively deployed.

Coal gasification power plants exist at the 100 and 160 MW levels and are planned up to 450 MW. Much of the impetus is now coming from the U.S. Department of Energy (DOE) clean coal program where three gasification projects are in progress and four more are planned, and gasification plants are under construction in Europe and Japan. Gasification not only leads to minimum atmospheric and solid emissions, but also provides an opportunity to take advantage of gas turbine advances. With the rapid a, advances now being introduced in CT technology, the coal gasification option is a leading turn-of-the-century candidate for new plant construction.

Clean Coal Technology Development

At an increasing rate in the last few years, innovations have been developed and tested that are aimed at reducing emissions through improved combustion and environmental control, in the near term, and, in the longer term, through fundamental changes in the way coal is preprocessed before converting its

chemical energy to electricity. Such technologies are referred to as "clean coal technologies" described as a family of precombustion, combustion/conversion, and postcombustion technologies (Torrens, 1990). They are designed to provide the coal user with added technical capabilities and flexibility and the world with an opportunity to exploit our most abundant fossil source. They can be categorized as

- *Precombustion*, where sulfur and other impurities are removed from the fuel before it is burned;
- *Combustion*, where techniques to prevent pollutant emissions are applied in the boiler while the coal burns;
- *Postcombustion*, where the flue gas released from the boiler is treated to reduce its content of pollutants;
- *Conversion*, where coal, rather than being burned, is changed into a gas or liquid that can be cleaned and used as a fuel.

Coal Cleaning

Cleaning of coal to remove sulfur and ash is well established in the United States with more than 400 operating plants, mostly at the mine. Coal cleaning removes primarily pyritic sulfur (up to 70% SO_2 reduction is possible) and in the process increases the heating value of the coal, typically about 10% but occasionally 30% or higher. Additionally, if slagging is a limiting item, increased megawatts may be possible, as occurred at one station which increased generation from 730 to 779 MW. The removal of organic sulfur, chemically part of the coal matrix, is more difficult, but may be possible using microorganisms or through chemical methods; research is underway (Couch, 1991). Finally, heavy metal trace elements can be removed also, conventional cleaning removing (typically) 30 to 80% of arsenic, mercury, lead, nickel, antimony, selenium, and chromium.

Cleaning of Low-Rank Coal

With large deposits of high-moisture, and sometimes high-ash, low-rank coals and lignites, there is interest, but as yet no large-scale activity, in cleaning these coals. Improvement in heating value and reduction of boiler **slagging and fouling** problems are outcomes. Economics will decide whether precleaning or direct combustion (perhaps in a fluidized bed) will be the future choice. Large subbituminous and lignite fields exist in the United States, the former U.S.S.R., Germany, and Eastern Europe, as Table 8.6.1 indicates.

TABLE 8.6.1 World Coal Production

Country	Total Coal Production, Mt	Bituminous, Mt	Subbituminous and Lignite, Mt	Approximate Amount Bituminous Cleaned, %
China	1018	985	33	20

Pulverized Coal Plants

There has been a perception that the PC power plant has come to the end of the road, that advanced coal technologies will quite soon make obsolete the PC plant with a scrubber, whose efficiency hovers around 35%. This perception may be premature. In fact, the PC plant has the capability for much improved heat rate (about 8500 Btu/kWh) even with full FGD. Beyond these units, the PC-fired CC with topping turbine (Figure 8.6.1) has a projected heat rate of 7200 Btu/kWhr, which includes full scrubbing capability. The PC plant is a proven, reliable power source with unit capabilities demonstrated at more than to 1000 MW using a single-shaft steam turbine. One plant, commercially available now, uses steam at 4500 psig and 1100°F, all ferritic materials for major boiler and turbine components, leading-edge technology in environmental controls, and the latest techniques in waste heat utilization (Poe et al., 1991). It is modular, fuel flexible, and designed for **on/off cycling capability**.

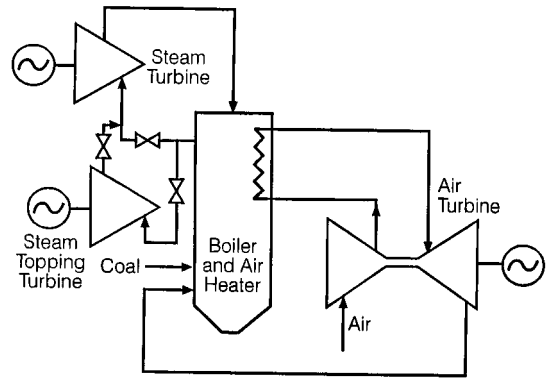

FIGURE 8.6.1 A PC CC with topping steam turbine has a projected heat rate of 7200 Btu/kWhr. The air turbine uses 1800°F air, or 2300°F air with supplemental firing. The topping turbine uses steam at 1300°F.

Higher steam temperatures (to 1150°F) and **supercritical steam pressures** are an important aspect of the modern advanced PC plant. They are possible now because of advances in ferritic materials technology that will extend life, provide greater creep and fatigue strength, and be resistant to **temper embrittlement** and, in the boiler, to coal ash corrosion (Armor et al., 1988).

Of particular note are

- **Coextruded tubing** or monotubing for superheaters and reheaters, resistant to coal ash corrosion.
- Super-9-chrome steel (P91), for steam piping, valves, headers, casings.
- Improved creep-resistant 12-chrome forgings for high-pressure/intermediate-pressure (HP/IP) turbines.
- "Superclean" 3.5 NiCrMoV rotors for low-pressure (LP) turbines, resistant to temper embrittlement.

Built in 1959, Eddystone 1 at PECO Energy was, and still is, the supercritical power unit with the highest steam conditions in the world. When constructed in the early 1960s, Eddystone 1 had a main steam pressure of 5000 psi, and main steam temperature of 1200°F. **Double reheat** of the steam was employed. PECO Energy continues to operate Eddystone 1, an impressive achievement for a prototype unit. More-recent advanced plants include the Chuba Electric Kawagoe unit in Japan, a 700-MW double-reheat supercritical with steam conditions of 4750 psi, 1050°F, and the Esbjerg unit of Elsam in Denmark, a 400-MW supercritical with steam conditions of 3700 psi, 1040°F. Both plants use advanced ferritic steels for turbine and boiler thick wall components. There are over 170 supercritical units in the United States, more than 220 in Russia (Oliker and Armor 1992), and over 60 in Japan. A number are installed in Germany, Denmark, Holland, and other European countries, and increasingly in the Far East.

Emissions Controls for Pulverized Coal Plants

Today, worldwide, about 40% of electricity is generated from coal and the total installed coal-fired generating capacity is more than 1000 GW, largely made up of 340 GW in North America; 220 GW in Western Europe, Japan, and Australia; 250 GW in Eastern Europe and the former U.S.S.R., and 200 GW in China and India. In the decade 1990 to 2000, 190 GW of new coal-fired capacity will likely be added. So the control of particulates, sulfur dioxides, and nitrogen oxides from those plants is one of the most pressing needs of today and of the future, together with the potential impact of carbon dioxide emissions, with their contribution to global warming. To combat these concerns, a worldwide move toward environmental retrofitting of older fossil-fired power plants is underway, focused largely on sulfur dioxide scrubbers and combustion or postcombustion optimization for nitrogen oxides.

Conventional Lime/Limestone Wet Scrubber

The dominant SO_2 scrubbing system is the wet limestone design, limestone being one quarter the cost of lime as a reagent. In this system (Figure 8.6.2) the limestone is ground and mixed with water in a reagent preparation area. It is then conveyed to a spray tower called an absorber, as a slurry of 90% water and 10% solids, and sprayed into the flue gas stream. The SO_2 in the flue gas is absorbed in the slurry and collected in a reaction tank where it combines with the limestone to produce water and calcium sulfate or calcium sulfate crystals. A portion of the slurry is then pumped to a thickener where these solids/crystals settle out before going to a filter for final dewatering. Mist eliminators installed in the system ductwork at the spray tower outlet collect slurry/moisture entrained in the flue gas stream. Calcium sulfate is typically mixed with fly ash (1:1) and lime (5%) and disposed of in a landfill.

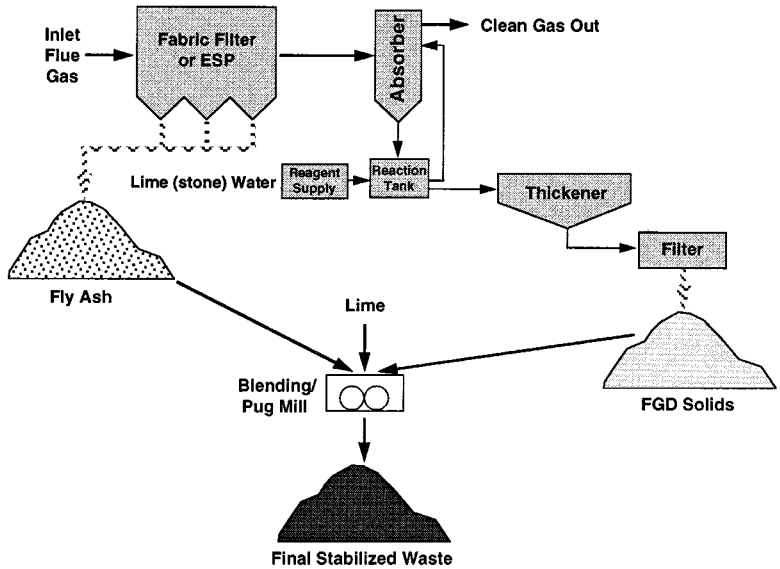

FIGURE 8.6.2 The conventional lime/limestone wet scrubber is the dominant system in operation in the United States. With recent refinements this system can be 98 to 99% effective in removing SO_2.

Various improvements can be made to this basic process, including the use of additives for performance enhancement and the use of a hydrocyclone for dewatering, replacing the thickener, and leading to a salable gypsum by-product. The Chiyoda-121 process (Figure 8.6.3) reverses the classic spray scrubber and bubbles the gas through the liquid. This eliminates the need for spray pumps, nozzle headers, separate oxidation towers, and thickeners. The Chiyoda process is being demonstrated in a DOE Clean Coal Technology (CCT) project on a 100-MW unit at the Yates plant of the Georgia Power Company.

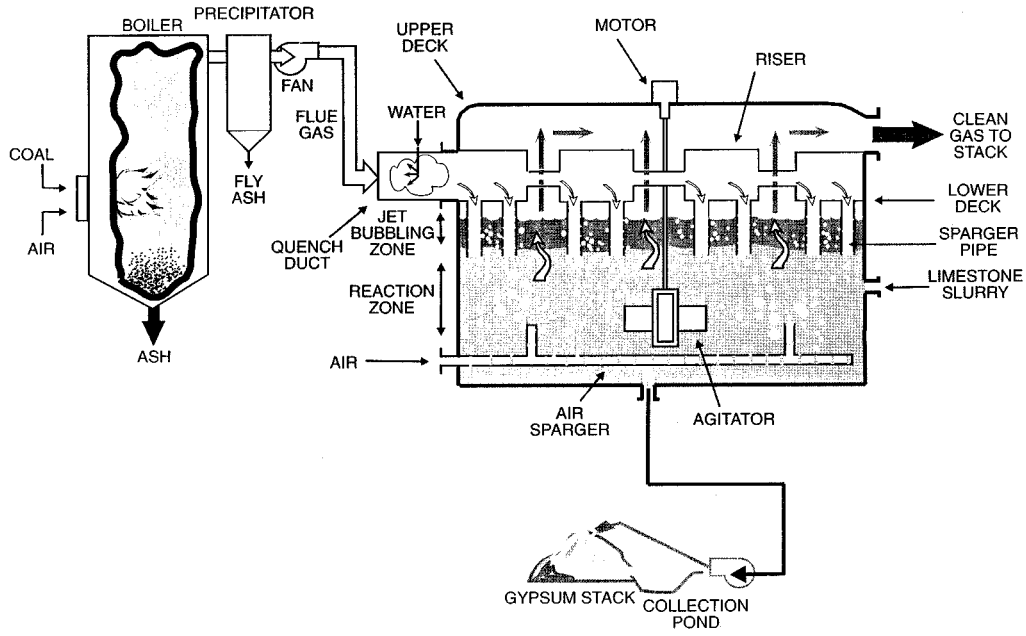

FIGURE 8.6.3 The Chioda-121 scrubber simplifies the process by bubbling the flue gas through the liquid, eliminating some equipment needs.

Spray Drying

Spray drying (Figure 8.6.4) is the most advanced form of dry SO_2 control technology. Such systems tend to be less expensive than wet FGD but remove typically a smaller percentage of the sulfur (90% compared with 98%). They are usually used when burning low-sulfur coals, and utilize fabric filters for particle collection, although recent tests have shown applicability to high-sulfur coals also.

Spray driers use a calcium oxide reagent (quicklime) which when mixed with water produces a calcium hydroxide slurry. This slurry is injected into the spray drier where it is dried by the hot flue gas. As the drying occurs, the slurry reacts to collect SO_2. The dry product is collected at the bottom of the spray tower and in the downstream particulate removal device where further SO_2 removal may take place. It may then be recycled to the spray drier to improve SO_2 removal and alkali utilization.

For small, older power plants with existing **electrostatic precipitators** (ESPs), the most cost-effective retrofit spray-dry configuration locates the spray drier and fabric filter downstream of the ESP, separating in this manner the spray drier and fly ash waste streams. The fly ash can then be sold commercially.

Control of Nitrogen Oxides

Nitrogen oxides can be removed either during or after coal combustion. The least-expensive option and the one generating the most attention in the United States is combustion control, first through adjustment of the fuel/air mixture and second through combustion hardware modifications. Postcombustion processes seek to convert NO_x to nitrogen and water vapor through reactions with amines such as ammonia and urea. Selective catalytic reduction (SCR) injects ammonia in the presence of a catalyst for greater effectiveness. So the options (Figure 8.6.5) can be summarized as

Operational changes. Reduced excess air and biased firing, including taking burners out of service;
Hardware combustion modifications. Low-NO_x burners, air staging, and fuel staging (reburning);
Postcombustion modifications. Injection of ammonia or urea into the convection pass, SCR, and wet or dry NO_x scrubbing (usually together with SO_2 scrubbing).

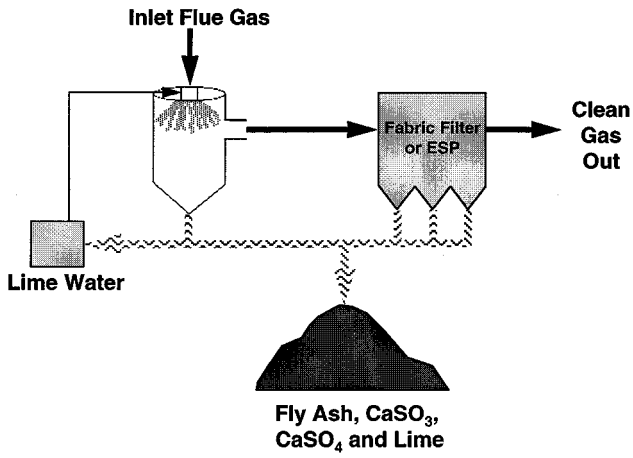

FIGURE 8.6.4 Spray driers use a calcium oxide reagent mixed with water, which is dried by the flue gas. A dry product is collected in a fabric filter.

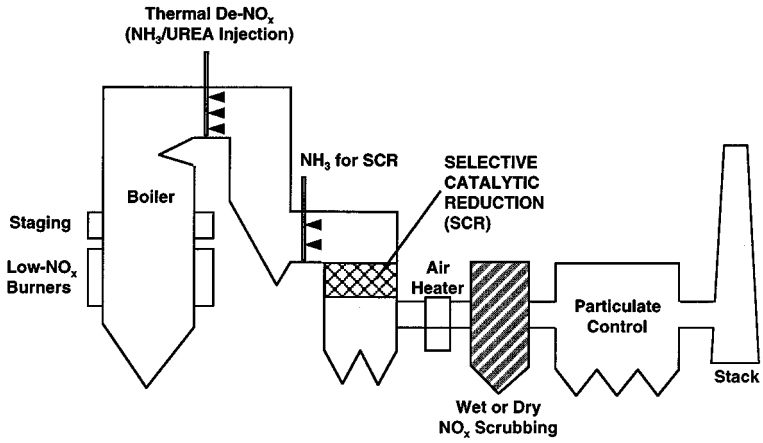

FIGURE 8.6.5 Control options for NO_x include operational, hardware, and postcombustion modifications.

Low-NO_x burners can reduce NO_x by 50% and SCR by 80%, but the low-NO_x burner option is much more cost-effective in terms of cost per ton of NO_x removed. Reburning is intermediate in cost per removed ton and can reduce NO_x 50 or 75% in conjunction with low-NO_x burners.

Fluidized Bed Plants

Introduced nearly 30 years ago, the **fluidized bed** combustion boiler has found growing application for power generation. From the first FBC boiler, generating 5000 lb/hr of steam in 1967, the technology has matured to the 250-MW-size units available today. In North America more than 170 units now

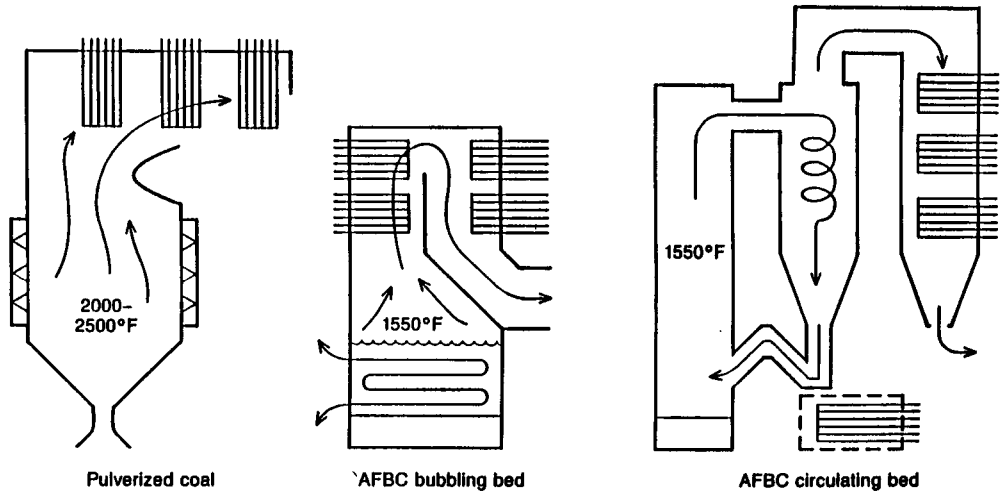

FIGURE 8.6.6 An illustration of the distinguishing features of PC and fluidized bed boilers. Noticeable in this diagram are the in-bed tubes characteristic of bubbling beds and the cyclone separator of the circulating bed.

generate in excess of 6000 MW. Burning coal in a suspended bed with limestone or dolomite permits effective capture of sulfur, and fuel flexibility allows a broad range of opportunity fuels. These fuels might include coal wastes (culm from anthracite, gob from bituminous coal), peat, petroleum coke, and a wide range of coals from bituminous to lignite. A low (1500°F) combustion temperature leads to low NO_x formation. The salient features of atmospheric fluidized bed boilers, compared with a PC boiler, are shown in Figure 8.6.6.

Utility-size demonstration projects at the Tennessee Valley Authority in 1989 (Shawnee, 160 MW) (Manaker, 1992) and Northern States Power in 1986 (Black Dog, 133 MW) (Hinrichsen, 1989) are examples of successful atmospheric bubbling bed units. The Black Dog unit has been dispatched in a daily cycling mode and has successfully fired a blend of coal and petroleum coke. But the focus of atmospheric FBC (AFBC) in the United States is now on the circulating fluid bed (CFB). In fact, more than 70% of operating fluid bed boilers in the United States are of the circulating type. The CFB unit at Nucla (Tri-State G&T Association) (Blunder, 1989) has been successful in demonstrating the technology at the 110-MW level, and commercial CFB plants have now reached 250 MW in size. Most fluidized bed units for electricity generation are being installed by independent power producers in the 50- to 100-MW-size range, where the inherent SO_2 and NO_x advantages over the unscrubbed PC plant have encouraged installations even in such traditional non-coal arenas as California (Melvin and Friedman, 1994). Worldwide, the AFBC boiler is employed largely for steam heat, with hundreds of them in operation in Russia and India, and thousands in China. The extension of the concept of fluidized beds to units where the fuel mixture is burned under several atmospheres pressure (PFBC) has now opened the way to smaller modular units with opportunities to move to efficient PFBC CCs.

Atmospheric Fluidized Bed Combustion

In the bubbling bed version of the AFBC, the fuel and inert matter, together with limestone or dolomite for SO_2 capture, is suspended through the action of fluidizing air, which flows at a velocity of 3 to 8 ft/sec in essentially a one-pass system. CFBs differ from bubbling beds in that much of the bed material passes through a cyclone separator before being circulated back to the boiler (Figure 8.6.7). In-bed tubes are generally not used for CFB units, permitting a much higher fluidizing velocity of 16 to 26 ft/sec. Since the early AFBC designs, attention has been directed toward increasing unit efficiency, and reheat designs are now usual in large units. When SO_2 capture is important, a key parameter is the ratio of calcium in the limestone to sulfur in coal. Typical calcium-to-sulfur ratios for 90% SO_2 reduction are

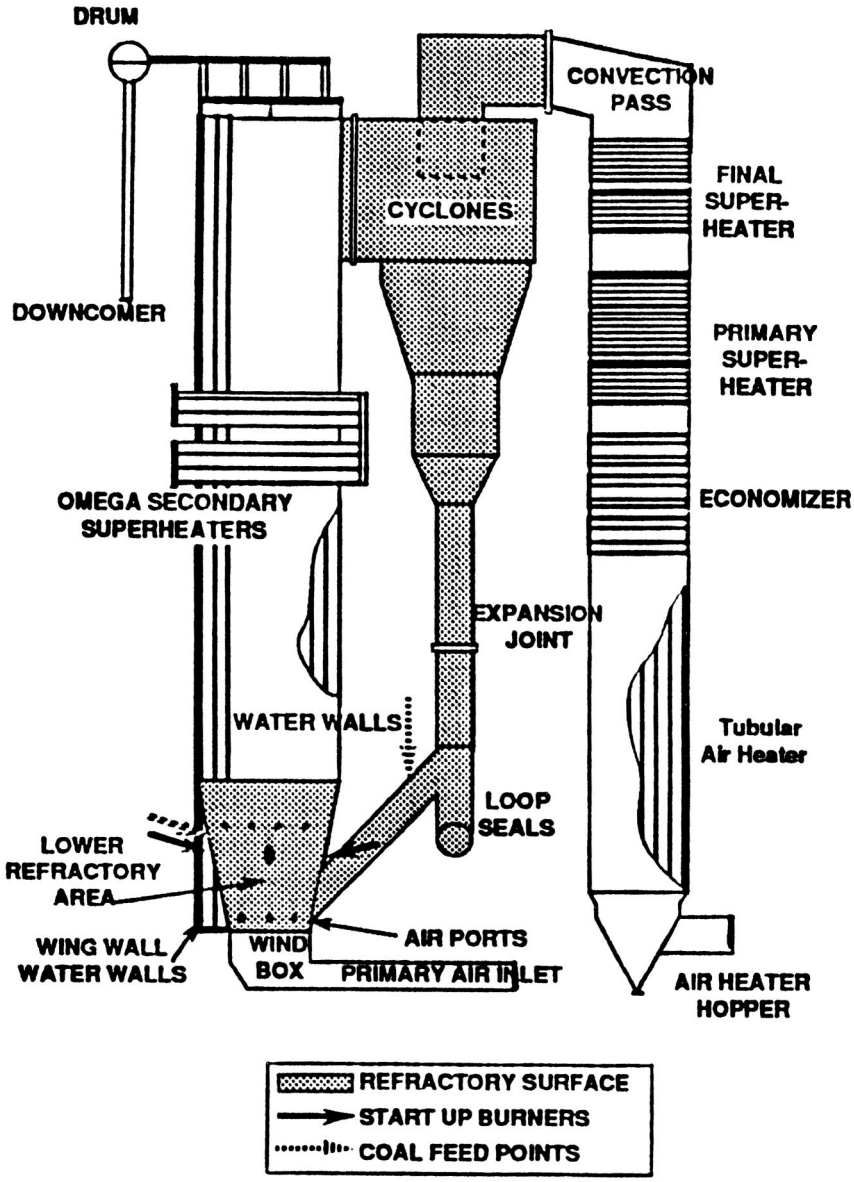

FIGURE 8.6.7 A Pyropower circulating fluid bed boiler installed at the ACE Cogeneration Company at Trona, California. This 108-MW unit burns low sulfur, western bituminous coal with limestone in a bed which circulates back to the boiler after passing through a cyclone separator.

in the range of 3.0 to 3.5 for bubbling beds and 2.0 to 2.5 for circulating beds. This depends on the fuel, however, and the 200-MW CFB units at the Conoco/Entergy plant in Lake Charles, Louisiana burning 100% **petroleum coke** (4.5% S), have a Ca/S ratio of below 1.7 for more than 90% sulfur capture. NO_x levels in AFBCs are inherently low and nominally less than 0.2 lb/MM Btu.

It is important to note that for CFBs, boiler efficiencies can be as high as a PC unit (Table 8.6.2). In fact, designs now exist for AFBCs with supercritical steam conditions, with prospects for cycles up to 4500 psia, 1100°F with **double reheat** (Skowyra et al., 1995).

TABLE 8.6.2 Typical Boiler Efficiencies, PC and Fluidized Beds

		Calculated Heat Loss %		
Loss/Gain Parameter	**PC**	**Highest-Efficiency CFB**	**Lowest-Efficiency CFB**	**Bubbling Bed**
Moisture in limestone	NA	0.06	0.10	0.10
Calcination	NA	1.02	1.69	2.70
Sulfation credit	NA	–1.60	–1.60	–1.60
Unburned carbon	0.25	0.50	2.0	4.0
Heat in dry flue gas	5.28	5.57	5.60	5.75
Moisture in fuel	1.03	1.03	1.03	1.03
Moisture from burning H_2	41.9	4.19	4.19	4.19
Radiation and convection	0.30	0.30	0.80	0.30
Moisture in air	0.13	0.14	0.14	0.14
Sensible heat in boiler ash	0.03	0.09	0.76	0.50
Bottom ash	0.05	NA	NA	NA
Fan-power credit	–0.25	–0.75	–0.40	–0.50

Pressurized Fluidized Bed Combustion

In a PFBC CC unit (Figure 8.6.8), coal in a fluid bed is burned with dolomite or limestone in a pressurized steel chamber, raising steam for a steam turbine generator. The pressurized flue gases are expanded through a gas turbine. Commercial plants at about the 80-MW level in Sweden, the United States, and Spain have demonstrated that bubbling bed PFBC plants with a calcium-to-sulfur molar ratio of about 1.5 offer sulfur capture up to 95%, together with inherently low NO_x emissions due to low combustion temperatures. Cleanup of the flue gas before entry to the gas turbines is a key technical objective, and first-generation units have used cyclones together with gas turbines ruggedized with special blade coatings. For more-advanced, higher-efficiency PFBC systems, hot-gas cleanup technology, where the gas is directed through large ceramic filter units, will likely be needed.

To date, the 80-MW units at Vaertan (Sweden) and Escatron (Spain) and the 70-MW unit at Tidd (AEP) have operated satisfactorily, and larger units up to 350 MW are now under development. The modular aspect of the PFBC unit is a particularly attractive feature leading to short construction cycles and low-cost power. This was particularly evident in the construction of the Tidd plant, which first generated power from the CC on November 29, 1990. The heat rate and capital cost of the PFBC plant are forecast to reach very competitive levels which, when combined with shortened construction schedules, will position the technology for a role in future generation plans, particularly where modular additions have advantages.

One promising use for PFBC units is for small in-city cogeneration plants where the inherent size advantages, high efficiencies, and effective coal gas cleanup approach permit compact plants to be retrofitted in place of heating boilers, while the small steam turbines can be easily adapted to both electricity and hot water supply (Olesen, 1985).

Advanced PFBCs

In conventional PFBC plants, the overall cycle efficiency is limited to less than 42%. That is because the operating temperature of the combustor — which must be held to 1650°F (900°C) or less to avoid sintering the ash and releasing alkali metals that could foul or corrode the gas turbine — in effect sets the gas turbine inlet temperature far below the 2350°F (1290°C) or so featured in the most-efficient heavy-frame machines currently in use firing natural gas or oil.

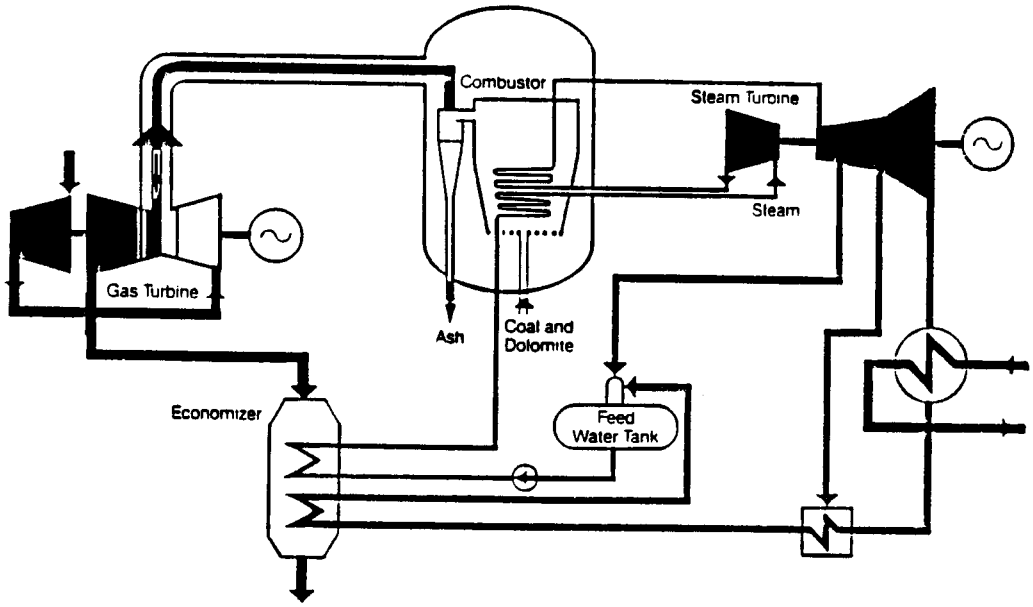

FIGURE 8.6.8 Pressurized fluidized bed with combined cycle. This 70-MW system has operated at the Tidd plant of American Electric Power.

Increasing the inlet temperature of the gas turbine, which typically provides 20 to 25% of the power in a PFBC plant, could raise the overall cycle efficiency to more than 45%. A simple means of boosting the flue gas temperature would be to fire a topping fuel, such as natural gas, ahead of the gas turbine. But 2350°F would be well above the **ash-softening temperature**, so high temperature, HP filtration systems would be essential to remove all particulate matter before firing the natural gas.

A further advance would be to use gas from coal rather than natural gas as the topping fuel. The coal would be pyrolyzed in a low-oxygen environment under pressure to produce both a low-Btu fuel gas and a residual char. The fuel gas would be passed through its own hot-gas cleanup filters before being fired in a topping combustor ahead of the gas turbine; the char would be burned in a circulating bed PFBC, from which the flue gas would also be filtered and then combined with the topping cycle gas stream. (Or the char could be simply fired in an AFBC.) With net heat rates below 7600 Btu/kWhr (45% efficiency), carbon dioxide emissions would be correspondingly low.

A U.S. DOE CCT project known as the Four Rivers Energy Modernization Project, involves building a Foster-Wheeler 95-MW advanced circulating-type PFBC unit at the Air Products chemical manufacturing facility in Calvert City, Kentucky. Steam from the unit, which will feature a coal-gas-fired topping combustor and a hot-gas cleanup system, will be used in chemical production, and the power will be sold to the Tennessee Valley Authority. The project is scheduled to begin commercial operation in October, 1998 (Carpenter and Dellefield, 1994).

Gasification Plants

One option of growing interest to coal-burning utilities is that of coal gasification. After the EPRI Cool Water demonstration in 1984 at the 100-MW level, the technology has moved ahead in the United States largely through demonstrations under the CCT program (U.S. DOE, 1994). Overseas, the 250-MW Buggenham plant in Holland is now operational, and the PSI/Destec 262-MW and TECO Energy 250-MW gasification plant demonstrations are also on-line. Beyond this, there is a 300-MW gasification unit scheduled for Endesa, Spain and a 330-MW unit for RWE in Germany (Figure 8.6.9).

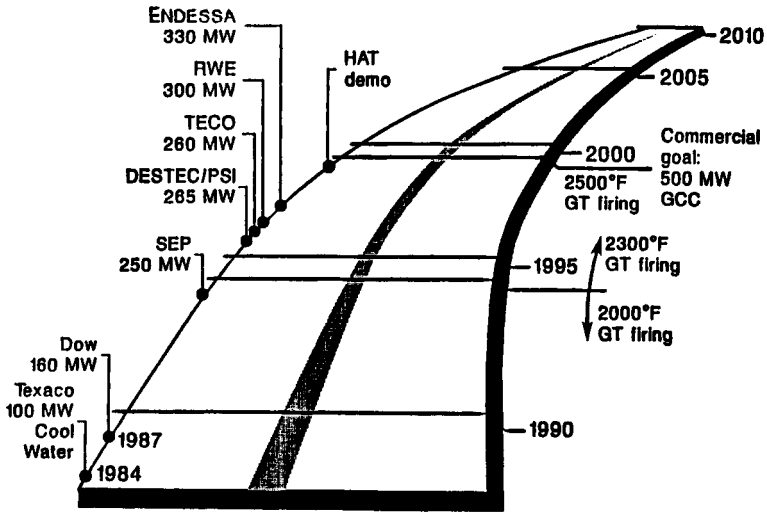

FIGURE 8.6.9 By building on the early success of the 100-MW Cool Water gasification-CC plant in California, demonstrations in the 250 to 350 MW range will be carried out in the 1995 to 2000 time frame.

Gasification-based plants have among the lowest emissions of pollutants of any central station fossil technology. Through use of the efficiency advantages of CCs, CO_2 emissions are also low. Fuel flexibility is an additional benefit since the gasifier can accommodate a wide range of coals, plus petroleum coke. Integrated gasification CC (IGCC) plants permit a hedge against long-term increases in natural gas prices since natural gas-fired CTs can be installed initially, and gasifiers at a later time when a switch to coal becomes prudent (Douglas, 1986).

The pioneering Cool Water plant, the first of its kind in the world, operated for more than 4 years, gasifying 1.1 million tons of coal and producing 2.8 million MWhr of electricity. The project was a collaborative effort of the industry involving the utility (Southern California Edison), equipment manufacturers (Texaco, General Electric), and consultants/research consortia (Bechtel, EPRI, and others). Particularly notable was the achievement of exceptionally low levels of emissions of SO_2, NO_x, and particulates, as shown in Figure 8.6.10.

Basically, IGCC plants replace the traditional coal combustor with a gasifier and gas turbine. Ultra-low emissions are realized, over 99% of the sulfur in the coal being removed before the gas is burned in the gas turbine. A gasification cycle can take advantage of all the technology advances being made in CTs and steam turbines, so as to enhance overall cycle efficiency. Net system efficiencies of 45% are expected to be demonstrated by the turn of the century, and when, in the next decade, the **fuel cell** begins to replace the gas turbine, plant efficiencies will climb to the 60% level. Major demonstrations are underway, as part of the CCT program, at Sierra Pacific Power, Pinon Pine (a KRW 99-MW air-blown, pressurized, fluidized bed coal gasifier); Tampa Electric, Polk County (a Texaco, 250-MW oxygen-blown, entrained-flow gasifier); at Tamco Power, Toms Creek (a 190-MVV joint gasification/PC plant with a Tampella Power fluidized bed gasifier); and at PSI Energy/Destec Energy, Wabash River (a 262-MW plant based on the Destec two-stage, entrained-flow, oxygen-blown gasifier). More-detailed descriptions of the Pinon Pine and Polk County gasification systems follow.

Pinon Pine IGCC

At the Sierra Pacific Power Pinon Pine plant (Figure 8.6.11), dried and crushed coal is introduced into a pressurized, air-blown, fluidized bed gasifier. Crushed limestone is added to the gasifier to capture a portion of the sulfur and to inhibit conversion of fuel nitrogen to ammonia. The sulfur reacts with the limestone to form calcium sulfide, which, after oxidation, exits along with the coal ash in the form of agglomerated particles suitable for landfill.

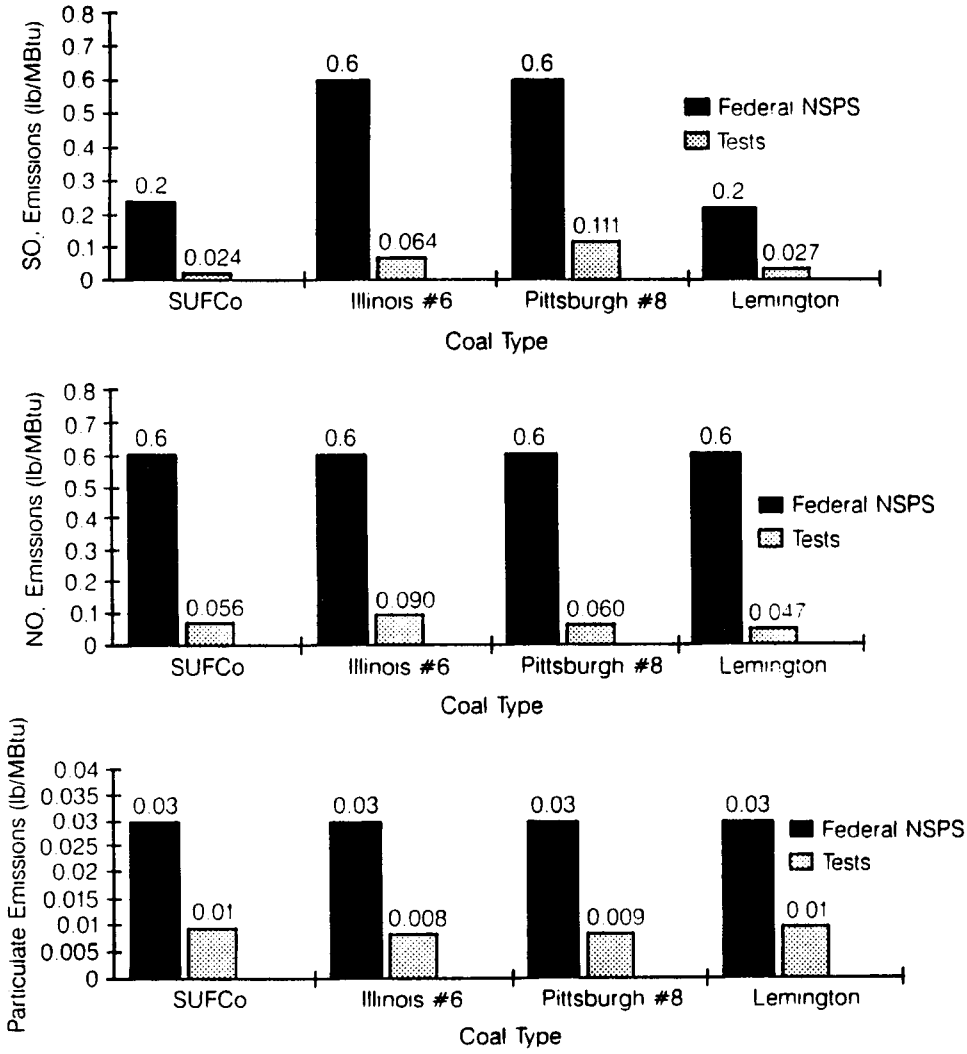

FIGURE 8.6.10 Tests at Cool Water on four coals show emissions of SO_2, NO_x, and particulates substantially below the Federal New Source Performance Standards.

Hot, low-Btu coal gas leaving the gasifier passes through cyclones, which return most of the entrained particulate matter to the gasifier. The gas, which leaves the gasifier at about 1700°F, is cooled to about 1100°F before entering the hot-gas cleanup system. During cleanup, virtually all of the remaining particulates are removed by ceramic candle filters, and final traces of sulfur are removed by reaction with metal oxide sorbent.

The hot, cleaned gas then enters the CT, which is coupled to a generator designed to produce 61 MW. Exhaust gas is used to produce steam in a heat-recovery steam generator. Superheated HP steam drives a condensing steam turbine/generator designed to produce about 46 MW.

Owing to the relatively low operating temperature of the gasifier and the injection of steam into the combustion fuel stream, the NO_x emissions are likely to be below 0.053 lb/M Btu. Because of the combination of in-bed sulfur capture and **hot-gas cleanup**, SO_2 emissions will be below 0.045 lb/M Btu (98% reduction).

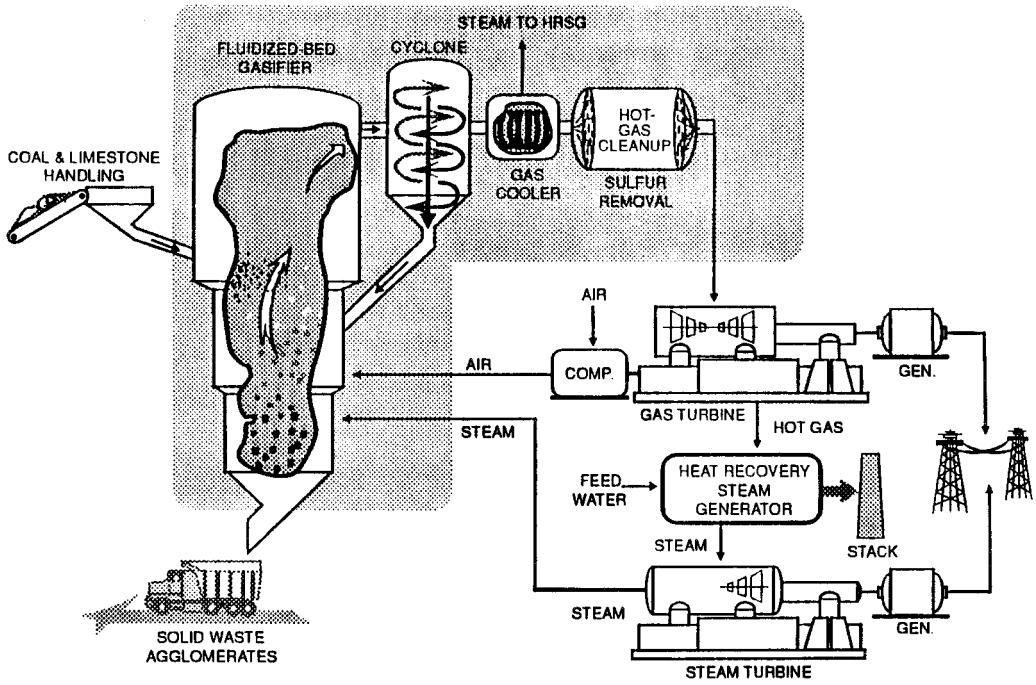

FIGURE 8.6.11 Integrated gasification CC at Sierra Pacific Power, Pinon Pine plant. This uses a KRW air-blown, pressurized fluidized bed coal gasifier, and produces 99 MW (net).

At Pinon Pine, 880 ton/day of coal are converted into 107 MW (gross), or 99 MW (net), for export to the grid. Western bituminous coal (0.5 to 0.9% sulfur) from Utah is the design coal although tests will be done using West Virginia or Pennsylvania bituminous coal containing 2 to 3% sulfur.

Polk County IGCC

The Texaco pressurized, oxygen-blown, entrained-flow gasifier will be used at the Tampa Electric Polk County plant to produce a medium-Btu fuel gas (Figure 8.6.12). Coal/water slurry and oxygen are combined at high temperature and pressure to produce a high-temperature syngas. Molten coal ash flows out of the bottom of the vessel and into a water-filled quench tank, where it is turned into a solid slag. The syngas from the gasifier moves to a high-temperature heat-recovery unit which cools the gases.

The cooled gases flow to a particulate-removal section before entering gas cleanup trains. A portion of the syngas is passed through a moving bed of metal oxide absorbent to remove sulfur. The remaining syngas is further cooled through a series of heat exchangers before entering a conventional gas cleanup train where sulfur is removed by an acid-gas removal system. These cleanup systems combined are expected to maintain sulfur levels below 0.21 lb/M Btu (96% capture). The cleaned gases are then routed to a CC system for power generation. A gas turbine generates about 192 MW. Thermally generated NO_x is controlled to below 0.27 lb/M Btu by injecting nitrogen as a diluent in the combustion section of the turbine. A heat-recovery steam generator uses heat from the gas turbine exhaust to reduce HP steam. This steam, along with the steam generated in the gasification process, is routed to the steam turbine to generate an additional 120 MW. The IGCC heat rate for this demonstration is expected to be approximately 8600 Btu/kWhr (40% efficient).

The demonstration project involves only the first 250-MW portion of the planned 1150-MW Polk County power station. Coals being used in the demonstration are Illinois 6 and Pittsburgh 8 bituminous coals having sulfur contents ranging from 2.5 to 3.5%.

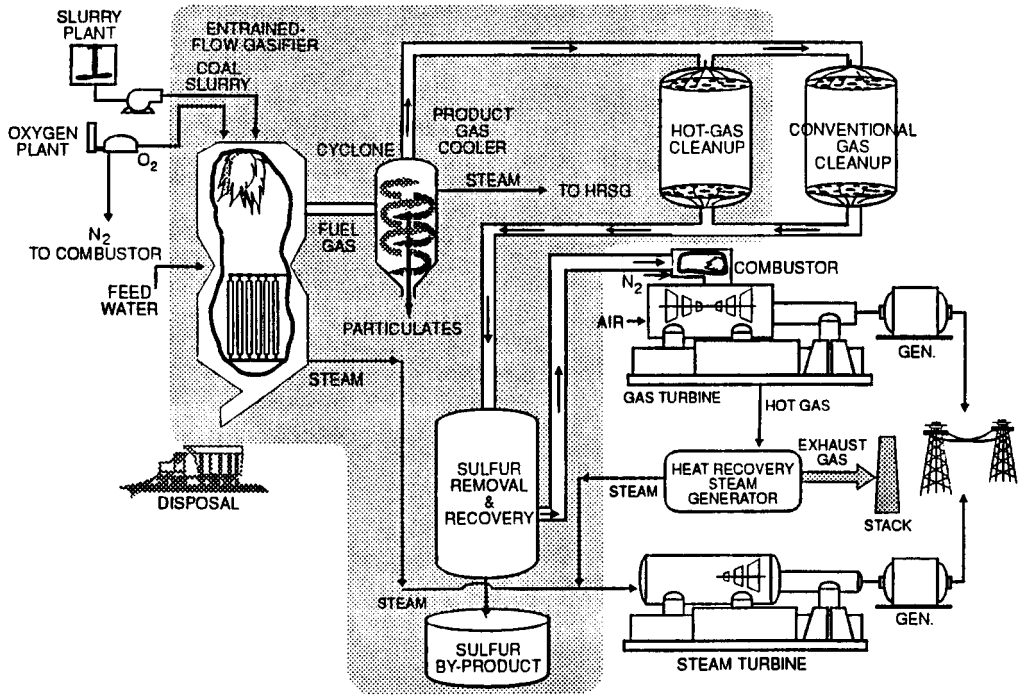

FIGURE 8.6.12 Integrated gasification CC at Tampa Electric, Polk County plant. A Texaco oxygen-blown gasifier is used. Total net generation is 250 MW.

By-products from the process — sulfuric acid and slag — can be sold commercially, sulfuric acid by-products as a raw material to make agricultural fertilizer and the nonleachable slag for use in roofing shingles and asphalt roads and as a structural fill in construction projects.

Buggenum IGCC

Meanwhile, tests are in progress on the 250-MW IGCC plant in Buggenum, Netherlands. After successful operations running on natural gas, a switch was made to coal gas using Columbia coals. Buggenum comprises a 2000-ton/day single reactor coal gasification unit and an air separation plant able to produce 1700 ton/day of 95% pure oxygen. Syngas drives a Siemens CC power unit, including a 156-MW V94.2 gas turbine and a 128-MW steam turbine. The gasifier, operating at 28 bar pressure and 2700°F is designed to produce syngas containing 42% nitrogen, 25% carbon monoxide, and 12% hydrogen, with a combustion value of 4.3 MJ/kg.

The environmental constraints are defined by permit requirements fixing upper limits of SO_2 at 0.22 g/kWhr, NO_x at 0.62g/kWhr, and particulates at 0.007 g/kWhr.

Key steps for limiting emissions include

- Removing fly ash with cyclone and candle filters after gas cooling;
- Removing halogens and other soluble pollutants with water scrubbing;
- Desulfurizing gas by catalytic and chemical processes. Sulfur is fixed in sulfinol-M solvent, which is further treated to produce elemental sulfur; and
- Desulfurized gas is mixed with nitrogen from the air separation units and saturated with water vapor to reduce its lower heating value from about 11,000 to 4300 kJ/kg greatly reducing NO_x production.

Combustion Turbine Plants

CT-based plants are the fastest growing technology in power generation. Through the turn of the century natural gas-fired CTs and CCs burning gas will account for 50 to 70% of the 900 to 1000 GW of new generation to be ordered worldwide. Almost all of these CT and CC plants will be gas fired, leading to a major expansion of gas for electricity generation (Armor et al., 1992).

It is likely that CTs and CCs will grow steadily more important in all generation regimes, peaking, midrange, and base load. If the present 2300°F firing temperature machines operate reliably and durably, CT and CC plants will begin to replace older steam plants and uneconomic nuclear plants. So until the emergence of large-scale fuel cells, CT plants will be a competitive choice for new fossil generation, and advanced CT cycles, with intercooling, reheat, possibly chemical recuperation, and most likely with humidification, will spearhead the drive to higher efficiencies and lower capital costs. Gasification, which guarantees a secure bridge to coal in the near term, will come into its own if natural gas prices rise under demand pressure, and by 2015 coal through gasification may be the economic fuel for a significant fraction of new base-load generation. The rate at which these trends develop depends in large measure on the speed of deregulation and advent of competition in the electricity industry.

Modern gas turbines for power generation are mostly heavy-frame machines, with ratings in a simple cycle configuration around 150 to 170 MW for the high firing temperatures (~2300°F) of the **"F-class" machines**. Efficiencies (LHV) are 36 to 38% in simple cycles. In CCs, the units are 220 to 350 MW in size and 53 to 55% efficient. The next generation of CTs, with efficiencies from 57 to 60% has recently been announced (Table 8.6.3). Smaller-scale aeroderivative machines have benefited from turbofan engines designed for wide-body aircraft and today are available in ratings of 35 to 65 MW and with efficiencies of 40% or more for turbine inlet temperatures around 2250°F. Beyond this, work is underway to design and build an advanced **aeroderivative turbine**, and three teams are involved: United Technologies/Fluor Daniel is looking at a humid air turbine at 200 MW and 55% efficiency; Rolls-Royce/Bechtel is studying an intercooled, regenerative design based on the Aero-Trent machine; and General Electric/Bechtel is melding the GE LM 6000 and the GE heavy-frame designs to achieve close to 60% efficiency in a 100-MW combined cycle.

Recently, General Electric announced a new concept which uses steam from the steam turbine to cool the gas turbine blades permitting a firing temperature of 2600°F. This avoids the losses due to the normal method of diverting compressor air for cooling. This "H" class turbine, it is said, will break the 60% barrier for a 400-MW CC. Comparison of the F- and H-class machines for General Electric is shown in Table 8.6.4.

Humidified Air Power Plants (Cohn, 1994)

A new class of CTs has been designed based on humidifying the combustion air. In these combustion turbine cycles the compressor exit air is highly humidified prior to combustion. This reduces the mass of dry air needed and the energy required to compress it, raising plant efficiency.

The continuous plant cycle for this concept is termed the **humid air turbine** (HAT). This cycle has been calculated to have a heat rate for natural gas about 5% better than current high-technology CCs. The HAT cycle is adaptable to coal gasification leading to the low emissions and high-efficiency characteristics of gasification CC plants but at a low capital cost since the steam turbine bottoming cycle is eliminated. A simple humidified air turbine cycle is shown in Figure 8.6.13. The addition of moisture means that perhaps 25% more mass flow goes through the turbine, than through the compressor. This suggests the use of separate spools for the turbine and compressor. By using present-day 2350°F firing temperatures it is reasonable to expect a HAT heat rate of about 6100 Btu/kWhr from this cycle.

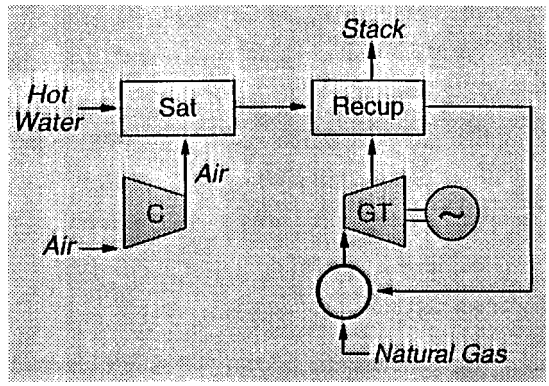

FIGURE 8.6.13 The HAT cycle adds moisture to the compressor exit air, reducing the air mass flow needed and increasing cycle efficiency.

As noted above, the ideal natural gas-fired HAT plant has been calculated to have higher efficiency (about 2 points higher) than a CC for the same turbine cooling technology. Thus, it would provide the lowest heat rate for a natural gas-fired thermal plant and would be utilized in base-load or long intermediate dispatch. The capital cost of this power plant has been calculated to be only slightly higher

than that of a CC. However, the anticipated development cost for the ideal turbomachinery has been estimated to be very high, in excess of $250 million.

In contrast, the CHAT (cascaded humid air turbine) plant utilizes turbine components, which are now available, with few exceptions, in a cascade arrangement that allows them to match together. The development cost of the CHAT equipment is currently estimated to be only in the $5 to 10 million range, making its development much more practical.

The HAT and CHAT cycles can be integrated with gasification. Because these cycles directly incorporate humidification, they can make direct use of hot water generated in the gasification plant, but cannot readily utilize steam. Thus, they match well with the lower-capital-cost, but lower-efficiency, quench types of gasifier. This provides an overall power plant with efficiency about the same as an IGCC. Moreover, the capital cost of the IGHAT plant has been calculated to be about $150/kW less than an IGCC plant. These humidification cycles have yet to be offered commercially. The main obstacle is the need to demonstrate experimentally low-emission, high-efficiency, full-scale combustors utilizing very humid air.

Other Combustion Turbine Cycle Enhancements

There are several variants of the CT-based Brayton cycle which increase plant efficiency and capacity (Lukas, 1986). **Regenerative cycles** use storage-type heat exchangers, where porous or honeycomb wall structures store energy from the hot gases. This is released later to the cold gases. A **recuperative cycle** uses a heat exchanger where the hot and cold streams are separated by walls through which heat transfer occurs. This is the approach commonly used in CTs allowing gains in efficiency and reduced fuel consumption, but no specific output increase.

Intercooling between compressor stages increases useful output by about 30% for a given air mass flow, by reducing the volume flow and increasing available energy to the power turbine. It has minimal effect on efficiency, since heat removed must be added back in the combustion chamber, but is commonly used in conjunction with recuperation.

In a reheat cycle the fuel is introduced at two locations, increasing the total energy available to produce work. A combination of intercooling, reheat, and recuperation is shown in Figure 8.6.14.

Steam injection, where the steam is injected directly into the combustion chamber, increases the mass flow through the turbine and results in increased output power. Steam-injected gas turbine (SIGT) cycles have been compared from the viewpoints of efficiency, power generation, capital and operating costs, and environmental impacts with CC systems (Esposito, 1989). Above 50-MW size, it was found that CC plants were more economical and achieved significantly better heat rates, although cooling tower fog, visible plumes, and drift deposition favored SIGT plants for a flat site.

Capital and Operating Costs of Power Plants

Table 8.6.5 lists typical costs for constructing and operating fossil fuel plants as of 1993. These costs are variable depending on plant design and location; the table assumes a plant in the Northeast United States burning Pittsburgh bituminous coal. Fuel costs, not listed explicitly, will be affected by the plant efficiency, listed in the table.

Costs will vary according to type of coal burned, the size of the unit, the plant location in the United States, and the extent of environmental control employed. In this table, Pittsburgh bituminous coal is assumed, which has 7% ash, 2% sulfur, 5% moisture, and a higher heating value of 13,395 Btu/lb. Wet scrubbers for PC plants use limestone-forced oxidation. Fixed O&M costs include labor, maintenance, and overhead. Variable O&M costs are largely consumables: water, chemicals, other materials.

Summary

The preceding section has described how the future for electric power generation will increasingly be dominated by environmental control needs, putting an emphasis on the base efficiency of new generation and on heat rate recovery for existing units. The PC-fired power plant with FGD will remain a focus of

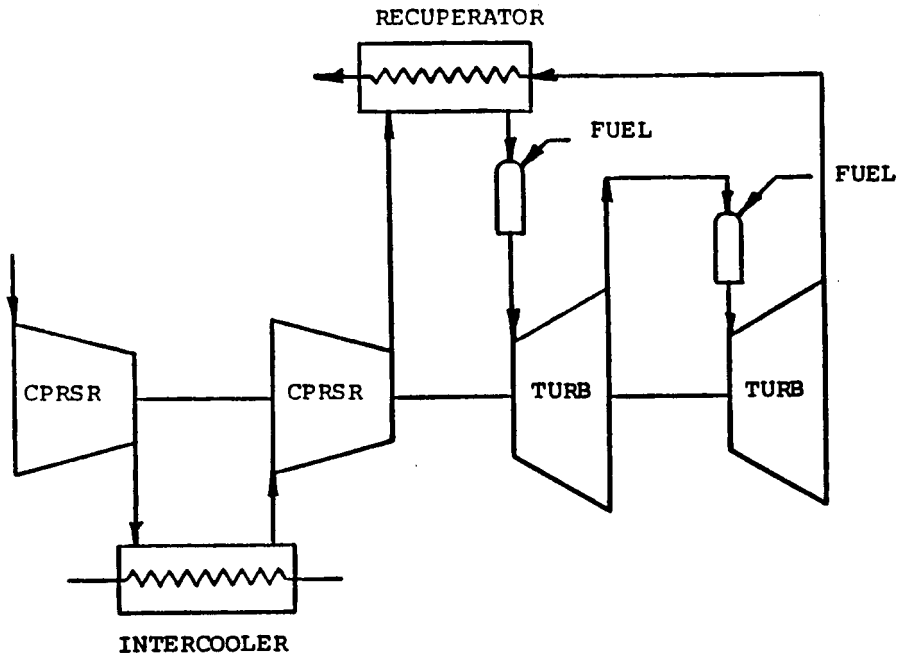

FIGURE 8.6.14 Improvement in CT performance is illustrated in this schematic, which combines an intercooler for the compressor, with a recuperator using CT exhaust heat, and a reheat cycle for the turbine to improve efficiency.

[a] Costs of new plants are likely to reduce, in real terms, over the next 10 years due to technology developments and increased worldwide competition for markets in the developing countries. New technologies (PFBC, IGCC, fuel cells) will lower capital costs as production capacity grows.

Source: Technical Assessment Guide, EPRI TR-102275-V1R7, Electrical Power Research Institute, Palo Alto, CA, June, 1993. With permission.

most near-term activity related to upgrades and retrofits. But new technology, based on coal gasification, is under development and being tested in a growing number of demonstration plants which promise extremely low emissions.

The future for many nations will be based on exploiting the opportunities offered by clean and efficient use of coal. This implies access to the range of new technologies now being tested at large scale in the United States and other developed nations. This strategy is both timely and prudent on a global basis, as the world increasingly voices concerns related to carbon combustion.

Base-load, central generation plants will largely be focused in the immediate future on the rapidly developing areas of the world — Asia (particularly China and India) and Latin America. In these areas the fuel of choice will likely be coal, particularly in Asia, and the generating unit most often will be a conventional PC unit, but also could be an atmospheric or pressurized fluidized bed unit. In North America, Europe, and Japan, gas-fired central plants using CTs, often in a CC, will dominate through the next decade. As the cost of natural gas, relative to coal, increases, this will then encourage the installation of gasification units enabling the enormous world coal reserves to be utilized. Then, sometime after the turn of the century, smaller distributed generating sources will begin to emerge, based on gas-fired fuel cells, small CTs, or possibly photovoltaics. As the economics for the distributed option become favorable, these smaller generating units could encourage broad electrification of the developing countries of the world.

Defining Terms

Aeroderivative turbine: In the 1960s gas turbines derived from military jet engines formed a source of utility peaking capacity. Now, modern airline fan-jets are being converted to utility service. These lighter CTs are highly efficient and can have low NO_x emissions, high pressure ratios, and low capital cost.

Ash-softening temperature: The tendency for fly ash to adhere to tube banks is increased as the ash softens and melts. The point at which the ash begins to soften is dependent on the type of coal and is difficult to predict, depending on the many coal constituents. Slagging and fouling of tubes can lead to severe tube corrosion.

Coal gasification: Coal can be converted into a mixture of carbon monoxide and hydrogen by burning it with a controlled deficiency of oxygen. Use of pure oxygen produces a medium-calorific-value gas, and air a low calorific value gas. This "syngas" can then be used to power a CT.

Coextruded tubing: Tubing for superheaters and reheaters must be strong enough to withstand the pressures and temperatures expected, and also corrosion resistant to depositions of fly ash. By making tubing with a strong inner layer and corrosion-resistant outer layer through an extrusion process, both concerns can be dealt with.

Cogeneration: Cogeneration refers to the production of multiple products from a power plant. Typically, process steam, or hot water for heating, is produced in addition to electricity. This approach leads to high plant utilization, the "effective" heat rate being 70% or more.

Combined cycle: Power stations which employ both CTs (Brayton cycle) and condensing steam turbines (Rankine cycle) where the waste heat from the CTs generates steam for the steam turbines, are called *combined* cycle plants. Overall plant efficiency improves.

Electrostatic precipitators: Flue gas particles, when electrically charged in an ionized gas flow, collect on electrodes in the presence of a strong electrostatic field. Collected dust is discharged by rapping into hoppers. A collection efficiency above 99% is possible.

Double reheat: Modern designs of fossil steam-generating units remove a portion of the steam before full expansion through the turbine and reheat it in the boiler before returning it to the turbine. This enhances the thermal efficiency of the cycle by up to 5%. For supercritical cycles two stages of reheat can be justified — double reheat.

F-class machines: Recent designs of CTs have increased efficiencies resulting from increased firing temperatures. The first generation of these machines has firing temperatures of about 2300°F. They have been termed F-class machines (for example the GE 7F). Even higher temperatures have now been incorporated into "G-class" turbines.

Flue gas desulfurization: Removal of sulfur dioxide, SO_2, from combustion gases is accomplished in a number of FGD methods. Most of these involve wet "scrubbing" of the gas using lime or limestone and result in a calcium sulfate waste product. A 95% removal efficiency, or higher, is possible.

Fluidized bed: A process of burning solid fuels, particularly coal, by suspending the fuel within a column of air supplied from below the furnace. This method permits effective combustion of poor-quality fuels, lowers NO_x emissions due to low combustion temperatures, and captures sulfur in the bed by mixing limestone or dolomite in with the fuel.

Fuel cell: Fuel cells convert gaseous or liquid fuels directly to electricity without any combustion process. Like a continuous battery, the fuel cell has electrodes in an electrolyte medium. Typically, hydrogen and air are supplied and DC electricity, water, and carbon dioxide are produced. They are currently high-cost, low-size devices, but with minimum environmental emissions.

Hot-gas cleanup: Cycles which use gas from the combustion of coal, typically pressurized fluidized bed or gasification cycles, need to clean up the ash particles before passing them through a gas turbine. This prevents severe erosion of the turbine blades and other components. Hot-gas cleanup can involve the application of hanging particulate traps, using ceramic filters.

Humid air turbine: A new type of CT uses humidified compressor exit air for the combustor. The mass of dry air needed is thus lessened for a given mass flow, and turbine efficiency increases. Several applications of this HAT appear attractive in gasification and compressed air storage cycles.

Intercooling: Increased output from a CT can be obtained by cooling the air between compressor stages. This reduces volume flow and increases energy to the power turbine.

Lower heating value: Fuels containing hydrogen produce water vapor as a product of combustion. The fuel heating value is said to be "lower" if the combustion process leaves all products in the gaseous state, but "higher" if the fuel heating value includes the latent heat of vaporization. Practice in the United States is to use the higher value.

On/off cycling capability: Generating units are often not required on a 24-hr basis. Some are shut down during low-demand times and started up perhaps hours later. This form of on/off cycling imposes thermal stresses on the equipment, leading to premature equipment failure unless special measures are taken to deal with this.

Petroleum coke: Petroleum coke is a residual product of the oil-refining process, and in its fuel-grade form is an almost pure carbon by-product. About 19 million tons of fuel-grade pet coke is produced each year in the United States. It is inexpensive although it may have high sulfur and vanadium content.

Recuperative cycle: Recuperative cycles for CTs use walls between the hot and cold streams through which heat is transferred. This improves efficiency and reduces fuel consumption.

Regenerative cycles: Combustion turbine cycles using heat exchangers to store and transfer heat from the hot gases to the cold gases are termed regenerative cycles.

Slagging and fouling: The mineral matter in coal can attach itself following combustion to the boiler walls and heat-exchanger surfaces. Oxides of silicon, aluminum, iron, calcium, and magnesium can foul all boiler surfaces, requiring soot blowers for cleaning. Hot ash can melt, becoming sticky and sometimes coalescing in the furnace to cause slagging problems.

Spray drying: Spray driers, for desulfurization, used typically when burning lower-sulfur coals, use a spray of quicklime which is dried by the hot flue gas and results in a dry solid product. A 90% removal efficiency is typical.

Steam injection: Injecting stream directly into the combustion chamber of a CT increases turbine mass flow and thus increases the output power.

Temper embrittlement: Tempering of steel in the manufacturing process removes some of the brittleness and is carried out by a heating and cooling process. During operation, though, it is possible that ductility can worsen close to specific tempering temperatures. The material is then said to be temper embrittled, and premature cracking may follow.

8.7 Energy Storage

Chand K. Jotshi and D. Yogi Goswami

Introduction

Energy storage is very important for utility load leveling, electrical vehicles, solar energy systems, uninterrupted power supply, and energy systems at remote locations. Two important parameters for energy storage are duration of storage and **specific energy** or **energy density**. Duration of energy storage may vary from many years to a fraction of a second. In a nuclear power plant, nuclear fuel is stored within a reactor for a year. Coal piles, gas and oil storage tanks, or pumped hydro are kept by power utilities for several days use, depending upon the need. Similarly for a solar energy system, requirement of energy storage may be on an hourly, daily, or weekly basis. Specific energy or energy density is a critical factor for the size of a storage system.

Energy can be stored as mechanical, thermal, chemical, electrical, or magnetic energy. In this section, storage of thermal, mechanical, and electrical energy are described.

Thermal Energy Storage (TES)

Thermal energy can be stored as sensible heat, latent heat, or as the heat of chemical reaction (thermochemical).

Sensible heat, Q, is stored in a material of mass m and specific heat C_p by raising the temperature of the storage material and is expressed by Equation (8.7.1):

$$Q = mc_p\Delta T \tag{8.7.1}$$

Most common sensible heat storage materials are water, organic oils, rocks, ceramics, and molten salts. Some of these materials along with their physical properties are listed in Table 8.7.1. Water has the highest specific heat value of 4190 J/kg · C.

TABLE 8.7.1 Physical Properties of Some Sensible Heat Storage Materials

Storage Medium	Temperature Range, °C	Density (ρ), kg/m³	Specific Heat (C), J/kg K	Energy Density(ρC) kWhr/m³ K	Thermal Conductivity (W/m K)
Water	0–100	1000	4190	1.16	0.63 at 38°C
Water (10 bar)	0–180	881	4190	1.03	—
50-ethylene glycol–50 water	0–100	1075	3480	0.98	—
Dowtherm A® (Dow Chemical, Co.)	12–260	867	2200	0.53	0.112 at 260°C
Therminol 66® (Monsanto Co.)	–9–343	750	2100	0.44	0.106 at 343°C
Draw salt ($50NaNO_3$-$50KNO_3$)[a]	220–540	1733	1550	0.75	0.57
Molten Salt ($53KNO_3/40NaNO_2/7NaNO_3$)[a]	142–540	1680	1560	0.72	0.61
Liquid sodium	100–760	750	1260	0.26	67.5
Cast iron	m.p. (1150–1300)	7200	540	1.08	42.0
Taconite	—	3200	800	0.71	—
Aluminum	m.p. 660	2700	920	0.69	200
Fireclay	—	2100–2600	1000	0.65	1.0–1.5

[a] Composition in percent by weight.
Note: m.p. = melting point.

Thermal energy, Q, can be stored as latent heat in a material of mass, *m*, that undergoes phase transformation as given by Equation (8.7.2):

$$Q = m\lambda \tag{8.7.2}$$

where λ = heat of phase transformation.

Four types of phase transformations useful for latent heat storage are: solid $\rightleftarrows$ liquid, liquid $\rightleftarrows$ vapor, solid $\rightleftarrows$ vapor, and solid $\rightleftarrows$ solid. Since phase transformation is an isothermal process, thermal energy is stored and retrieved at a fixed temperature known as the transition temperature. Some common phase change materials (PCMs) used for thermal storage are paraffin waxes, nonparaffins, inorganic salts (both anhydrous and hydrated), and eutectics of organic and/or inorganic compounds. Table 8.7.2 lists some PCMs with their physical properties.

TABLE 8.7.2 Physical Properties of Latent Heat Storage Materials or PCMs

Storage Medium	Melting Point °C	Latent Heat, kJ/kg	Specific Heat (kJ/kg °C)		Density (kg/m³)		Energy Density (kWhr/m³ K)	Thermal Conductivity (W/m K)
			Solid	Liquid	Solid	Liquid		
$LiClO_3 \cdot 3H_2O$	8.1	253	—	—	1720	1530	108	—
$Na_2SO_4 \cdot 10H_2O$	32.4	251	1.76	3.32	1460	1330	92.7	2.25
$Na_2S_2O_3 \cdot 5H_2O$	48	200	1.47	2.39	1730	1665	92.5	0.57
$NaCH_3COO \cdot 3H_2O$	58	180	1.90	2.50	1450	1280	64	0.5
$Ba(OH)_2 \cdot 8H_2O$	78	301	0.67	1.26	2070	1937	162	0.653ℓ
$Mg(NO_3) \cdot 6H_2O$	90	163	1.56	3.68	1636	1550	70	0.611
$LiNO_3$	252	530	2.02	2.041	2310	1776	261	1.35
$LiCO_3/K_2CO_3$, (35:65)[a]	505	345	1.34	1.76	2265	1960	188	—
$LiCO_3/K_2CO_3/Na_2CO_3$ (32:35:33)[a]	397	277	1.68	1 63	2300	2140	165	—
n-Tetradecane	5.5	228	—	—	825	771	48	0.150
n-Octadecane	28	244	2.16	—	814	774	52.5	0.150
HDPE (cross-linked)	126	180	2.88	2.51	960	900	45	0.361
Steric acid	70	203	—	2.35	941	847	48	0.172ℓ

[a] Composition in percent by weight.

Note: ℓ = liquid.

Thermochemical energy can be stored as heat of reaction in reversible chemical reactions. In this mode of storage, the reaction in the forward direction is endothermic (storage of heat), while the reverse reaction is exothermic (release of heat). For example,

$$A + \Delta H \rightleftarrows B + C \tag{8.7.3}$$

The amount of heat *Q* stored in a chemical reaction depends on the heat of reaction and the extent of conversion as given by Equation (8.7.4):

$$Q = a_r m \Delta H \tag{8.7.4}$$

where a_r = fraction reacted, ΔH = heat of reaction per unit mass, and m = mass.

Chemical reaction is generally a highly energetic process. Therefore, a large amount of heat can be stored in a small quantity of a material. Another advantage of thermochemical storage is that the products of reaction can be stored at room temperature and need not be insulated. For sensible and latent heat storage materials, insulation is very important. Examples of reactions include decomposition of metal hydrides, oxides, peroxides, ammoniated salts, carbonates, sulfur trioxide, etc. Some useful chemical reactions are reported in Table 8.7.3.

TABLE 8.7.3 Properties of thermochemical storage media

Reaction	Condition of Reaction: Pressure, kPa	Condition of Reaction: Temperature, °C	Component (Phase)	Pressure, kPa	Temperature, °C	Density, kg/m³	Volumetric Storage Density, kWhr/m³
$MgCO_3$ (s) + 1200 kJ/kg =	100	427–327	$MgCO_3$(s)	100	20	1500	
MgO (s) + CO_2(g)			$CO_2(\ell)$	7400	31	465	
							187
$Ca(OH)_2$(s) + 1415 kJ/kg =	100	572–402	$Ca(OH)_2$(s)	100	20	1115	
CaO(s) + H_2O(g)			$H_2O(\ell)$	100	20	1000	345
SO_3(g) + 1235 kJ/kg =	100	520–960	$SO_3(\ell)$	100	45	1900	
SO_2(g) + $^1/_2O_2$(g)			$SO_2(\ell)$	630	40	1320	
			O_2(g)	10000	20	130	280

Note: s = solid, ℓ = liquid, g =gas.

Applications and Examples

Cool Storage has major applications in space cooling of buildings, food and medicine preservation, and transportation of items that need to be stored at low temperatures. A major application of cool storage is in the use of off-peak electricity for air-conditioning during peak hours. During off-peak hours electricity can be used to make ice or chilled water, which can be used later for air-conditioning of buildings during the peak hours. The advantage of using ice as a storage medium over chilled water is that a much larger amount of coolness can be stored in ice; 1 kg of ice stores 335 kJ, whereas 1 kg of water stores only 42 kJ for a temperature swing of 10°C. The disadvantage of ice is its lower thermal conductivity, which is responsible for lower heat-transfer rates.

Cool storage systems have been used in several buildings in the United States and Canada. The Merchandise Mart of Chicago boasts the largest ice storage system in the world: each day more than 2 million lb of ice are made and melted. For long-term cool storage, aquifers have been used for chilled water storage. Examples include cooling of buildings at the University of Alabama and the United States Postal Service in Long Island, NY, using chilled water stored in aquifers (Tomlinson and Kannberg, 1990). Other materials which have been found to have cool storage potential are PCMs like $LiClO_3 \cdot 3H_2O$, a eutectic of Glauber's salt, paraffins and their mixtures, and some gas hydrates or clatherates.

Heat Storage has major applications in space heating, crop drying, cooking, electric power generation, industrial process heat (air and steam), waste heat utilization, and solar energy utilization, etc. Heat storage in water is the most economical and well-developed technology. Epoxy-lined steel, fiberglass-reinforced polymer, concrete with plastic liner, and wood tanks are suitable containment materials for systems using water as the storage material. The storage tanks may be located above or below ground. In North America and China, aquifers have been used for long-term storage of hot water and chilled water. Pressurized water tanks are used to store heat from off-peak electricity (ASHRAE, 1995). For example, water is heated to maximum temperatures of about 138°C in a tank at a pressure of 50 psig.

Molten nitrate salt (50 wt% $NaNO_3$/50 wt% KNO_3) also known as Draw salt, which has a melting point of 222°C, has been used as a storage and a heat-transfer fluid in an experiment in Albuquerque, NM. It was the first commercial demonstration of generating power from storage (Delameter and Bergen, 1986). Solar Two, a 10-MW solar thermal power demonstration project in Barstow, CA, is also designed to use this molten salt to store solar energy (Chavez et al., 1995). Another molten nitrate salt is 40 wt% $NaNO_2$/7 wt% $NaNO_3$/53 wt% KNO_3, known as HTS (heat-transfer salt) with a melting point of 142°C. This salt has been widely used in the chemical industry.

For applications in heating and cooling of buildings the containment of PCM can become an integral part of the building. It may be part of the ceiling, wall, or floor of the building and may serve a structural or a nonstructural function. Tubes, trays, rods, panels, balls, canisters, and tiles containing PCMs have been studied in the 1970s and 1980s for space-heating applications (Moses and Lane, 1983). The PCMs used were mostly salt hydrates such as Glauber's salt ($Na_2SO_4 \cdot 10H_2O$), Hypo ($Na_2S_2O_3 \cdot 5H_2O$),

$NaCH_3COO \cdot 3H_2O$, $Na_2HPO_4 \cdot 12H_2O$, $Ba(OH)_2 \cdot 8H_2O$, $MgCl_2 \cdot 6H_2O$, and $Mg(NO_3)_2 \cdot 6H_2O$. Paraffin mixtures have been used for thermal storage in wall boards. Some PCMs, such as salt hydrates, exhibit supercooling and phase segregation problems during heat removal. Low thermal conductivity and complex mechanism of heat transfer during melting and freezing introduce complexities in the design of their containment systems.

Mechanical Energy Storage

Mechanical energy may be stored as potential or kinetic energy.

Kinetic Energy

Kinetic energy can be stored in the rotating mass of a wheel, commonly known as a flywheel. Kinetic energy of a rotating body is given by Equation (8.7.5):

$$KE = \frac{1}{2} I\omega^2 \tag{8.7.5}$$

where I = moment of inertia, and ω = angular velocity.

The maximum specific energy of a flywheel is expressed by the following equation (Jenser, 1980):

$$\frac{KE_{max}}{m} = A\frac{\rho_{max}}{\rho} \tag{8.7.6}$$

where A = shape factor, and its value depends on the geometry of flywheel; $A = 1.0$ for a constant stress disk and 0.5 for a thin-rimmed flywheel. This equation shows that high tensile strength and low density are the key parameters to store maximum energy. Tensile strength, density, and specific energy of some materials are given in Table 8.7.4.

TABLE 8.7.4 Flywheel Rotor Materials

Material	Design Stress, MN/m²	Density, kg/m³	Specific Energy, Whr/kg
Composite fiber[a]/epoxy	750	1550	51.5
E-glass fiber[a]/epoxy	250	1990	14.0
S-glass fiber[a]/epoxy	350	1900	19.6
Kevlar fiber[a]/epoxy	1000	1400	76.2
Maraging steel	900	8000	24.2
Titanium alloy	650	4500	30.8

[a] 60% fiber.

Storing energy in a flywheel is one of the oldest techniques used in ancient potteries. Present-day flywheels are much more advanced as a result of superstrong/ultralight composite materials and frictionless high-performance magnetic bearings.

Potential Energy

If a body of mass m is elevated against the gravitational force g to a height Δh, the potential energy stored is given by

$$PE = mg\Delta h \tag{8.7.7}$$

From Equation (8.7.7), 1 Wh of energy can be stored in 1 kg mass of a body by raising it to a height of 367 m.

Potential energy is also stored in a spring, either by compressing or expanding. Here, energy stored is given by

$$PE = (1/2)kx^2 \tag{8.7.8}$$

where k = spring constant and x is the distance to which the spring is compressed or expanded. Springs have been widely used to power toys and watches mainly because of very low values of energy density.

Pumped Hydro

Water may be pumped from a lower reservoir to a higher reservoir using electricity during off-peak hours, which may be used to generate electricity using hydraulic turbines during peak hours. Figure 8.7.1a shows a schematic diagram of an above-ground pumped hydro system. Advantages of pumped hydro units include simple operation, high reliability, low maintenance, long life, quick start from standstill, and economic generation of peaking electrical energy. In the United States a large number of such systems are in operation. Power-generating capacities of these systems vary between 5 and 2000 MW (Makansi, 1994). The overall efficiencies of these power plants vary between 65 and 90%, which includes the efficiencies of pumps, hydraulic turbines, generators, and losses from the upper reservoir. In spite of the technical and economic viability of pumped hydro, the requirement of a specific type of topography and some environmental concerns limit its application. To overcome these problems, a concept of underground pumped hydro storage as shown in Figure 8.7.1b can be used. In this case, large caverns or aquifers can be used as the lower reservoir.

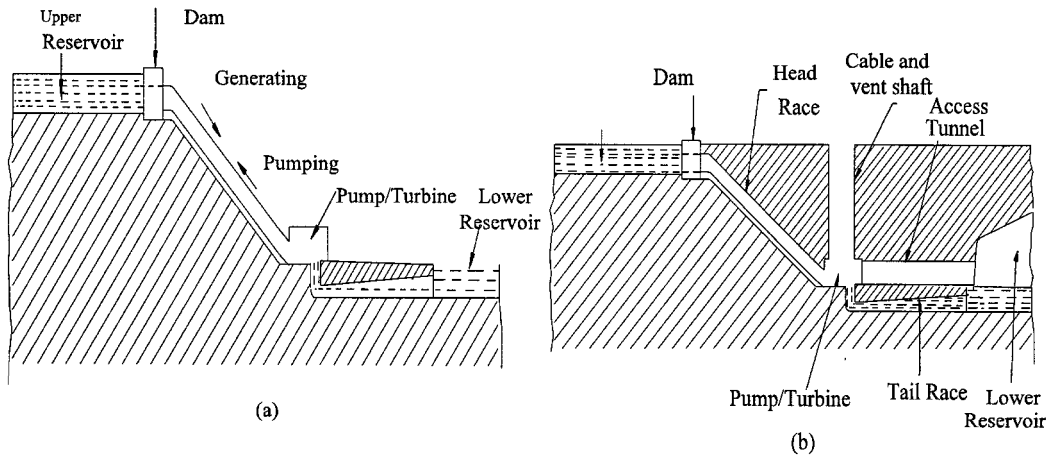

FIGURE 8.7.1 Pumped hydrostorage: (a) above ground; (b) underground.

Compressed Air Storage

In a fossil fuel power plant, approximately half of the output of a conventional gas turbine is used to drive the compressors. If the air is compressed during off-peak hours and stored, it can be used later during peak hours. Compressed air can be stored underground in abandoned mines, oil or gas fields, sealed aquifers, or natural caverns. A compressed air storage plant in Huntorf, Germany that has been in operation since 1978 is the oldest unit. A 110-MW demonstration facility at the Alabama Electric Cooperative (AEC), Inc., McIntosh, Alabama , site has been in operation since 1991. The Hunterof unit is a 4-hr facility and the AEC site is a 26-hr facility (Makansi, 1994).

Electrical Energy Storage

Electrochemical energy storage, more commonly known as battery storage, stores electrical energy as chemical energy. Batteries are classified as primary and secondary batteries. Only secondary batteries are rechargeable and are therefore suitable for energy storage applications. Lead-acid and nickel-cadmium are well-known rechargeable batteries that are most commonly used. Lead-acid batteries have been used for over a century and are still the most popular batteries.

Electrochemical operation of a cell during discharge and charge is shown in Figures 8.7.2a and b. During discharge when a cell is connected to a load, electrons flow from the anode to the cathode. In this operation oxidation, or loss of electrons, takes place at the anode, and reduction, or gain of electrons, occurs at the cathode. The cell chemistry of a lead-acid battery is as follows: the anode is lead (Pb) and the cathode is lead oxide (PbO_2); the electrolyte is H_2SO_4. The cell reaction is

$$2H_2SO_4 \rightarrow 4H^+ + 2SO_4^-$$

$$\text{Anodic reaction:} \quad Pb + SO_4^{2-} = PbSO_4 + 2e^- \tag{8.7.9}$$

$$\text{Cathodic reaction:} \quad PbO_2 + SO_4^{2-} + 4H^+ + 2e^- = PbSO_4 + 2H_2O \tag{8.7.10}$$

Theoretical voltages and capacities of some known batteries are reported in Table 8.7.5.

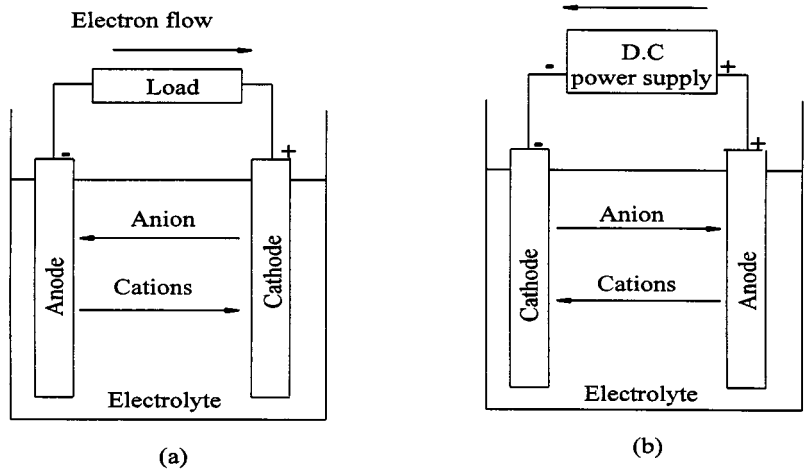

FIGURE 8.7.2 Electrochemical operation of a cell: (a) discharge; (b) charge.

TABLE 8.7.5 Properties of Some Rechargeable Batteries

No.	System	Electrolyte	Temp. °C	O.C.V. (V)	Energy Density (Theoretical), Whr/kg	Energy Density (Achievable), Whr/kg	In/Out Electrical Effciency	Cycle Life
1	Lead-Acid	H_2SO_4	20–30	2.05	171	50	75	1000
2	Nickel-Iron	KOH	20–30	1.37	267	60	55	2000
3	Zinc-Iron	KOH	50–60	1.65	1084	90	45	600
4	Sodium-Sulfur	β-Al_2O_3	300–375	1.76–2.08	664	120	75	2000
5	Lithium-Iron Sulfide	LiCl-KCl (eutectic)	400–450	1.6	869	150	75	1000

Note: O.C.V. = open cell voltage.

Applications

Battery storage is used in a wide range of applications. Currently, the main emphasis of research is on applications in vehicles and load leveling.

Electric Vehicles. For electric vehicles, the specific energy and specific power are two important parameters. The greater the specific energy, the farther a vehicle can travel. If specific power is high, a vehicle can accelerate more quickly and have a higher top speed. Other important requirements are the ability to charge and discharge a large number of times, to retain charge over an extended period of time, and to charge and discharge over a wide range of temperatures. Table 8.7.5 provides information about some rechargeable batteries.

Power Plants. Recent start-up of a commercial unit for the Puerto Rico Electric Power Authority (PREPA) is the latest development in large-scale application of lead-acid batteries. The facility stores 20 MW for 20 min, both for peaking requirement and voltage and frequency control. Maximum discharge is limited to 10 MW (Makanasi, 1994).

Defining Terms

Cool storage: The storage of thermal energy at temperatures below the nominal temperature required by the space or process.

Heat storage: The storage of thermal energy at temperatures above the nominal temperature required by the space or process.

Energy density: Amount of energy stored per unit volume, kJ/m^3 or kWhr/m^3.

Specific energy: Amount of energy stored per unit mass, kJ/kg or kWhr/kg.

8.8 Nuclear Power

Roberto Pagano and James S. Tulenko

Nuclear power refers to power generated through reactions involving atomic nuclei (i.e., nuclear reactions). These reactions fall into three broad categories — fusion reactions, fission reactions, and radioisotopes. In fusion, two light nuclei (most commonly isotopes of hydrogen) combine to form a heavier nucleus (usually helium), with energy being released in the process. Nuclear fusion is the source of energy generated in the stars (our sun). In artificial applications, the technology to induce fusion reactions has been available for several decades, but such reactions have been essentially uncontrolled (the hydrogen bomb). Once initiated, fusion reactions generate huge amounts of energy, which is subsequently released explosively. Means to produce and release energy from fusion in a sustained, controlled manner are still being developed. Extensive research is ongoing, both in the United States and abroad, on the development of nuclear fusion as a controlled source of power.

Nuclear fission, in contrast, is the basis of a mature technology applied to the generation of power. Fission is the fragmentation of a heavy nucleus into two, sometimes three, lighter nuclei. Certain nuclides found in nature fission spontaneously, that is, with no external intervention. However, spontaneous fission in naturally occurring nuclides takes place at a very slow rate. Fission can be induced through a nuclear reaction. Of primary interest here is the fissioning of several specific nuclei through interactions with neutrons. Again, the fissioning of a nucleus is accompanied by the release of energy.

At present, the element of primary importance with respect to nuclear fission power is uranium. Naturally occurring uranium consists of three isotopes — ^{238}U, ^{235}U, and ^{234}U. In a mixture of isotopes of an element, the abundance of any one is usually expressed as the number of atoms of that isotope present per 100 atoms of the mixture, abbreviated as atom percent a/o or weight percent w/o. Natural uranium consists of 99.2745 a/o ^{238}U, 0.7200 a/o ^{235}U, and 0.0055 a/o ^{234}U.

Radioisotope power is the third form of nuclear energy. When radioisotopes decay, high-energy electrons (beta particles), helium atoms (alpha particles), and gamma rays (photons) are emitted. When the energy of these radiations is stopped and converted to heat, a power source is created. Radioisotopes decay energies range from 0.01 to 10 MeV. Radioisotopes are generally separated from radioactive wastes produced from nuclear power plants. The most common radioisotopes are polonium-210 (alpha emitter of 5.3 MeV), plutonium-238 (alpha emitter of 5.46 MeV), cesium-144 (beta emitter of 1.25 MeV), and strontium-90 (beta emitter of 1.10 MeV).

The Fission Process

Consider first the fission of a nucleus of ^{235}U caused by an interaction with a neutron. A compound nucleus of ^{236}U is initially formed. If fission occurs, it does so within a very short time. Normally with thermal reaction, 85% of the interaction leads to fission. Alternatively, the compound nucleus dissipates energy by emitting a gamma photon, no fission occurs and the nucleus remains as ^{236}U. This latter process occurs in 20% of the interaction of ^{235}U with a neutron.

The fissioning of a nucleus produces fission fragments called fission products, a number of neutrons and gamma photons. Most frequently, the number of neutrons is 2 or 3, ranging in extreme cases from 0 to 8. In the fissioning of ^{235}U, the average number of neutrons released, designated by υ, has a value of 2.42. This value applies strictly if the fission is induced by a neutron of relatively low kinetic energy, called a thermal neutron.

In a nuclear reactor, which is a special material medium in which ^{235}U is dispersed for the reactor to work, one of the neutrons liberated in the fissioning of a nucleus must go on to induce a fission in another nucleus. This leads to the idea of a self-sustaining chain reaction or, more specifically, a **critical configuration** in which a self-sustaining chain reaction can be maintained indefinitely. To this end, an adequate supply of ^{235}U must be on hand and replenished as needed. Further, the configuration must be

such that the likelihood that any particular neutron ultimately induces a fission is adequately high to ensure that on average one neutron will induce a fission.

The energy liberated in fission results from Einstein's equation $E = Mc^2$, which says that mass and energy are equivalent. A summation of the masses of the fission fragments and the neutrons resulting from fission shows that the combined mass of the products of a fission is less than the mass of the compound nucleus before fission occurs. It is found that the energy released is equal to $E = \Delta Mc^2$ when ΔM is the difference in the masses. This nuclear energy is traditionally expressed in units of electron volts (eV), with the equivalence of 1 eV = 1.602×10^{-19} J. The single fission of a single uranium atom releases approximately 200×10^6 eV, or 200 MeV, of energy. When one realizes that the combusion of a single carbon atom ($C + O_2 \rightarrow CO_2$) releases 4 eV, a quantity 50 million times smaller, one gets a true appreciation of the concentrated power of nuclear energy.

Most of the energy liberated in a fission appears as the kinetic energy of the fission fragments (168 MeV, or 84%) and the kinetic energy of the neutrons (5 MeV, or 2.5%). The remainder is distributed among the gamma photons appearing instantaneously with the fission and the energy associated with the radioactive decay of the fission fragments. These fragments are readily stopped in the reactor. Their range is of the order of 0.01 to 0.001 mm. Thus, the major portion of the energy from a fission is deposited within a very short distance from the site of the fission.

In the largest power reactors in operation in the United States today, heat is generated at the rate of 3800 MW. At 200 MeV per fission, fissioning in such reactors must occur at the rate of 1.2×10^{20} fissions/sec to produce the power. In terms of ^{235}U, this requires the fissioning of all the nuclei contained in 0.047 g of ^{235}U, or the fissioning of approximately 4 kg per day. Thus, as a rule of thumb, the fissioning of all the nuclei present in 1 g of ^{235}U is sufficient to generate 1 MW day of thermal energy. In contrast, the generation of the same amount of energy from coal requires the combustion of 4 tons of coal of typical heating value. With the combustion of coal there is the associated release of a large quantity of carbon dioxide (~14 tons) to the atmosphere with its effects on global warming.

Cross Sections

A measure of the probability of a particular nuclide to interact with a neutron is provided by a quantity known as a **cross section**. Numerical values of cross sections are determined experimentally and are expressed in units of barns (b), with 1 b defined as 10^{-24} cm^2, or 10^{-28} m^2.

As a quantity, a cross section may be interpreted as a target area — the larger the cross section, the more likely the interaction of the nucleus with a neutron in its vicinity. For example, the cross section for fission of ^{235}U, denoted by σ_f^{235}, has a value of 582 b if the interacting neutron is traveling at the velocity associated with thermal energy (2200 m/sec). If the neutron is traveling at high energy, the cross section may drop to a value of approximately 2 b. With respect to the radiative capture of a neutron in ^{235}U leading to the formation of ^{236}U, the cross section is given by $\sigma_c^{235} = 99$ b, if the neutron is thermal. In summary, a cross section is a property specific to a given nuclide, but it is a property whose value depends on the energy of the interacting neutron.

Cross sections are additive. Thus, the cross section for the absorption of a thermal neutron in ^{235}U — whether the absorption gives rise to a fission or a radiative capture — is given by $\alpha_a = \alpha_f + \alpha_c = 582$ b + 99 b = 681 b. Further, the probability of a fission occurring as a result of a thermal neutron being absorbed in ^{235}U is given by $\alpha_f/\alpha_a = 582$ b/681 b = 0.85. Fission is, therefore, the more likely outcome of an interaction between a ^{235}U nuclide and a thermal neutron.

On average, the neutrons arising from the fissioning of ^{235}U have a kinetic energy of 2 MeV, corresponding to a speed of 2×10^7 m/sec. These neutrons are four orders of magnitude greater than the speed at which a neutron is considered to be thermal (2200 m/sec).

Categories of Nuclear Reactors

A prerequisite for a self-sustaining chain reaction is that sufficient ^{235}U be present in the medium to ensure that the absorption of a neutron in a nucleus of ^{235}U is a likely occurrence. If the population of neutrons present in the medium at any instant consists predominantly of slow neutrons, a far lesser amount of ^{235}U is needed to ensure criticality than would be the case if the population were to consist of fast neutrons. This comes about because of the difference in the values of the cross sections mentioned previously.

There is, from this particular standpoint, an incentive to slow down the neutrons originating in fission in order to reduce the inventory of ^{235}U needed to maintain criticality. In the power reactors operating today, means are provided to slow down the neutrons. The slowing down is effected through multiple elastic scatterings of the neutrons with the nuclei of light elements deliberately present in the medium acting as so-called **moderators**. Notable among such elements are hydrogen present in water, deuterium in heavy water, and carbon in the form of graphite.

All of the reactors in which substantive moderation of the neutrons occurs are categorized as **thermal reactors**. This term stems from the distinguishing feature that the neutron population is in, or near, thermal equilibrium with the nuclei of the moderator. As a consequence, there is no net exchange of energy between the neutron population and its surroundings. The neutrons are then referred to as thermal neturons.

In a population of **thermal neutrons**, the distribution of the speeds of the neutrons is characterized, adequately in many cases, by the Maxwell-Boltzmann distribution, originally formulated to apply to the molecules of an ideal gas. According to this distribution, the most probable speed of the neutrons at the reference temperature of 20°C is 2200 m/sec and the kinetic energy corresponding to the most probable speed is 0.025 eV.

Reactors that are not thermal reactors fall in the category of **fast reactors**. In these reactors, the moderation of neutrons is much reduced for reasons discussed later.

Nuclear Fuel

In light-water reactors (LWR), the type of power reactors most commonly in service today, the nuclear fuel is uranium with a content of 2 to 4% of ^{235}U. This fuel is produced by enriching natural uranium in ^{235}U by one of several technologies, principally gaseous diffusion and gaseous centrifugation (Benedict et al., 1981). Neutrons of all energies, down to and including thermal energies, can induce fission in ^{235}U. For this reason, ^{235}U is said to be fissile.

In contrast, ^{238}U, present to the extent of 96 to 98% in the fuel, can be fissioned to a significant extent by neutrons with energies in excess of a threshold of roughly 2 MeV. Fissions of ^{238}U, referred to as fast fissions, play only a slight role in the chain reaction in an LWR. However, ^{238}U absorbs neutrons radiatively to yield ^{239}U. This nuclide is radioactive and decays to ^{239}Np which, in turn, decays to ^{239}Pu, a **fissile nuclide**. Thus, in LWR fuel ^{239}Pu, produced from ^{238}U, is available for fissioning by neutrons of all energies and contributes to the chain reaction. Because of its ability to form fissile ^{239}Pu, ^{238}U is termed a **fertile nuclide**.

Conversion and Breeding

To characterize the unique capability of nuclear fuel simultaneously to produce and consume fissile material, a figure of merit known as the **conversion ratio** (CR) is informative. It is defined by the relation:

$$\text{CR} = \frac{\text{number of fissile nuclei produced from fertile nuclei}}{\text{number of fissile nuclei consumed}}$$

In fuel irradiated in an LWR, the conversion ratio typically has a value of 0.5. If the appropriate combination of materials, design, and operating parameters could be found to raise the conversion ratio

to a value greater than unity, a reactor would become a breeder reactor, that is, one that produces more fissile material than it consumes in its operation.

To illustrate the possibility of breeding, consider a parameter known as the reproduction factor and given by

$$\eta = \upsilon \frac{\text{number of neutrons causing fission in fuel}}{\text{total number of neutrons absorbed in fuel}} = \nu \frac{\sigma_f^{\text{fuel}}}{\sigma_a^{\text{fuel}}}$$

In the case of ^{235}U and thermal neutrons, the value of η is given by $\eta_{235} = 2.42 \times 582/(589 + 99) = 2.42 \times 0.85 = 2.07$.

If a chain reaction is to be self-sustaining in a reactor, the condition $\eta > 1$ must apply. To achieve breeding requires that $\eta > 2$. In other words, one neutron from fission would be available to sustain the chain reaction and another to produce a fissile nucleus from a fertile nucleus. Practical considerations indicate that the value of η must be substantially greater than 2, since neutrons will be lost by absorption in structural materials, heat removal medium, fission fragments, the moderator, if present, and by escaping from the physical confines of the reactor.

As shown, ^{235}U has a value of η slightly above 2 with neutrons at thermal energies. Breeding or near-breeding conditions could arise, in principle, if very judicious choices of materials and parameters prevail. A more attractive fuel from the standpoint of breeding is ^{233}U. This isotope of uranium is produced artificially by placing the naturally occurring nuclide ^{232}Th in a reactor. A radiative capture of a neutron in ^{232}Th leads to the formation of the radioactive nuclide ^{233}Th. Two successive radioactive decays yield ^{233}U. In a thermal reactor, the value of η with ^{233}U is 2.29, approaching the level where breeding might be contemplated. Intermediate between the two fissile isotopes of uranium is ^{239}Pu, which at thermal energies yields a value of η of 2.15.

Figure 8.8.1 shows the behavior of η as the energy of the neutrons inducing fission increases. A little above thermal energies the value of η for ^{239}Pu and ^{235}U drops below 2, indicating that breeding is impossible at such energies. As energy increases, the values of η for both reach the threshold of 2 and continue to increase steadily, with ^{239}Pu clearly the more attractive fuel from the standpoint of breeding. The value of ^{239}Pu for ^{235}U is relatively insensitive to increases in energy and remains continuously above 2. Again, at higher energies, η is the more attractive fuel.

Research on the development of **breeder reactors** has focused on the ^{239}Pu fuel cycle, both in the U.S. and abroad. Representative of these reactors is the liquid metal fast breeder reactor (LMFBR) in which liquid sodium is the heat-removal fluid and provides the small amount of moderation needed. Breeder reactors with ^{233}U as fuel, represented by an adaptation of the high-temperature gas-cooled reactor (HTGCR), in which the heat-removal fluid is helium and the moderator is graphite, although less attractive, in principle, as breeders, might with further research and development prove to be viable alternatives to the LMFBR.

LWR Fuel

Nuclear fuel in light water is in the form of small cylindrical pellets of the ceramic UO_2, with the uranium enriched to 2 to 4% in ^{235}U, as mentioned previously. These pellets are stacked vertically in tubes and the ends of the tubes are sealed off. The dimensions and further details given here apply strictly to the more common type of LWR, known as the pressurized water reactor (PWR), but may be taken as generally representative of LWRs.

The tubes containing the fuel pellets are referred to as fuel rods. They are 4.3 to 4.7 m in length and 0.0095m in outside diameter. An array typically of 17 × 17 rods constitutes a fuel assembly, as shown in Figure 8.8.2. Certain fuel rods within the assembly are replaced by guide sheaths in which absorber rods can be moved vertically. These rods absorb neutrons, thus providing one of the means of controlling the chain reaction as the rods are inserted or withdrawn. Within the fuel assembly the fuel rods are placed on a pitch of 0.0127 m, leaving vertical passages through which water can flow. A total of

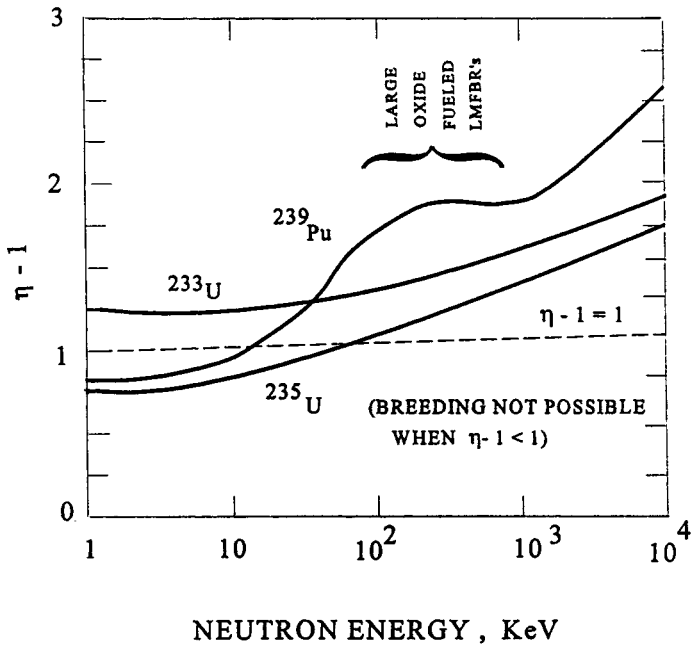

FIGURE 8.8.1 Dependence of reproduction factor of neutron energy.

approximately 200 fuel assemblies, juxtaposed to form a roughly cylindrical configuration constitute the core of the reactor. Water is circulated through the core where the water serves both to moderate the neutrons and to remove the heat generated by fissions in the nuclear fuel.

Light-Water Reactors

LWRs currently make up the largest portion of the installed nuclear generating capacity throughout the world. Among these, the PWRs are more numerous. By operating at a sufficiently high pressure, bulk boiling of the reactor coolant is suppressed in a PWR. In contrast, the coolant is allowed to boil in a boiling water reactor (BWR) and a portion of the coolant is converted to steam as it circulates through the core.

Pressurized Water Reactors

A schematic of a PWR system is shown in Figure 8.8.3. At the heart of the system is the core made up of fuel assemblies and associated control rods. The core is contained in a reactor vessel, or pressure vessel, designed to operate at a pressure typically of 15.5 mPa. Water is circulated through the core where it acts as a moderator and also removes the heat generated through fission. Typical operating temperatures at full power are 295°C at the inlet and 330°C at the outlet, an increase of 35°C as a result of the water passing through the core.

From the reactor vessel, the coolant is circulated to steam generators and returned to the reactor vessel to complete the so-called primary loop. This loop constitutes the nuclear steam supply (NSS). Steam emerging from the steam generators is directed toward the secondary loop, or balance of plant, consisting of turbine generator, condenser, and feedwater pumps. Extremely small quantities of radioactive contaminants may be present in the steam generated in PWRs, and all releases to the environment from the secondary side of the plant are carefully monitored and controlled. Otherwise, steam from the NSS differs from steam generated in fossil fueled plants only inasmuch as its grade is inferior.

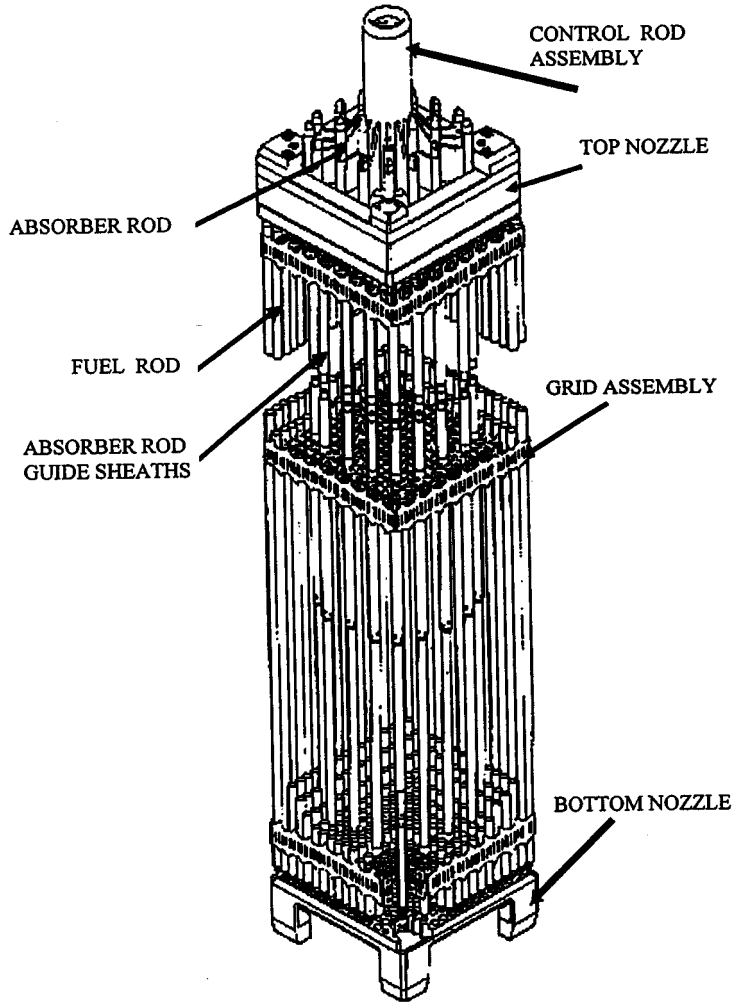

FIGURE 8.8.2 PWR fuel assembly.

Boiling Water Reactors

Figure 8.8.4 is a schematic of a BWR system. A reduced operating pressure of 7.2 MPa causes a portion of the coolant to flash to steam. Steam separators and driers allow dry steam to emerge from the reactor vessel, thus eliminating the need for separate steam generators and a secondary loop. Steam from the reactor vessel flows through a turbine generator and condenser, from which circulating pumps return the condensate to the reactor. Large quantities of radioactive contamination may be present in the steam produced by a BWR because of the direct cycle, so releases must be carefully monitored. A distinguishing feature of the BWR are the jet pumps, typically 24 in number, placed along the periphery of the core. These pumps augment the flow of coolant through the core.

Defining Terms

Breeder reactors: Reactors in which the conversion ratio is greater than unity.

Conversion ratio: The ratio of the number of fissile nuclei produced in a reactor to the number of fissile of nuclei consumed.

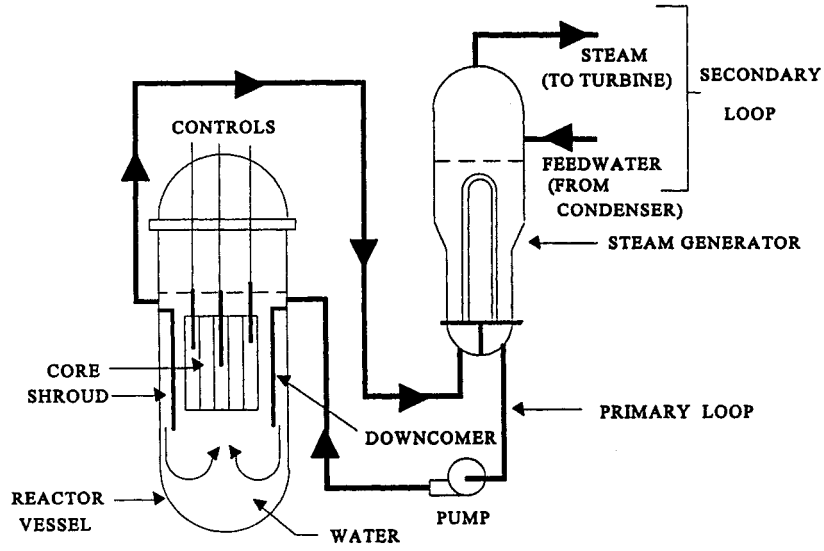

FIGURE 8.8.3 Schematic of a pressurized water reactor.

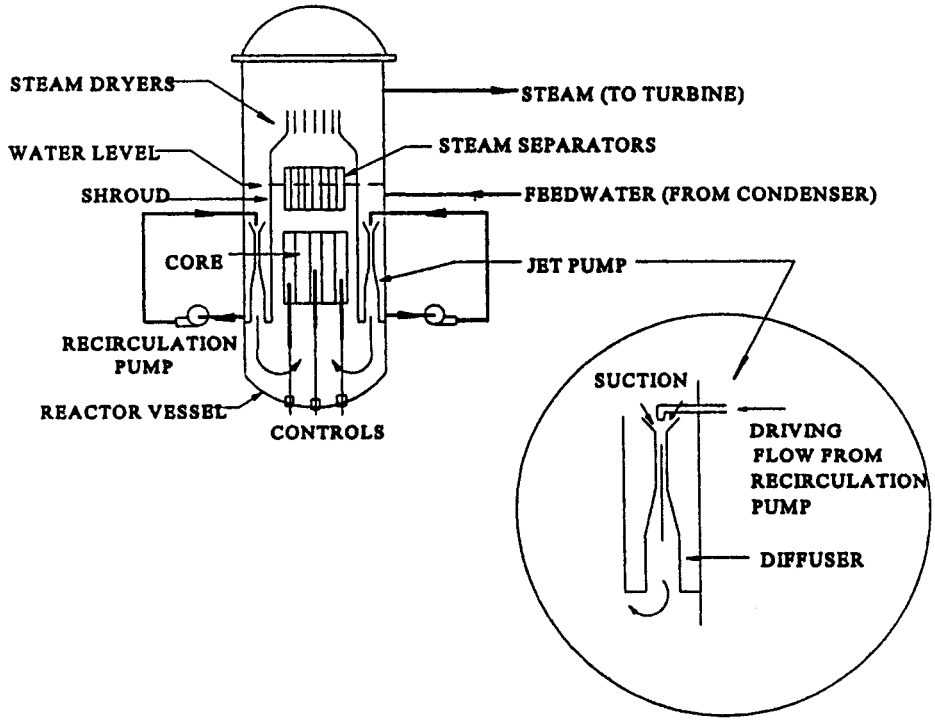

FIGURE 8.8.4 Schematic of a boiling water reactor.

Critical configuration: A medium containing nuclear fuel in which a self-sustaining chain reaction can be maintained.

Cross section: A numerical quantity, determined experimentally, related to the probability that a specific nuclide will undergo a given nuclear reaction.

Fast reactors: Reactors in which little moderation of the neutrons occurs and the neutron populations consist of neutrons of relatively high speeds.

Fertile nuclide: A nuclide that, through the absorption of a neutron and subsequent radioactive decays, can produce a fissile nuclide.

Fissile nuclide: A nuclide that can be fissioned by neutrons of all energies, down to and including thermal energies.

Moderator: A component of a reactor present expressly to slow down neutrons and produce a population of thermal neutrons.

Thermal neutrons: A population of neutrons in, or near, thermal equilibrium with the nuclei of a medium in which the populations exists.

Thermal reactors: Reactors in which the neutron populations consist predominantly of thermal neutrons.

8.9 Nuclear Fusion

Thomas E. Shannon

Introduction

Nuclear fusion holds the promise of providing almost unlimited power for future generations. If the process can be commercialized as envisioned by reactor design studies (Najmabadi et al., 1994), many of the problems associated with central electric power stations could be eliminated. Fusion power plants would not produce the pollution caused by the burning of fossil fuel and would eliminate the concern for meltdown associated with nuclear fission. The amount of radioactive waste material produced by a fusion reactor will be much less than that of a fission reactor since there is essentially no radioactive ash from the fusion reaction. If **low activation advanced materials** such as silicon carbide composites can be developed for the reactor structural material, the problem of disposal of activated components can also be eliminated.

Fusion Fuel

Although a number of different atomic nuclei can combine to release net energy from fusion, the reaction of **deuterium and tritium** (D-T) is the basis of planning for the first generation of fusion reactors. This choice is based on considerations of reactor economy. The D-T reaction occurs at the lowest temperature, has the highest probability for reaction, and provides the greatest output of power per unit of cost (Shannon, 1989). The disadvantages of D-T as a fusion fuel are twofold. Tritium does not occur naturally in nature and must be bred in the fusion reactor or elsewhere. Second, tritium is a radioactive isotope of hydrogen with a relatively long **half-life** of 12.3 years. Since tritium can readily combine with air and water, special safety procedures will be required to handle the inventory necessary for a fusion reactor. There is hope that a less reactive fuel, such as deuterium alone (D-D) will eventually prove to be an economically acceptable alternative (Shannon, 1989).

Confinement Concepts

Magnetic fusion, based on the tokamak concept, has received the majority of research funding for fusion energy development. However, other magnetic fusion concepts, such as the stellarator, the spherical torus, reversed-field pinch, and field-reversed configurations, are being developed as possible alternatives to the tokamak (Sheffield, 1994). It may also be possible to develop fusion power reactors by inertial confinement concepts (Waganer et al., 1992). Research on these concepts has been done primarily in support of weapons development; therefore, the level of scientific understanding for power reactor applications is significantly less than that of magnetic fusion. The remainder of this discussion on reactor development, fusion energy conversion, and transport will consider only the tokamak magnetic fusion concept.

Tokamak Reactor Development

The tokamak device has proved to be the most effective means of producing the conditions necessary for magnetic fusion energy production. In 1994, researchers at the Princeton Plasma Physics Laboratory achieved in excess of 10 MW of D-T fusion power in a research tokamak, the Tokamak Fusion Test Reactor (TFTR). This accomplishment, coupled with worldwide progress in 40 years of magnetic fusion research, has established the scientific feasibility of the tokamak concept. The next major step, the International Thermonuclear Experimental Reactor (ITER) is being carried out under an international agreement among Europe, Japan, Russia, and the United States (Conn et al., 1992). A drawing of the ITER tokamak is shown in Figure 8.9.1. If the project is approved for construction, it will be in operation

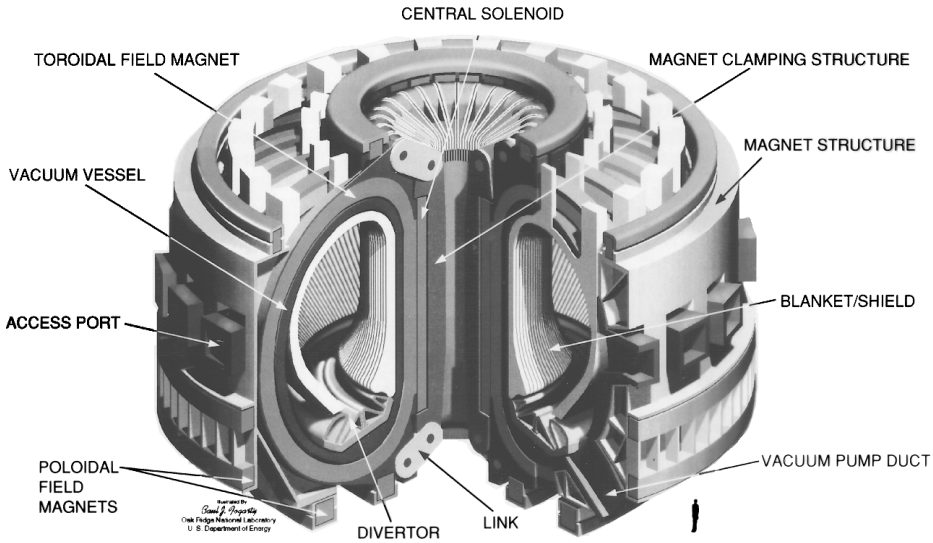

FIGURE 8.9.1 The International Thermonuclear Experimental Reactor (ITER).

around 2005. The ITER is being designed to produce a fusion power in excess of 1000 MW. This will be a significant step on the path to commercial fusion power.

The U.S. Department of Energy has proposed a strategy, shown in Figure 8.9.2, which will lead to a demonstration power reactor by the year 2025. Supporting research and development programs necessary to achieve this goal are shown in this figure.

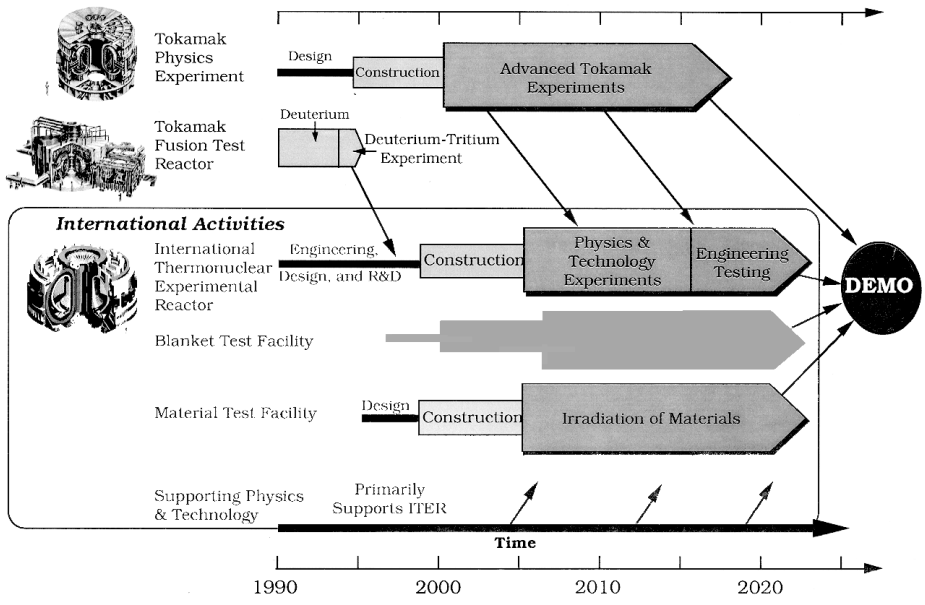

FIGURE 8.9.2 The U.S. Department of Energy magnetic fusion energy strategy.

Fusion Energy Conversion and Transport

The energy from fusion is created in the form of charged particles and neutrons. The D-T reaction produces a neutron with an energy of 14.1 MeV and an alpha particle (helium) with an energy of 3.5 MeV in the reaction

$$D + T \rightarrow He^4\ (3.5\ MeV) + n(14.1\ MeV)$$

In the tokamak device, the reaction will take place in the toroidal vacuum vessel as previously shown in the ITER drawing, Figure 8.9.1. The D-T fuel, in the form of a **plasma**, will absorb energy from the positively charged alpha particles to sustain the temperature necessary for the reaction to continue. The neutron, having no charge, will escape from the plasma and pass through the wall of the vessel and penetrate into the surrounding blanket/shield structure. The kinetic energy of the alpha particles from the fusion reaction is eventually deposited on the wall of the vacuum vessel by radiation and conduction heat transfer from the plasma while the neutron deposits most of its energy within the cross section of the blanket/shield. The resulting thermal energy is transferred by a coolant such as water to a steam generator where a conventional steam to electric generator system may be used to produce electricity. An overall schematic diagram of the energy conversion and heat-transport system is shown in Figure 8.9.3.

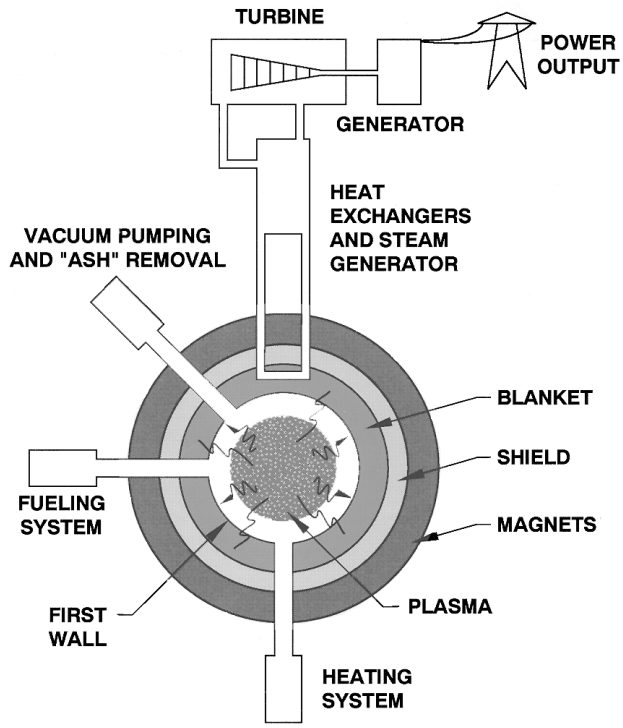

FIGURE 8.9.3 Schematic Diagram of a Magnetic Fusion Reactor Power Plant.

Defining Terms

Deuterium and tritium: Isotopes of hydrogen as the fuel for fusion reactors.
Half-life: The time required for half of the radioactive material to disintegrate.
Low activation advanced materials: Structural materials that significantly reduce the radioactivity induced by exposure to fusion neutrons.

Plasma: A gas such as a mixture of deuterium and tritium raised to a very high temperature at which the electrons and the nuclei of the atoms separate. The plasma, consisting of electrons and ions, can conduct electricity and react to magnetic fields.

8.10 Solar Thermal Energy Conversion

D. Yogi Goswami

Introduction

Solar thermal energy applications such as space and water heating have been known for a long time. Researchers over the past few decades have developed a number of additional solar thermal applications, such as industrial process heat, refrigeration and air-conditioning, drying and curing of agricultural products, and electric power production by solar thermal conversion. This section will cover solar thermal energy conversion including solar thermal collectors and conversion systems.

Solar Thermal Collectors

A simple **solar thermal collector** consists of (1) an absorber surface (usually a dark, thermally conducting surface), (2) some insulation behind the surface to reduce heat loss, (3) a trap for thermal reradiation from the surface such as glass, which transmits the shorter-wavelength solar radiation but blocks the longer-wavelength radiation from the absorber, and (4) a heat-transfer medium such as air, water, etc. High-temperature collectors require reflectors of sunlight that concentrate solar radiation on the absorber. The technology of solar collectors is developed to achieve temperatures as high as 1000°C or even higher. The design of a solar collector and the choice of working fluids depend on the desired temperature and the economics of the application. Table 8.10.1 lists the types of solar thermal collectors based on their temperature range.

TABLE 8.10.1 Types of Solar Collectors and Their Typical Temperature Range

Type of Collector	Concentration Ratio	Typical Working Temperature Range (°C)
Flat plate collector	1	≤70
High-efficiency flat plate collector	1	60–120
Fixed concentrator	2–5	100–150
Parabolic trough collector	10–50	150–350
Parabolic dish collector	200–2000	250–700
Central receiver tower	200–2000	400–1000

Source: Compiled from Goswami, D.Y., *Alternative Energy in Agriculture,* Vol. 1, CRC Press, Boca Raton, FL, 1980.

Flat Plate Collectors

Flat plate collectors may be designed to use liquids (water, oil, etc.) or air as the heat-transfer fluid. Figure 8.10.1 shows a typical liquid-type flat plate collector. The choice of materials for glazing and absorber needs special attention.

Glazing. The purpose of **glazing** is to (1) transmit the shorter-wavelength solar radiation, but block the longer-wavelength reradiation from the absorber plate, and (2) reduce the heat loss by convection from the top of the absorber plate. Glass is the most widely used glazing material. Transmittance of low iron glass in the visible and near infrared wavelength range can be as much as 91%, while for the longer-wavelength radiation (>3 μm) its transmittance is almost zero. Other materials than can be used as glazings include certain plastic sheets such as polycarbonates (Lexan® and Tuffac® — transmittance ~75%), acrylics (Plexiglass® and Lucite® — transmittance ~92%), and thin plastic films such as polyethylene. A major advantage of the plastics is that they are shatterproof; however, they scratch easily and lose transparency over time.

Absorbers. Copper is the most common material used for absorber plates and tubes because of its high thermal conductivity and high corrosion resistance. For low-temperature applications such as swimming pool heating, a plastic material called ethylene propylene polymer (trade names EPDM, HCP,

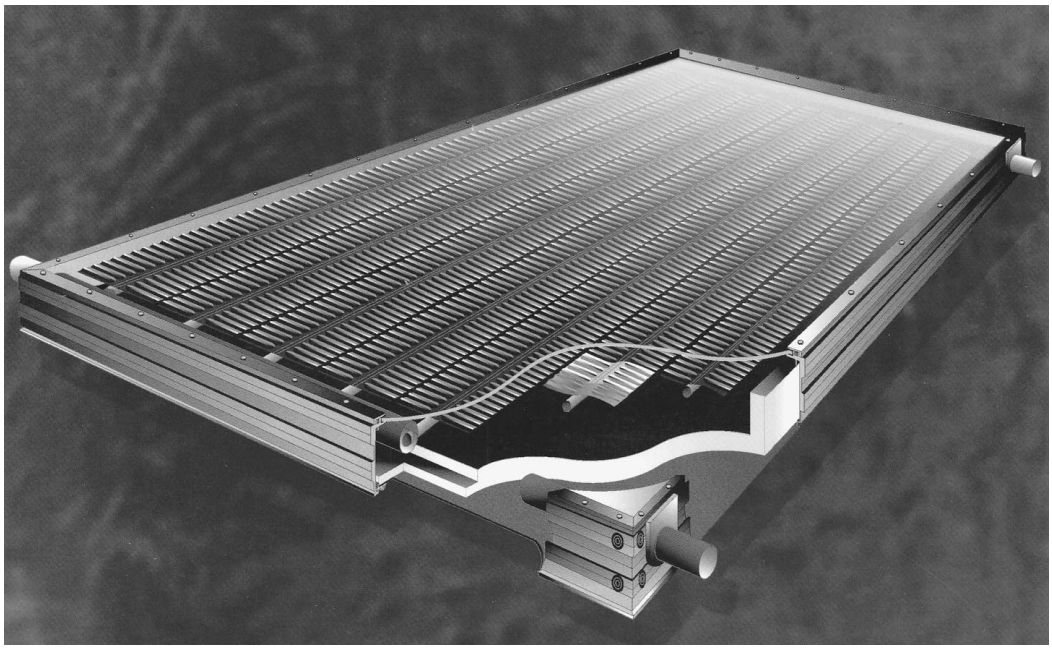

FIGURE 8.10.1 A typical liquid flat plate collector. (Courtesy of American Energy Technologies, Green Cove Springs, FL.)

etc.) can be used to provide inexpensive absorber material. To compensate for low thermal conductivity of these materials, a large surface area is provided for heat transfer. In order to increase the absorption of solar radiation and to reduce the emission from the absorber, the metallic absorber surfaces are painted or coated with flat black paint or some selective coating. Absorptivities and emissivities of some common **selective surfaces** are given in Table 8.10.2.

TABLE 8.10.2 Absorptivity and Emissivity of Common Selective Surfaces

Surface	Absorbtivity	Emissivity
Black chrome	0.95	0.1
Black nickel	0.9	0.08
Copper oxide	0.9	0.17
Lead sulfide	0.89	0.2
Flat black paint	0.98	0.98

Source: Compiled from Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, John Wiley and Sons, New York, 1980.

Evacuated Tube Collectors. Evacuated tube collectors have essentially a vacuum between the absorber and the glazing tube. This eliminates most of the heat loss by conduction and convection. Therefore, these collectors give a very high efficiency at higher temperatures. Evacuated tube collectors are typically used in the temperature range of 80 to 140°C

Concentrating Collectors. Concentrating collectors use reflectors or lenses to focus solar radiation from a large area onto a small area, thereby creating higher temperatures. Such collectors are usually used for temperatures higher than 100°C. Figure 8.10.2 shows schematics of some of the concentrating collectors.

Nontracking Concentrators. The simplest concentrating collector can be made by using flat wall reflectors to concentrate the solar radiation on a flat plate collector. Concentration ratios of two to three can be

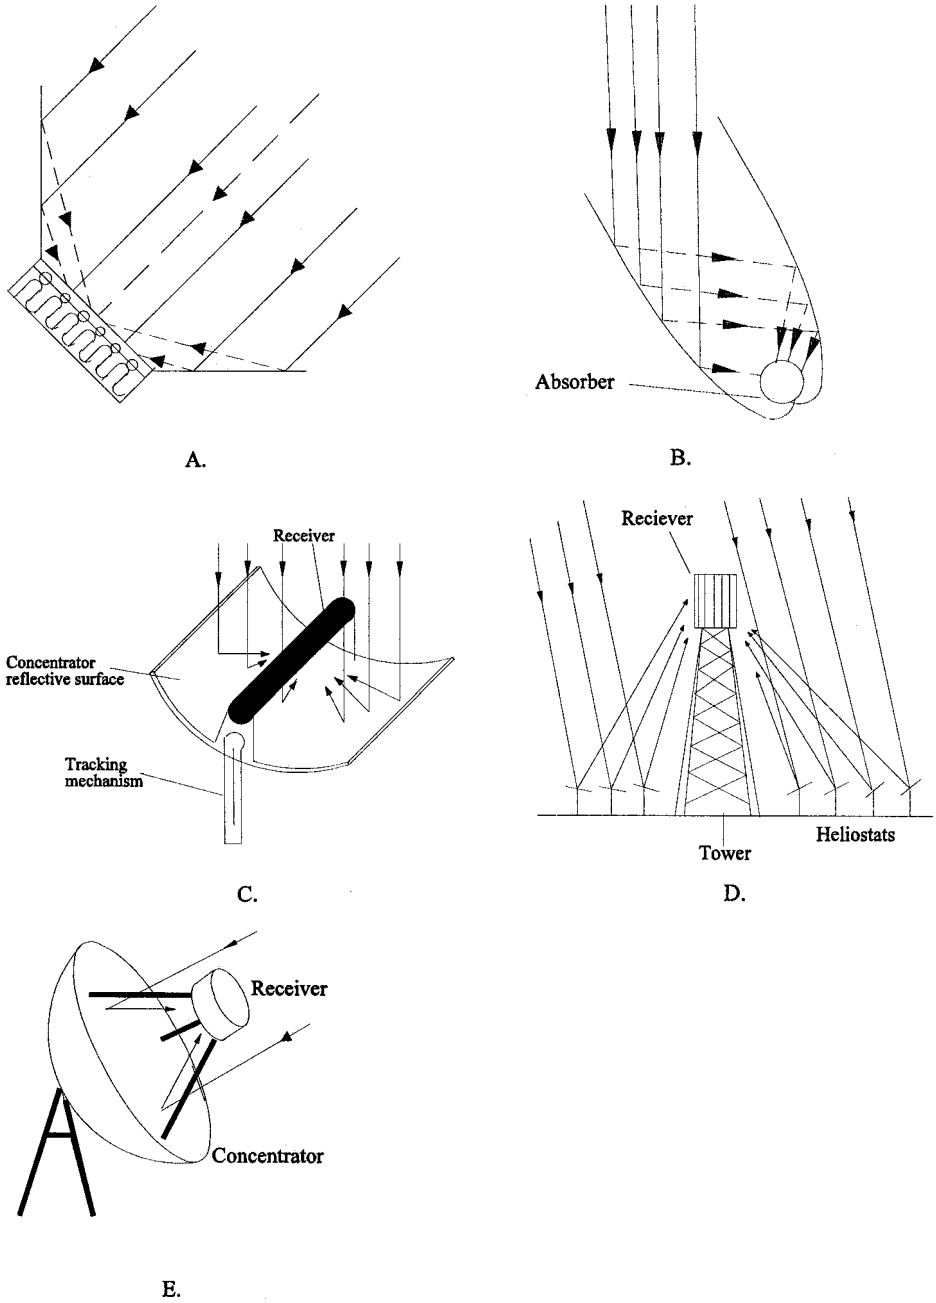

FIGURE 8.10.2 Types of concentrating collectors. (A) Flat plate collector with reflective wings; (B) Compound parabolic concentrator; (C) parabolic trough; (D) central receiver; (E) parabolic dish.

achieved this way. For slightly higher concentration ratios, a novel design, developed by Roland Winston, called a "compound parabolic concentrator" (CPC) can be used (Winston, 1974).

Tracking Concentrators. For temperatures up to 350°C, cylindrical parabolic trough collectors are used. These collectors focus solar radiation on a line focus where the absorber is located. These collectors usually require tracking on one axis only with seasonal adjustment on the other axis. A reflecting spherical or paraboloidal bowl is used when temperatures of the order of 250 to 500°C are needed. These collectors

require two-axis tracking. In some cases, the dish is kept stationary while the receiver is moved to track the focus of the reflected solar radiation. Finally, for extremely high temperatures (500 to 1000°C) needed for large-scale thermal power generation, a large field of tracking flat mirrors (called heliostats) is used to concentrate solar radiation on a receiver that is located on top of a central tower.

Collector Thermal Performance

The instantaneous efficiency of a collector is given by

$$\eta = \frac{\text{Useful energy collected}}{\text{Incident solar energy}} = \frac{Q_u / A}{I} \tag{8.10.1}$$

where

$$Q_u = mC_p\left(T_o - T_i\right) \tag{8.10.2}$$

and A = area of the collector, I = incident solar energy per unit area, m, C_p, T_i, and T_o are the mass flow rate, specific heat, and inlet and outlet temperatures of the heat-transfer fluid.

The efficiency of a flat plate solar collector can also be written by the Hottel–Whillier–Bliss equation:

$$\eta = F_R(\tau\alpha)_e - F_R U_L \frac{\left(T_i - T_{\text{amb}}\right)}{I} \tag{8.10.3}$$

where F_R, called the collector heat-removal factor, is a convenient parameter that gives the ratio of the actual useful energy gain of a flat plate collector to the useful gain if the whole collector surface were at the inlet fluid temperature; $(\tau\alpha)_e$ = effective transmittance absorptance product; and U_L = collector heat-loss coefficient.

Equation 8.10.2 suggests that if the efficiency, η, is plotted against $(T_i - T_{\text{amb}})/I$, the resulting curve will have a y intercept equal to $F_R\,(\tau\alpha)_e$ and a slope of $F_R U_L$. A linear curve usually gives an adequate approximation. Figure 8.10.3 shows an example of a performance curve for a water-heating flat plate collector, which is a linear least square curve fit to the actual test data.

Solar Ponds

A solar pond combines collector and energy storage in one unit. Solar radiation that enters the pond travels some distance through the water before being totally absorbed, thus increasing the temperature of the water at that depth. The heat thus collected can be stored in the pond by creating a stagnant, transparent, insulating layer in the top part of the pond. The most common method is by the addition of a salt into the pond to increase the density of water in the lower section of the pond. This type of pond is called a **salt gradient solar pond**. Reid (1987) reviewed the progress in the design and applications of salt gradient solar ponds. Figure 8.10.4 shows a schematic of a salt gradient pond along with a density profile in the pond.

The theory of salt gradient solar ponds has been described by Tabor (1981). The most important aspect of such ponds is the creation and maintenance of the salt gradient. Theory shows that the condition for maintaining stability is

$$\frac{\partial S}{\partial Z} > -1.14 \frac{\partial \rho}{\partial T} \times \frac{\partial T}{\partial Z} \frac{\partial \rho}{\partial S} \tag{8.10.4}$$

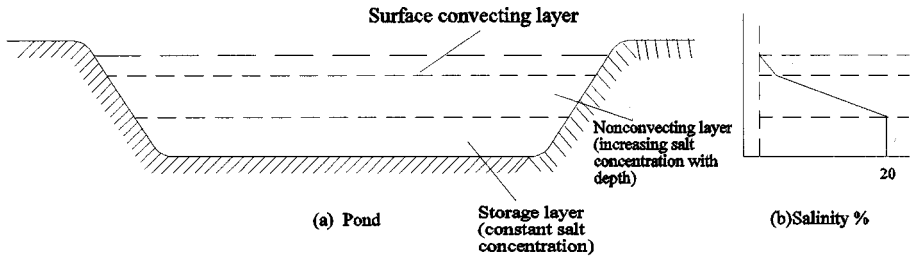

FIGURE 8.10.4 Schematic of a salt gradient solar pond.

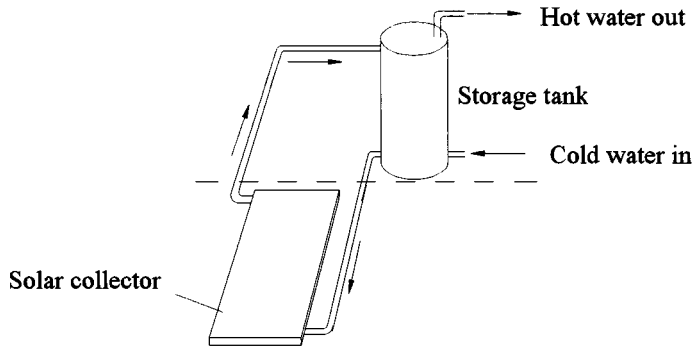
where S is the salt concentration in kilograms per cubic meter, Z is the depth from the surface in meters, ρ is the density in kilograms per cubic meter, and T is the temperature in Kelvin. The two most common salts considered for solar pond applications are NaCl and $MgCl_2$. According to the above criteria, there is no difficulty in obtaining stability with $MgCl_2$ and it is somewhat difficult but possible to get stability with NaCl.

Solar Water-Heating Systems

Solar water-heating systems represent the most common application of solar energy at the present time. Small systems are used for domestic hot water applications while larger systems are used in industrial process heat applications. There are basically two types of water-heating systems: **natural circulation or passive solar system** (thermosyphon) and **forced circulation or active solar system**.

Natural Circulation

Figure 8.10.5 shows a schematic of a natural circulation solar water-heating system. It is also called a thermosyphon or passive solar water heater because it does not require a pump to circulate water. The storage tank is located above the collector. When the water in the collector gets heated, it rises into the tank, because of density change, setting up a circulation loop.



FIGURES 8.10.5 Schematic of a thermosyphon solar water-heating system.

Forced Circulation

Figure 8.10.6 shows three configurations of forced circulation systems: (1) open loop, (2) closed loop, and (3) closed loop with drainback. In an open loop system, the collectors are empty when they are not providing useful heat and the storage tank is at atmospheric pressure. A disadvantage of this system is the high pumping power required to pump the water to the collectors every time the collectors get hot. This disadvantage is overcome in the pressurized closed loop system (Figure 8.10.6B) since the pump has to overcome only the resistance of the pipes. Because water always stays in the collectors of this system, antifreeze (propylene glycol or ethylene glycol) is required for locations where freezing conditions can occur. During stagnation conditions (in summer), the temperature in the collector can become very high, causing the pressure in the loop to increase. This can cause leaks in the loop unless some fluid is allowed to escape through a pressure-relief valve. In both cases, air enters the loop causing the pump to run dry. This disadvantage can be overcome in a closed loop drainback system (Figure 8.10.6C). In this system, when the pump shuts off, the water in the collectors drains back into a small holding tank, which can be located where freezing does not occur. The holding tank can be located at a high level to reduce pumping power.

Industrial Process Heat Systems

For temperatures of up to about 100°C, required for many industrial process heat applications, forced circulation water-heating systems described above can be used. The systems, however, will require a large collector area, storage and pumps, etc. For higher temperatures, evacuated tube collectors or concentrating collectors must be used.

Space-Heating Systems

Solar space-heating systems can be classified as active or passive depending on the method utilized for heat transfer. A system that uses pumps and/or blowers for fluid flow in order to transfer heat is called an *active system*. On the other hand, a system that utilizes natural phenomena for heat transfer is called a *passive system*. Examples of passive solar space-heating systems include direct gain, attached greenhouse, and storage wall (also called Trombe wall).

Active space-heating systems store solar collected heat in water or rocks. Heat from water storage can be transferred to the space by convertors or by fan-coil units. A system using a fan-coil unit can be integrated with a conventional air system as shown in Figure 8.10.7. Heat from rock storage can be transferred to air by simply blowing air over the rocks.

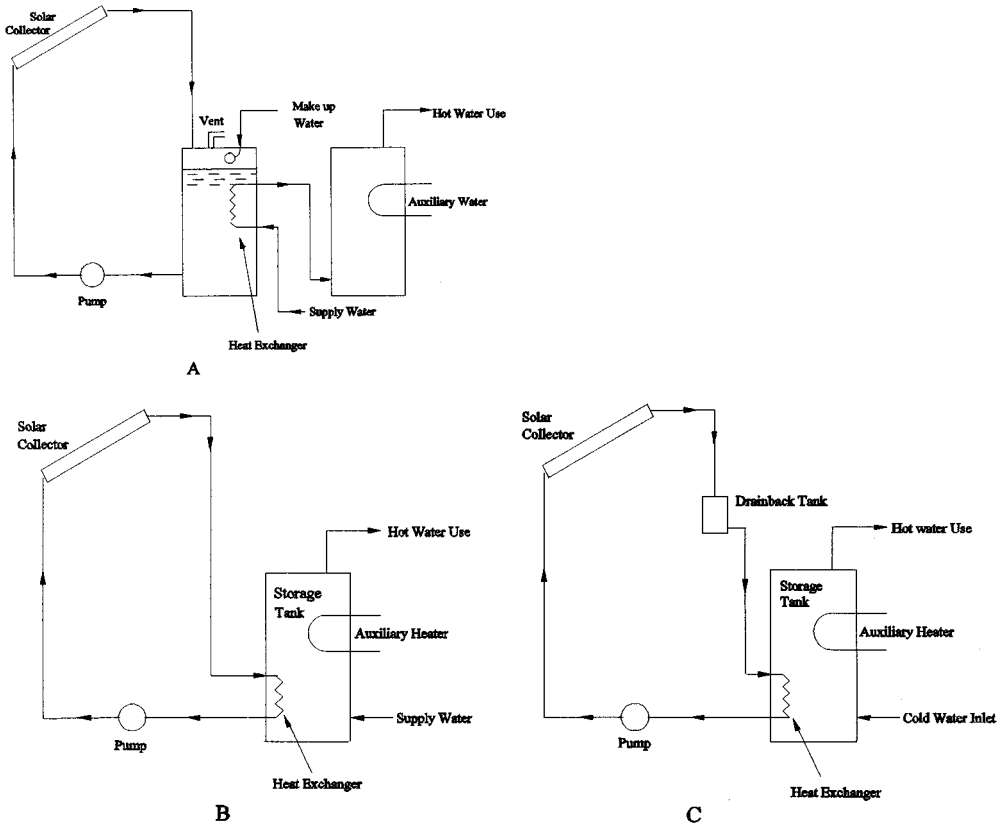


FIGURE 8.10.6 Typical configurations of solar water-heating systems: (A) open loop system, (B) closed loop system, (C) closed loop drainback system. (Adapted from Goswami, D.Y., *Alternative Energy in Agriculture,* Vol. 1, CRC Press, Boca Raton, FL, 1986.)

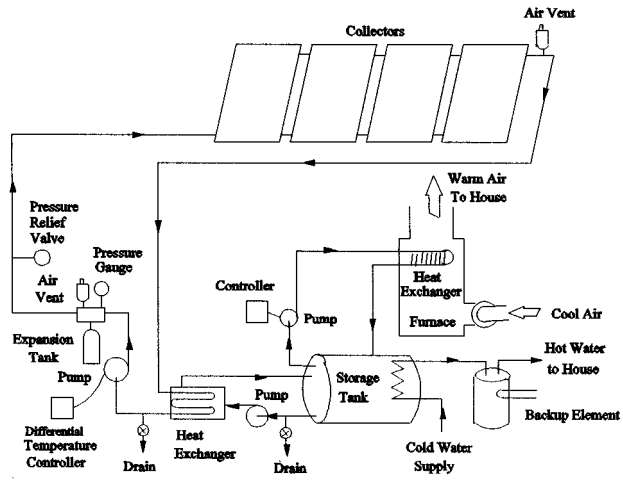

FIGURE 8.10.7 Schematic of an active solar space-heating system.

Solar Thermal Power

Solar thermal energy can be used to produce electrical power using conventional thermodynamic power cycles such as Rankine, Stirling, and Brayton cycles. The choice of power cycle and the working fluids depends on the temperature obtainable in the solar system, which depends on the type of solar collectors used. At present, developed solar thermal power systems include

Parabolic trough systems
Central receiver systems
Parabolic dish-Stirling engine system

Parabolic Trough Systems

Parabolic trough systems are simple in concept and, therefore, the most developed commercially. In 1984, Luz Company installed a Solar Electric Generating System (SEGS I) of 14 MW_e capacity in Southern California, utilizing parabolic trough solar collectors and natural gas fuel for superheat and backup. From 1984 to 1991, Luz Company installed eight additional plants, SEGS II to SEGS IX, with the total capacity of the nine plants being 354 MW_e. With each successive SEGS plant the technology was improved and the cost reduced. The cost of electricity was reduced from about 30¢/kWhr for the first plant to about 8¢/kWhr for the last plant. A schematic of the SEGS IX is shown in Figure 8.10.8, and some important data for the system are given in Table 8.10.3.

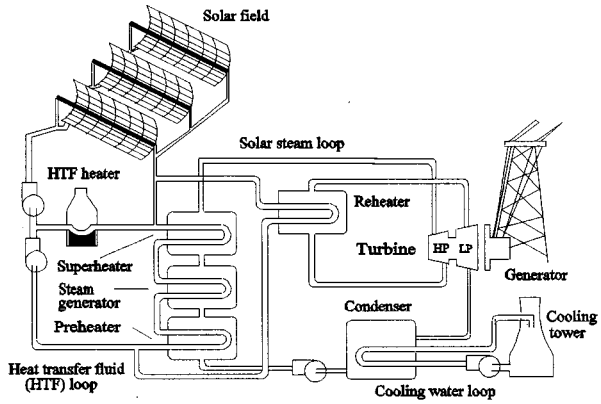

FIGURE 8.10.8 Schematic of SEGS IX power plant.

TABLE 8.10.3 Plant Characteristics — SEG IX

Power Block		Solar Field	
Gross power	88 MWe	Number of collectors	888
Net power	80 MWe	Aperature area	483,960 m^2
Steam inlet pressure	100 bar	Inlet temperature	293°C
Steam inlet temperature	371°C	Outlet temperature	390°C
Reheat pressure	17.2 bar	Annual thermal efficiency	50%
Reheat temperature	371°C	Peak optical efficiency	80%
Conversion efficiency	37.6%	Heat-transfer fluid (HTF)	Oil (VP-1)
Annual gas use	25.2×10^9 m^3	HTF volume	1289 m^3

It has been recognized that this design does not utilize the energy of the natural gas efficiently. It has been suggested that energy of natural gas can be better utilized by combining the solar system with a natural gas turbine combined-cycle power plant (DeLaquil et al., 1993; Washom et al., 1994). Such a

hybrid system would use the exhaust of a natural gas turbine for superheating and preheating of water, while the solar field would be used for steam generation. Such a hybrid system can achieve conversion efficiency as high as 60%. A schematic of a **solar hybrid combined cycle** is shown in Figure 8.10.9.

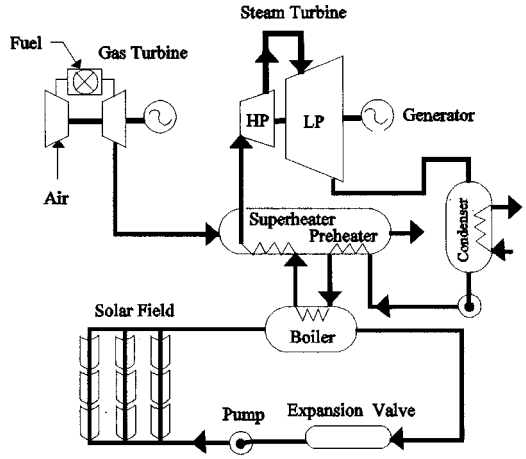

FIGURE 8.10.9 Solar hybrid combined cycle. (Adapted from Washom, B. et al., paper presented at the 1994 ASES Annual Conference, San Jose, CA, 1994.)

Central Receiver System

A central receiver system can potentially operate at very high temperature and therefore can have much higher efficiency than parabolic trough systems. However, the system can be economical only at larger capacities, such as 100 MW and above. The central receiver absorber can heat the working fluid or an intermediate fluid to a temperature as high as 600 to 1000°C which can be used to drive a Rankine cycle or Brayton cycle.

Solar One, a 10-MW_e central receiver power plant started operating in 1982 in Barstow, California. This plant generated superheated steam at 510°C and 10.3 MPa in the receiver absorber, which was used to drive a simple steam Rankine power cycle. The plant operated successfully for 6 years and provided a good learning experience. The plant has now been redesigned as Solar Two in which molten sodium nitrate is used as the heat-transfer fluid as well as for storage. Use of molten salt allows operation of the receiver absorber at much lower pressures The constraint is that the salt must always be above its melting point (220°C). Figure 8.10.10 shows a schematic of the Solar Two power plant.

Parabolic Dish Systems

Parabolic dish systems can achieve very high temperatures. The high temperatures produced by parabolic dishes can be used to drive Rankine, Stirling, and Brayton power cycles. So far, Rankine and Stirling cycles have been successfully demonstrated with parabolic dishes for electrical power production.

Early versions of parabolic dishes were made from die-stamped aluminum petals made reflective using a metallized polymer film. Later designs used simpler flat mirror facets fixed on a structure in such a way as to approximate a parabolic dish. The latest designs use a polymer film stretched on a circular frame (Mancini, 1994). The film is given a slight concave curvature by providing a vacuum behind it. These stretched polymer films are fixed on a structure to approximate a parabolic dish. Because of the low weight of the polymer film, the dish structure can be made out of light tubular members, thereby reducing the cost of the dish considerably. Parabolic dishes require two-axis tracking.

McDonnell Douglas Corporation successfully demonstrated a 25-KW_e parabolic dish system using a Stirling engine and a generator assembly fixed at the focal point of the dish in 1985 (Gupta, 1987). The concept is very attractive because it provides a modular design of stand-alone power plants for small

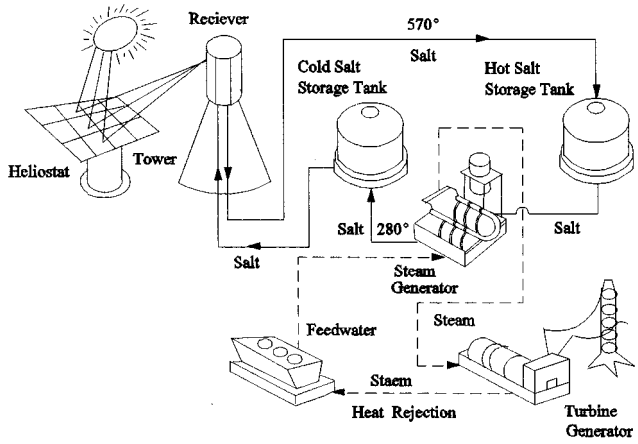

FIGURE 8.10.10 Schematic of Solar Two.

communities and independent power applications. Cummins Power Generation Company, in Indiana, has developed this concept further (Mancini, 1994). The Cummins system uses stretched polymer film facets for a parabolic dish, a heat pipe receiver absorber, a free-piston Stirling engine, and a linear alternator, resulting in a very compact power generation system. Figures 8.10.11 shows the latest version of the Cummins Dish Stirling power system. A detailed discussion of Stirling engines is given in Section 8.5.

Nomenclature

A = area of collector
C_p = specific heat
m = mass flow rate
T = temperature
I = incident solar radiation
Qn = useful heat collected
F_R = collector heat-removal factor
U_L = collector heat-loss coefficient
S = salt concentration
Z = depth

Greek Symbols

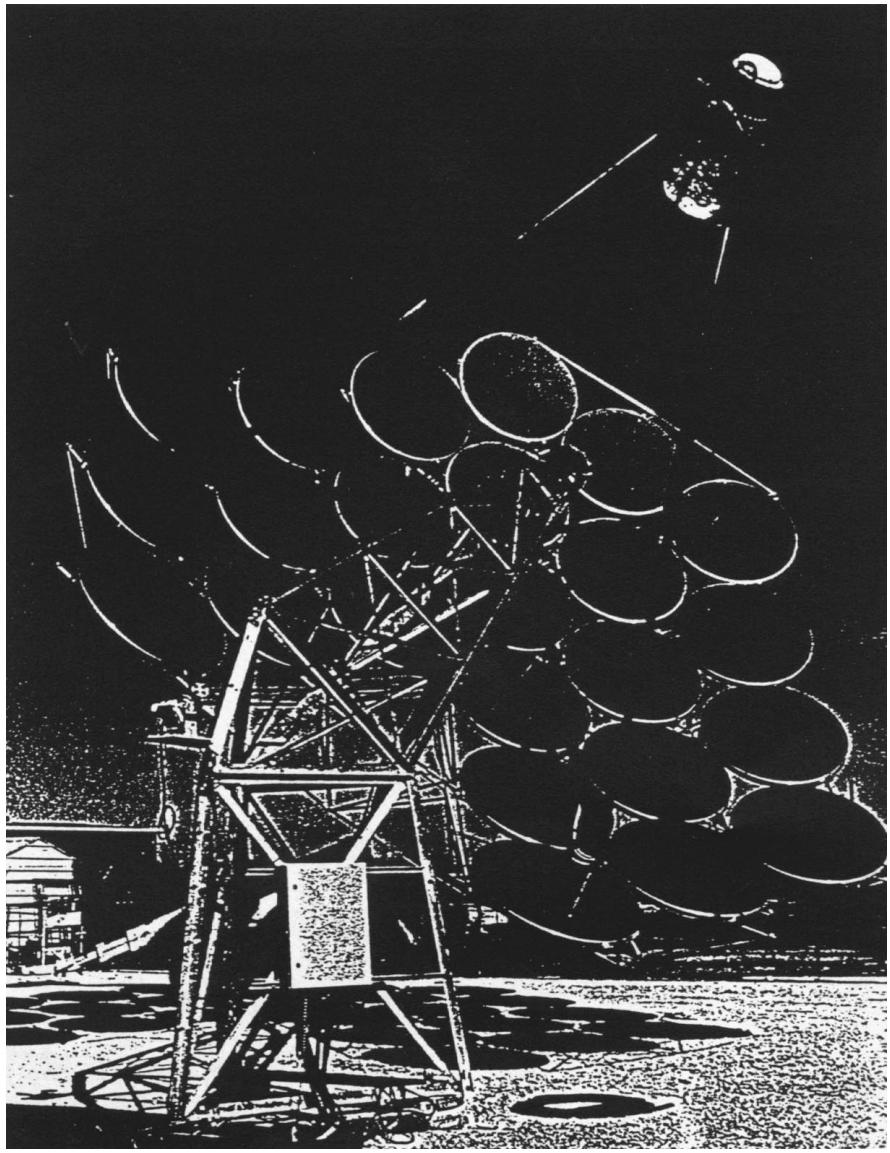
α = absorptance
τ = transmittance
η = efficiency
ρ = density

Subscripts

i = inlet
o = outlet
amb = ambient
e = effective

Defining Terms

Forced circulation or active solar system: A solar thermal system that uses active means, such as pumps, for fluid flow and heat transfer.



Figures 8.10.11 A parabolic dish — Stirling Engine Power System.

Glazing: A material used in a solar collector that transmits short-wavelength solar radiation and blocks longer-wavelength reradiation from the absorber plate.

Natural circulation passive solar system: A solar thermal system that uses natural means, such as the thermosyphon effect, for fluid flow and heat transfer.

Salt gradient solar pond: A solar pond that uses high salt concentration in the lowest layer and a concentration gradient in the middle layer to make those layers nonconvective.

Selective surface: A surface that has high absorptance in short wavelengths and low emittance in longer wavelengths.

Solar hybrid combined cycle: A hybrid of solar and natural gas turbine combined cycle.

Solar thermal collector: A solar collector that absorbs sunlight and converts it to heat.

8.11 Wind Energy Conversion*

Dale E. Berg

Introduction

Wind energy conversion machines have evolved over the past 2000 years, mostly by trial and error. Although there are many different configurations of wind machines, most of them can be classified as either horizontal-axis wind turbines (HAWTs), which utilize rotors that rotate about a horizontal axis parallel to the wind, or vertical-axis wind turbines (VAWTs), which have rotors that rotate about a vertical axis. Figure 8.11.1 illustrates the main features of both HAWTs and VAWTs. Figure 8.11.2 shows both types of turbines in a wind farm in the Altamont Pass area of California. HAWTs have all of their drivetrain equipment located on a tower, which makes servicing somewhat difficult, their blades are subjected to cyclic stresses due to gravity as they rotate, and they must be oriented with respect to the wind. However, they may be placed on tall towers to access the stronger winds typically found at greater heights. VAWTs, on the other hand, have most of their drivetrain on the ground, do not experience cyclic gravitational stresses, and do not require orientation with the wind. VAWTs, however, cannot be placed on tall towers to exploit the stronger winds at greater height, and their blades are subject to severe alternating aerodynamic loading due to rotation. The most common type of modern HAWT is the propeller-type machine, and these machines are generally classified according to the rotor orientation (upwind or downwind of the tower), blade articulation (rigid or teetering), and number of blades (generally two or three). The most common types of modern VAWTs are the Darrieus, with curved blades that are fixed in pitch, and the fixed-pitch, straight-bladed machines. The following discussion will focus on these types of turbines.

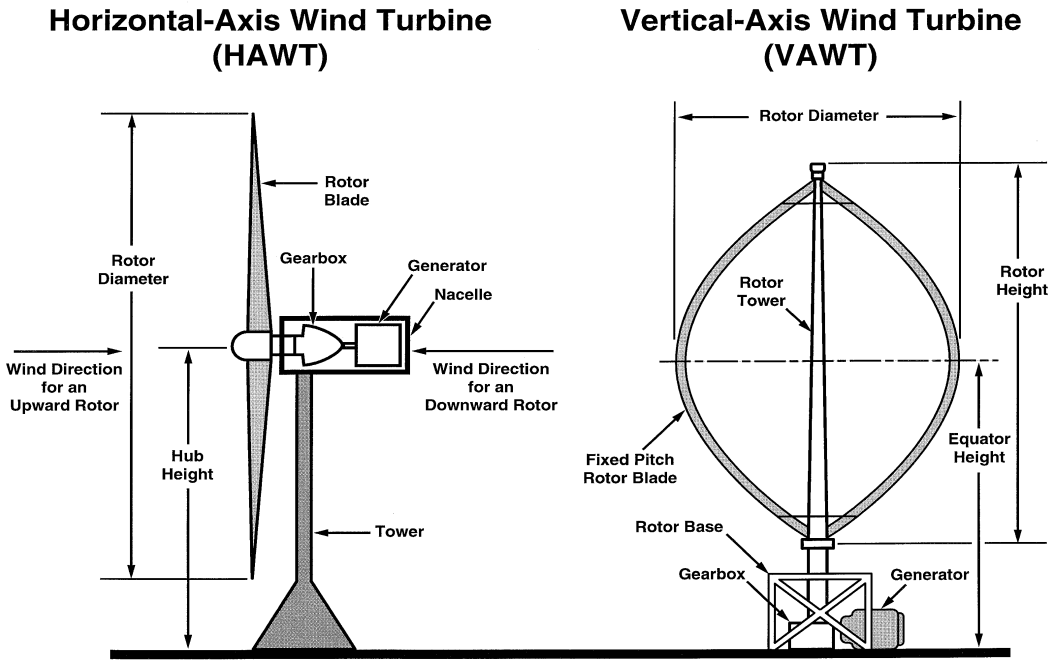

FIGURE 8.11.1 Wind turbine configurations.

FIGURE 8.11.2 Wind farm both horizontal-axis and vertical-axis turbines.

While small and even medium-sized machines have been developed primarily through trial and error, developing larger, more-complex, and highly efficient machines this way becomes very expensive and time-consuming. A large cost-effective machine can be developed at a reasonable cost only if the designers can accurately predict the performance of conceptual machines and investigate the effects of design alternatives. In the past two decades numerous techniques to predict the aerodynamic and structural dynamic performance of wind turbines have been developed. These analytical models are not, in general, amenable to simple approximations, but must be solved with the use of computer codes of varying complexity. These models and codes will be summarized in the following sections.

Wind Turbine Aerodynamics

Items exposed to the wind are subjected to both drag (in the direction of the wind) and lift (perpendicular to the wind) forces. The earliest wind machines used drag to produce power. The European and American windmills discussed in Section 7 of Chapter 7 were primarily drag devices, but they did make some use of lift. Modern wind turbines rely on airfoil-shaped blades that generate large amounts of lift to produce power more efficiently than the drag machines. Let us consider how efficient these machines are at extracting energy from the wind.

Figure 8.11.3 illustrates the flow field about a translating drag device. The drag results from the relative velocity between the wind and the device, and the power that is generated by the device (the product of the drag force and the translation velocity) is given by

$$P = Dlv = \left[0.5\rho(U - v)^2\right]C_D clv \tag{8.11.1}$$

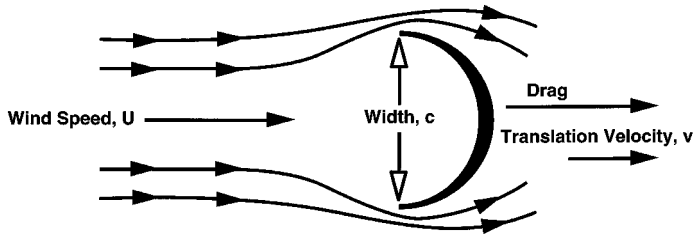

FIGURE 8.11.3 Schematic of translating drag device.

where

P = power extracted in watts
D = drag force per unit spanwise length in n/m
l = length of device (distance into the page) in m
v = translation velocity in m/sec
ρ = air density in kg/m^3
U = steady free-stream wind velocity in m/sec
C_D = drag coefficient; function of device geometry function
c = width of device (perpendicular to wind) in m

The velocity of the device must always be less than the wind velocity, or no drag is generated. The **power coefficient** (the ratio of the power extracted to the power available in the area occupied by the device) for this machine is

$$C_p = \frac{P}{0.5\rho U^3 cl} = \frac{v}{U}\left[1 - \frac{v}{U}\right]^2 C_D \tag{8.11.2}$$

Now consider a device that utilizes lift to extract power from the wind. Figure 8.11.4 illustrates an airfoil that is translating at right angles to the wind direction and is subject to both lift and drag forces. The relative velocity across this surface is the vector sum of the free-stream wind velocity and the wind speed induced by translation. The angle between the direction of the relative velocity and the chord line of the airfoil is termed the angle of attack α. In this case, the power is given by

$$P = 0.5\rho U^3 cl \frac{v}{U}\left[C_L - C_D \frac{v}{U}\right]\sqrt{1 + \left(\frac{v}{U}\right)^2} \tag{8.11.3}$$

where c = airfoil chord length in m and C_L, C_D = lift and drag coefficients, respectively; functions of airfoil shape and α. The power coefficient then is

$$C_p = \frac{v}{U}\left[C_L - C_D \frac{v}{U}\right]\sqrt{1 + \left(\frac{v}{U}\right)^2} \tag{8.11.4}$$

Figure 8.11.5 compares Equations (8.11.2) and (8.11.4) using $C_L = 1.0$ and $C_D = 0.10$ for the airfoil (easily achieved with modern airfoils) and a maximum drag coefficient of 2.0 for the drag machine. The airfoil has a maximum power coefficient of 15, compared with 0.3 for the drag device, or 50 times more power per unit of projected area. Moreover, operating a lifting device at velocities well in excess of the wind velocity is easily achieved with rotating machines.

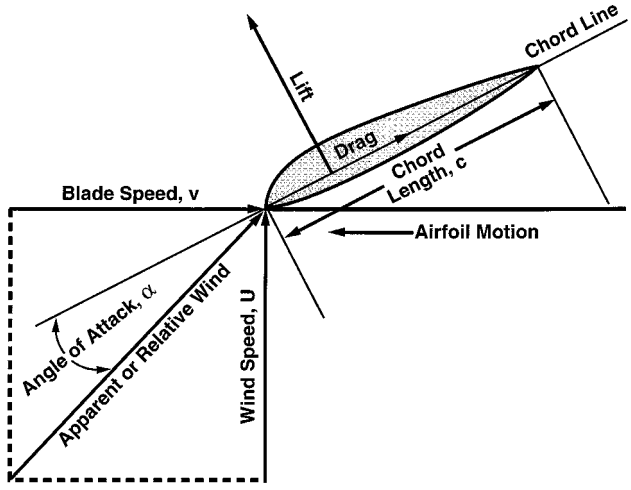

FIGURE 8.11.4 Schematic of translating lift device.

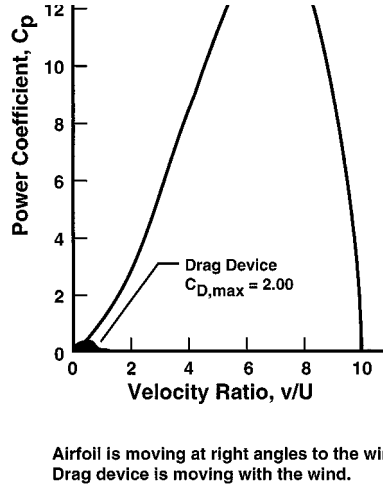

FIGURE 8.11.5 Comparison of power coefficients for a translating airfoil and a translating drag device. The airfoil is moving at right angles to the wind direction. The drag device is moving in the wind direction.

Machines discussed in this section utilize lift-producing blades to capture wind energy.

Aerodynamic Models

The aerodynamic analysis of a wind turbine has two primary objectives: (1) to predict the power produced by of the turbine and (2) to predict the detailed aerodynamic loads which will act on the turbine rotor blades. In general, the same models are used to accomplish both objectives. The aerodynamics of wind turbines are far too complex to model with simple formulas that can be solved with hand-held calculators; computer based models ranging from very simplified to very complex are required. The various models commonly used today are described below.

Momentum Models

The simplest aerodynamic model of a wind turbine is the actuator disk model or **momentum theory** in which the turbine is modeled as a single porous disk. In this model the axial force acting on the rotor or disk is equated to the time rate of change of momentum of the airstream passing through the rotor

or disk. By utilizing the conservation of mass, the conservation of axial momentum, the Bernoulli equation, and the first law of thermodynamics and by assuming isothermal flow, the power produced by the turbine (the product of the axial force and the air velocity at the disk) may be found to be

$$P = 2\rho AV^3 a(1-a)^2 \tag{8.11.5}$$

where V is the freestream wind velocity, $a = (V - v)/V$ and v is the wind velocity at the disk. The power coefficient for the turbine becomes

$$C_p = 4a(1-a)^2 \tag{8.11.6}$$

This is maximized for $a = {}^1/_3$, and we get $C_{p,\max} = 16/27 = 0.593$, the **Betz limit**, as the maximum fraction of available energy that can be extracted from the wind by a turbine.

The typical performance of various types of wind machines is compared with the Betz limit in Figure 8.11.6 where the variation of the turbine power coefficients with the **tip–speed ratio** (the ratio of the speed of the blade tip to the free-stream wind speed) are presented. Even though the maximum performance of modern HAWTs and VAWTs is well above that of the older machines, it still falls more than 10% below the Betz limit.

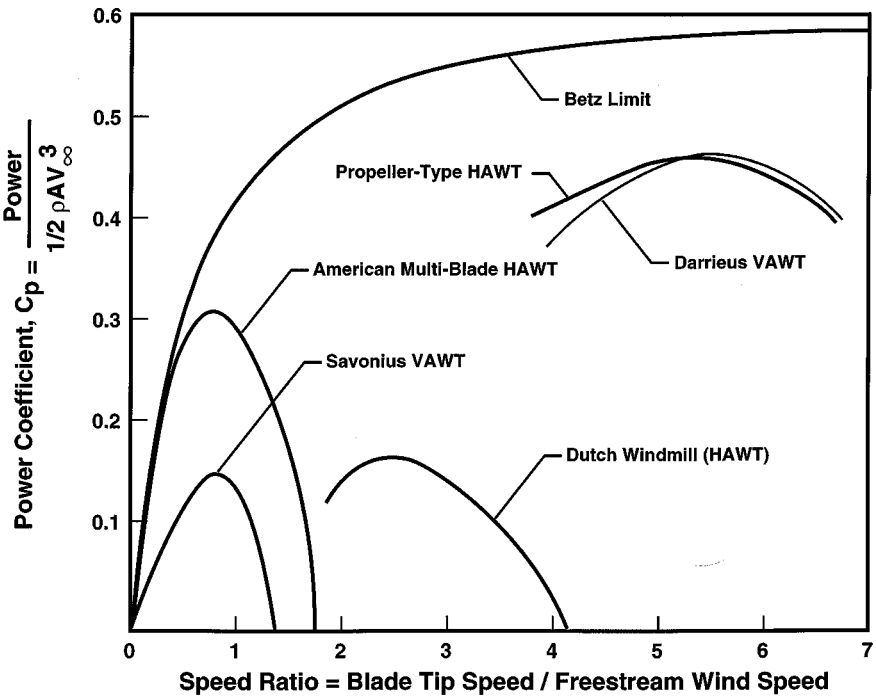

FIGURE 8.11.6 Typical performance of various types of wind turbines.

For HAWTs, momentum theory can be expanded to the blade element or strip theory, which includes the effects of blade lift and drag, wake rotation, and number and type of blades. Numerous corrections are applied to account for the three-dimensional flow near blade tips, the thick blade sections near the root, and gaps along the blade span. Additional information on these models may be found in Hansen and Butterfield (1993) and Wilson (1994).

Momentum theory may also be expanded for vertical-axis turbines into the multiple streamtube and the double-multiple streamtube theories that are the VAWT equivalent of the HAWT blade element theory. Additional information on these models may be found in Touryan et al. (1987) and Wilson (1994).

Wind shear and local Reynolds number variations may be readily accounted for with both the blade element and multiple streamtube methods. These models are extremely popular with wind turbine designers because they are simple, fast, and fairly accurate for performance prediction. However, they are very approximate methods based upon the assumption of steady flow and streamtubes that are fixed in time and space. More-complex models such as vortex and local circulation models are needed for the analysis of yawed flow, unsteady aerodynamics, and other complex flows, all of which can have large impacts on turbine performance and loads.

Vortex Models

Vortex models, based on the vorticity equation, can use either lifting line or lifting surface formulations for the blades with either free-wake or fixed- (or prescribed-) wake models, although there are a number of variations of these models. The three-dimensional, lifting-surface, free-wake formulation is the most physically realistic model, but a computer program implementing such a model will require a tremendous amount of computer resources and time. The problem with vortex codes is one of finding a balance between model simplification (and limitation) and computation time. Additional information on vortex models may be found in Strickland et al. (1981) and Kocurek (1987).

Local Circulation Method

The local circulation method (LCM) utilizes a balance between the force on the blade and the change in wind momentum as it passes through the rotor, similar to what is done with the momentum models. The blade, however, is represented as a superposition of imaginary blades of different spans with elliptical circulation distributions. Unlike the streamtube models, LCM models may be formulated to analyze unsteady flow, and are able to yield detailed flow field velocity and blade-loading information. The LCM yields better answers than the momentum models, avoids the convergence problems of the vortex models, and, with an appropriate wake model, requires far less computer time than the vortex models. However, this model has not been widely used. Additional information may be found in Nasu and Azuma (1983), Masse (1986), and Oler (1989).

Common Model Limitations

All of the aerodynamic models in use today use airfoil section characteristic tables (lift and drag coefficients as functions of angle of attack and Reynolds number) to determine the blade loading and turbine performance. Static two-dimensional wind tunnel test results or two-dimensional static airfoil design code predictions are modified with empirical, semiempirical, or analytic methods and used to estimate blade loads under three-dimensional, dynamic conditions. The greatest difficulty in obtaining accurate load predictions with any performance code is the determination of the appropriate airfoil section characteristics.

Additional information and references on turbine aerodynamics may be found in Hansen and Butterfield (1993) and Wilson (1994) for HAWTs and in Touryan et al. (1987) and Wilson (1994) for VAWTs.

Wind Turbine Loads

Wind turbine aerodynamic loads are of two types — the narrowband harmonic or cyclic loads resulting from the steady atmospheric wind, wind shear, rotor rotation, and other steady effects; and the broadband random loads resulting from nonuniformity or turbulence in the wind. The prediction of these loads is more complicated than the prediction of the aerodynamic performance and requires the use of computer-based models. The harmonic loads are generally predicted with the same codes that are used to predict wind turbine performance. The random loads are typically estimated with empirical relations, although a few analysts do utilize a performance code with a nonuniform wind model to predict them. A wind

turbine will experience hundreds of millions of loading cycles in a 30-year lifetime, and small errors that lead to underpredicting component loads can result in costly short-term component failure.

Accurate prediction of turbine performance does not guarantee accurate prediction of detailed aerodynamic loads — the performance predictions result from the integration of loads over the entire turbine, and significant errors may be present in the detailed loads but balance out in the performance predictions. While there is a considerable body of data showing good agreement of predicted performance with measured performance, there are very few data available against which to compare detailed aerodynamic load predictions.

Wind Turbine Dynamics

Horizontal-Axis Turbines

Horizontal-axis turbine designs usually use fairly rigid, high-aspect-ratio blades, cantilevered from a rigid hub and main shaft, although they may sometimes use relatively slender, quite flexible blades, attached to a less rigid hub and/or main shaft. This assembly rotates and yaws about a tower which may be flexible. These structures have many natural vibration modes, and some of them may be excited by the wind or the rotation frequency to cause a **resonance** condition in which the vibrations are amplified and cause large stresses in one or more components. Careful structural analysis during the design can ensure that the turbine that is built is dynamically stable under turbine operating conditions. Ignoring the structural analysis or failing to properly conduct parts of it will likely result in a machine that experiences resonances and fails very quickly. Relatively rigid systems are less likely to experience these stability problems than are very flexible, highly dynamic systems.

Detailed analysis of the structural response of a turbine is a rather daunting task requiring the formulation and solution of the full governing equations of motion, usually performed with a finite-element structural model. Those equations must account for the interaction between the blades and the steady centrifugal forces, the time-dependent gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces. They must also model nonsteady airflow, the yaw motion of the nacelle, pitch control of the blades, teetering blades, the interaction between the rotor and the supporting tower, starting and braking sequences, etc. The rotor must be modeled in a rotating coordinate frame with time-dependent coefficients, while the tower must be modeled in a fixed coordinate frame, with the exciting forces arising from the nonlinear, time-dependent coupling of the rotor and the time-dependent loading of the wind.

Malcolm and Wright (1994) provide a list of some of the available HAWT dynamics codes that have been developed, together with their limitations.

Vertical-Axis Turbines

Darrieus turbine designs normally use relatively slender, high-aspect-ratio structural elements for the blades and supporting tower. The result is a very flexible, highly dynamic structure, with many natural modes of vibration which, again, must be carefully analyzed to ensure that the turbine is dynamically stable under all operating conditions. Typically, the guy cables and turbine support structure can be analyzed with conventional methods, but the tower and blades require a more refined analysis, usually performed with a finite-element structural program.

The blades and tower must be modeled in the rotating coordinate frame with time-independent coefficients. The equations of motion are determined by the steady centrifugal and gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces, together with the turbine physical properties. Detailed information on the modeling may be found in Lobitz and Sullivan (1983).

Aerodynamic Loads/Blade Motion Coupling

The blades themselves are driven by aerodynamic as well as structural dynamic forces. The motion of slender, high-aspect-ratio blades may couple with the aerodynamic loads acting on them. This coupling may increase the motion of the blades, creating a potentially fatal condition known as flutter instability,

or it may decrease the motion of the blades, creating a beneficial condition known as aerodynamic damping.

Stochastic Wind Effects

The wind is **stochastic** in nature, with significant short-term variations in both direction and velocity. As turbines become larger, the relative extent of these variations becomes smaller than the size of the turbine, and the effects become more pronounced. Analysis of the effect of fluctuating wind loads on the response of the turbine shows an increase in the broadband response, accompanied by a decrease in the magnitude of the dominant narrowband responses at multiples of the rotation frequency. This increase in broadband response can include excitation of turbine vibration modes that are close to a narrowband response frequency, but that are not predicted to be excited by a uniform wind (Lobitz, 1984).

Wind Turbine Controls

In general, wind turbines are designed to operate when the incident wind is high enough to generate electricity and to shut down when the wind speeds exceed 25 to 30 m/sec. In spite of the tremendous amount of power which is present in the high winds, the amount of energy that can be captured is usually more than offset by the fatigue damage that is sustained by the turbine.

Brakes

Most turbines utilize mechanical brakes, frequently in conjunction with aerodynamic brakes, to stop the rotor and to keep it from rotating when the turbine is not generating electricity. A few turbines rely solely on aerodynamic braking devices to accomplish this. Whatever type of braking system is used, it should be a fail-safe design that will automatically activate to slow or stop the rotor in the event of an electrical system failure.

Yaw Systems

Virtually all upwind and a few downwind HAWT turbines incorporate an active yaw control system, using wind-direction sensors and electric or hydraulic drive motors, to orient the rotor with respect to the wind. VAWTs do not require yaw systems.

Peak Power Regulation

All turbines incorporate some method of limiting the peak power produced. This enables the generator to operate near its design power rating, where it is most efficient, over a range of wind speeds. The increase in generator efficiency at lower wind speeds, together with the lower cost of the drivetrain, more than offset the energy that is lost as a result of power limiting. Most horizontal-axis turbines use one of three common techniques to limit peak power — stall regulation with fixed-pitch blades (passive control), full- or partial-span pitch control, or partial-span control surfaces such as ailerons and/or flaps. With stall regulation, the blades are designed so that airfoil **stall**, which creates decreased lift and increased drag, limits the power output in high winds. However, rotor drag loads continue to increase as the wind speed increases. Another disadvantage is the difficulty of controlling aerodynamic loads in deep stall. With full- or partial-span blade pitch control, peak power is controlled by decreasing blade pitch angle as wind speed increases, limiting peak power and decreasing rotor drag loads. A major disadvantage of pitch control is the poor peak power control during high-wind stochastic (or turbulent) conditions — power excursions can exceed twice the rated power levels before the pitch-control system can respond. Partial-span control surfaces limit the peak power by decreasing the lift and increasing the drag of a portion of the airfoil. They can respond to wind changes somewhat faster than full-span pitch control systems can. Sample power curves for both stall and pitch-regulated turbines are shown in Figure 8.11.7.

Several other methods of pitch control have also been used, but on a limited basis. Passive pitch-control techniques automatically adjust the blade pitch angle using cams activated by centrifugal loads or using tailored blade materials that permit the blade to twist as the aerodynamic loads increase. The

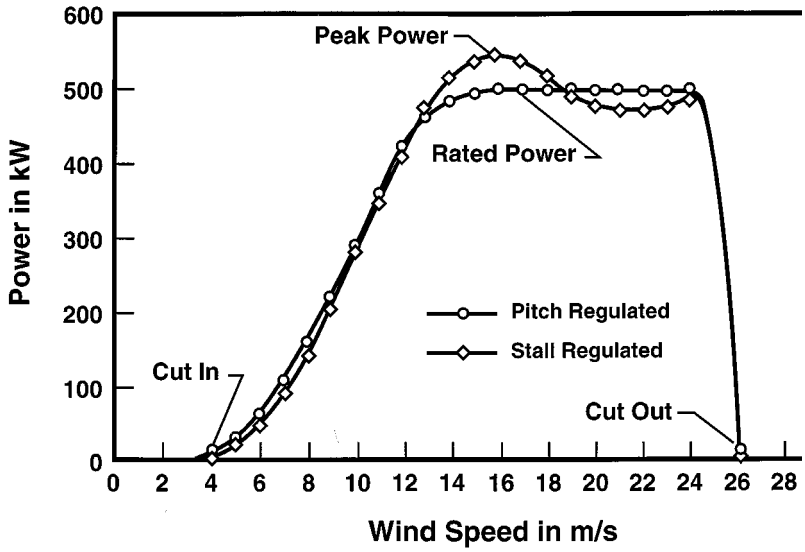

FIGURE 8.11.7 Sample power curves for stall-regulated and pitch-regulated wind turbines.

Italian Gamma 60 turbine utilizes a novel means to control peak power — it is the only large-scale turbine that yaws a fixed-pitch rotor out of the wind to limit rotor power.

Virtually all VAWTs utilize stall regulation with fixed-pitch blades to control peak power.

Controller

Every wind turbine contains a controller, usually a microprocessor-based system, to control turbine operations. The basic turbine controller will start and stop the machine and connect or disconnect the generator output lines to the grid, as needed; control the operation of the brake system; control the operation of the yaw and pitch systems, if present; perform diagnostics to monitor the operation of the machine; and perform normal or emergency shutdown of the turbine as required. However, the controller can incorporate many other functions as well, functions such as recording turbine performance characteristics and controlling the operating state of a variable-speed machine.

Wind Turbine Electrical Generators

Once a wind turbine has converted the kinetic energy in the wind into rotational mechanical energy, the energy is usually converted into electricity which can be readily transported to where it is needed. While small wind turbines may utilize permanent magnet alternators to generate electricity, most grid-connected turbines today use either synchronous or induction electrical generators. Induction machines are cheaper than synchronous machines, are easier to control, and provide some power train damping, but they require reactive power that must be supplied by the grid. This can cause problems, but those problems can be usually be solved fairly quickly and at low cost.

Generator efficiency drops off rapidly as the generated power falls below the rated generator capacity, and single-generator systems tend to be very inefficient at low wind speeds where there is little power available in the wind. Some systems address this by having a second, smaller generator which is used for low-wind operation, where it operates close to its rated power. At higher winds, the smaller generator is disconnected and the larger generator is used. Similar results can be obtained with a single generator utilizing pole switching or dual windings. The two-generator operation may yield a sizeable increase in energy capture, but the additional costs of the smaller generator or the generator modification and additional controls must be balanced against the increased energy capture to determine if this is cost-effective.

While most turbines operate at a single fixed rotational speed, some operate at two or more fixed rotational speeds, and some operate anywhere within a range of speeds. Variable-speed turbine operation offers two major advantages over fixed-speed operation:

1. The aerodynamic efficiency of the rotor at low to moderate wind speeds may be improved by more closely matching the rotor speed to the short-term average wind speed. At higher wind speeds, the blades are either in stall or are pitched to control peak power, so matching rotor speed to wind speed is less important.
2. System dynamic loads are attenuated by the "flywheel" action of the rotor as it speeds up and slows down in response to wind gusts.

In addition, variable speed permits the operation of the turbine in a variety of modes, including operation at maximum efficiency for all wind speeds to maximize energy capture or operation to minimize fatigue damage. However, certain rotational speeds within the operating-speed range will likely excite turbine vibration modes, causing resonance and increased rates of fatigue damage. These rotational speeds must be avoided during operation, and turbine control can become quite a complicated issue.

Variable-speed operation, in general, generates variable-frequency power. Most applications, including interfacing with power grids, require high-quality power at a reference frequency. Sophisticated power electronics may be used to accomplish this interface (Smith, 1989).

Wind-Diesel Systems

Wind turbines are increasingly being coupled with diesel engine-powered generators to create **wind-diesel systems**. In these systems, the diesel engine provides dependable, consistent power and the wind turbines generate some of the power, reducing the engine fuel consumption and the system cost of energy. A large variety of wind-diesel systems and concepts have been investigated over the past decade (Infield, et. al., 1992). Although quite a few of these have been technically successful, very few of them have been commercially successful. While the potential market for wind-diesel systems appears to be very large, it has yet to materialize, for the reliability of the technology has not yet been well proven.

Water-Pumping Applications

The multibladed, mechanical windmill (the so-called "American" windmill) with a mechanical piston pump has been used for over a century to pump water in remote areas. Over the past few years some changes to improve operation in low wind speeds have been made to the design of these machines.

Researchers at the U.S. Department of Agriculture facility at Bushland, Texas have reported considerable success in using variable-voltage, variable-frequency electricity produced by small stand-alone wind turbines to directly power submersible water pumps. Clark (1994) compares the pumping performance of one of these wind–electric systems and that of the traditional American windmill with a piston pump. He found that the wind–electric system performed significantly better than the mechanical system, even though the price of the two systems was nearly identical. The wind–electric system offers another advantage as well — while the windmill for the mechanical pump must be mounted directly over the well, the wind turbine for a wind–electric system may be mounted some distance away, at a better wind location.

Defining Terms

Betz limit: Maximum fraction of available wind energy that can be extracted by a wind turbine rotor, according to momentum theory.

Momentum theory: A method of estimating the performance of a turbine by equating the time rate of change of air stream momentum through the turbine to the force acting on turbine blades.

Power coefficient: The ratio of captured energy to the energy available in the reference area.

Resonance: A vibration of large amplitude caused by a relatively small excitation at or near a system natural frequency.
Stall: A condition in which an airfoil experiences a decrease in lift and a large increase in drag.
Stochastic: Containing variations from a smooth, uniform flow.
Tip-speed ratio: The ratio of the speed of the blade tip to the free-stream wind speed.
Wind–diesel system: An electrical-generation system that utilizes both diesel engine–powered generators and wind turbines to create a dependable, consistent power system.

8.12 Energy Conversion of the Geothermal Resource

Carl J. Bliem and Gregory L. Mines

This section discusses the uses of the geothermal resource. The primary use of the energy from geothermal resources to date has been in the production of electrical energy. Other applications, such as process heat and space conditioning, have also been made and will be discussed under the topic of direct use. This section begins with a discussion of the geothermal resource as it applies to the use of the energy. Then discussion of the three types of electrical generating facilities presently in use: — the **direct steam system**, the **flashed steam system**, and the **binary system** — is given. Finally, some discussion of direct-use applications is given.

Geothermal Resource Characteristics Applicable to Energy Conversion

Geothermal energy as defined here applies to hot fluids under pressure found at a reasonable depth (1 to 2 km) in the earth's crust. If one disregards the complex geological details relating to the formation of such naturally occurring reservoirs of hot fluids, Figures 8.12.1 and 8.12.2 present schematic representations of these reservoirs. High-temperature fluid (200 to 300°C) is created by the convection of water through the porous rock. As the water circulates, it dissolves various amounts of minerals containing sodium, potassium, calcium, silica, carbonates, and chlorides and gases such as nitrogen and carbon dioxide. In **geopressured resources** of the Gulf of Mexico, high pressures and significant amounts of dissolved methane are seen.

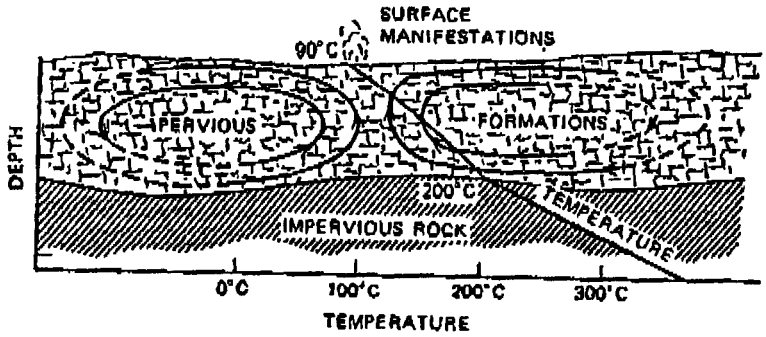

FIGURE 8.12.1 Schematic diagram of the convective cells in a geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

The convective cells operate over large horizontal distances of as much as 30 km. The time in which the transfer of energy from the magma to the water takes place is of the order of 10^5 to 10^6 years. At the present time, it is difficult to say whether or not the resource can be considered "renewable." If natural circulation or the injection of spent geothermal liquid into the reservoir can make up for the liquid extracted during the energy conversion process, the reservoir can be considered at least of a very long life. (Individual wells generally have a life of about 10 years.)

The resources considered in this section are said to be **hydrothermal**. (Work is being done on creating artificial reservoirs by injecting water into hot dry rock, but this development is in its early stages and will not be considered here. The geopressured resource will not be considered either.)

As the geofluid is extracted from a reservoir, it flows to a region of lower static pressure. If this pressure falls below the saturation pressure for the temperature of the geofluid (close to but not equal to the saturation pressure of pure water because of the presence of the dissolved solids and gases), the

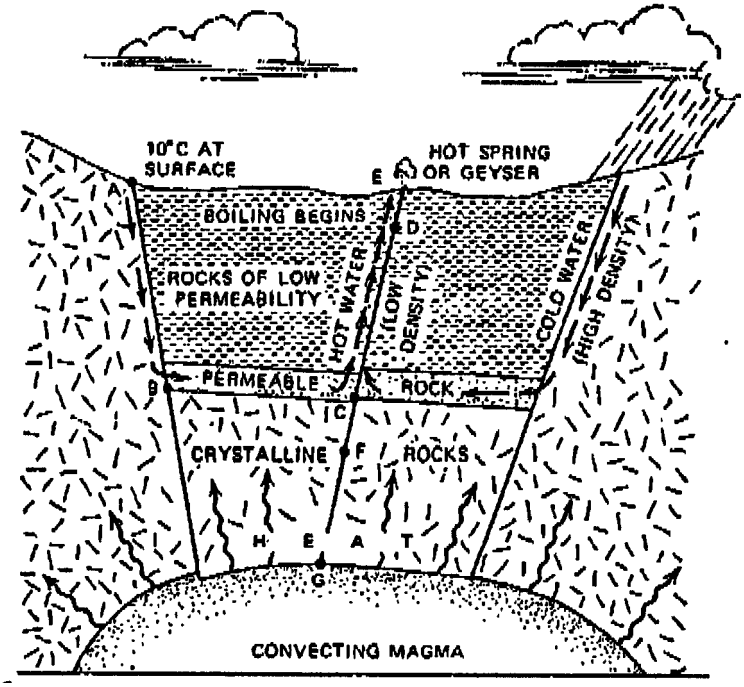

FIGURE 8.12.2 Schematic diagram of a characteristic geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

geofluid will flash into steam. Therefore, the person using this energy source may have a number of different physical forms to consider:

1. Wet steam from a *vapor-dominated resource*;
2. Superheated or saturated steam from a vapor-dominated resource;
3. Liquid at a pressure above the saturation pressure from a *liquid-dominated resource*;
4. A mixture of liquid and vapor at a relatively low quality from a liquid-dominated resource.

Electrical Energy Generation from Geothermal Resources

The type of energy conversion system used to produce electrical power depends on the type and quality (temperature) of the geothermal resource. Vapor-dominated resources use systems where steam is expanded directly through a turbine, similar to conventional fossil fuel steam plants. Liquid-dominated resources use flash steam systems and binary systems, with binary systems predominantly used for the lower-quality resources. The term **binary system** is used to describe a power cycle where the geothermal fluid provides the source of thermal energy for a closed-loop Rankine cycle using a secondary working fluid. In this closed loop, the working fluid is vaporized using the energy in the geofluid, expanded through a turbine, condensed, and pumped back to the heater completing the closed loop.

Hydrothermal resources typically contain varying amounts of numerous dissolved minerals and dissolved gases. In power cycles where steam is extracted from the geothermal resource directly (vapor dominated) or indirectly (flashing liquid dominated) and expanded through a condensing turbine, the design and operation of the power cycle must account for the removal of the noncondensable gases. If the gases are not removed from the condenser, they will accumulate in the condenser, raising the turbine back pressure and decreasing the power output. In systems where the liquid geofluid is handled (binary cycle heat exchangers and piping and flash steam flash tanks and piping), measures must be taken to

prevent the precipitation of the dissolved solids and/or to provide a means of removal of the resulting scale.

Direct Steam Systems — Vapor-Dominated Resources

For a geothermal resource producing a superheated or saturated vapor steam (Case 2), the vapor from the geothermal production well is sent to a conventional steam turbine as shown in Figure 8.12.3. (This is done after appropriate removal of rocks and debris and possibly after scrubbing with water to remove corrosive substances.) Normally, the turbine is a condensing type, as shown in the figure, although in some applications a back-pressure turbine is used, exhausting the steam to the atmosphere. The back-pressure turbine is typically used for small systems with the possible later addition of another turbine and a condenser to increase the power generated by the geofluid flow from the wells.

Figure 8.12.3 shows a system with a direct-contact condenser and a wet cooling tower. In this type of system, the condensate from the condenser is more than enough to make up the evaporation and blowdown from the cooling tower. Therefore, the figure shows some of the condensate being injected into the reservoir. In many cases, direct-contact condensers are not feasible because of the hydrogen sulfide in the steam which would be released in the cooling tower exhaust. When hydrogen sulfide is in the steam, the majority of it appears as noncondensable and the noncondensable gas from the condensers must be treated. For these systems, surface condensers are normally used in conjunction with wet cooling towers. The actual hardware configuration is dictated by the process for removal of the sulfur. Again, some of the condensate can be used for cooling tower makeup if the sulfur is removed from the process. A number of processes have been developed to remove sulfur from the process.

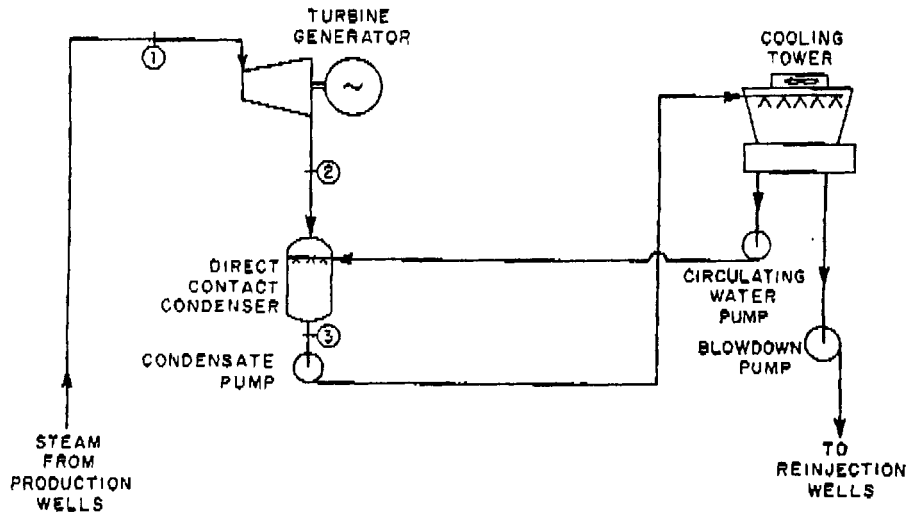

FIGURE 8.12.3 Schematic diagram of a direct dry-steam plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Figure 8.12.4 depicts a system which is similar to the one described above, but one which receives wet steam (Case 1). Here, the liquid is separated from the vapor prior to the entry of the vapor into the turbine. Otherwise, the system is the same as the one in Figure 8.12.3 and the same comments apply.

Flash Steam Systems — Liquid Dominated Resources

When the geofluid is flashed before it leaves the well, flash steam systems are generally used. This indicates that the resource is at a relatively high temperature. Figures 8.12.5 and 8.12.6 depict single- and dual-flash systems schematically. The single-flash system in Figure 8.12.5 is quite similar to the system in Figure 8.12.4. The only difference is that the geofluid pressure is dropped further before the steam is separated and sent to the turbine. An optimum flash pressure exists because the lower the flash

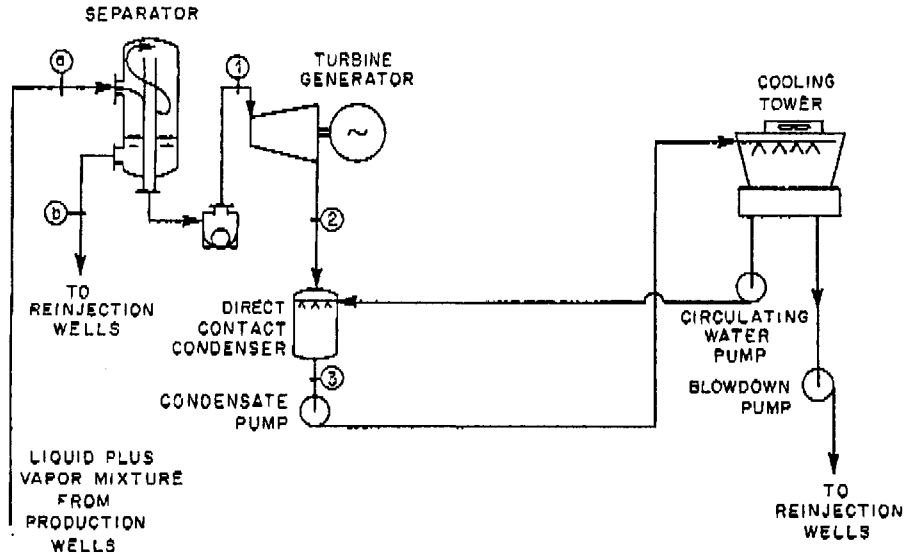

FIGURE 8.12.4 Schematic diagram of a plant using a two-phase resource. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

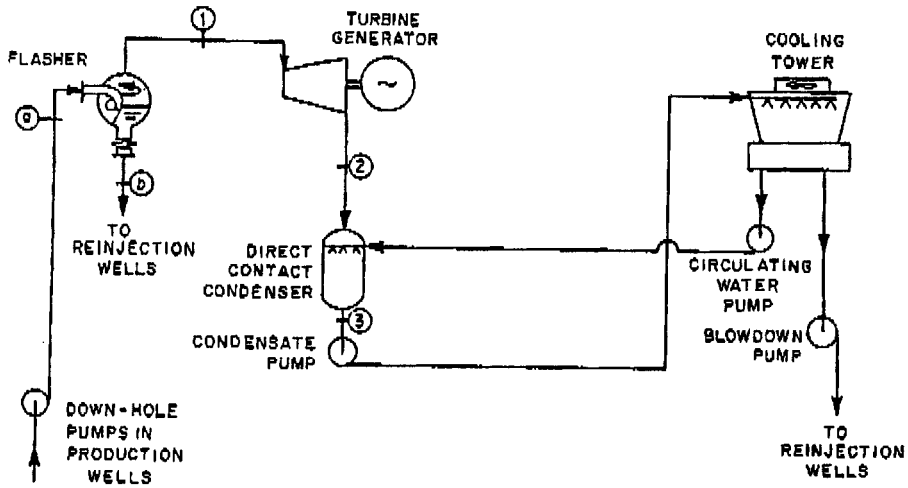

FIGURE 8.12.5 Schematic diagram of a single-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

pressure, the more steam which is evolved. However, the work done per unit mass of steam flowing through the turbine will also decrease with the lower flash pressure. For a given set of geofluid conditions entering the plant, a flash pressure exists that will maximize the energy produced per unit mass of geofluid and also minimize the levelized energy cost (LEC). The performance and cost optima will be near, but not generally at the same pressure.

The flash steam system can also be utilized in applications where the fluid enters the plant as a liquid (single phase). In these systems, the geothermal fluid is throttled with an expansion valve to the desired flash pressure. This flashing process can be considered adiabatic, where the amount of steam evolved can be determined from energy and mass balances of a simple throttling calculation.

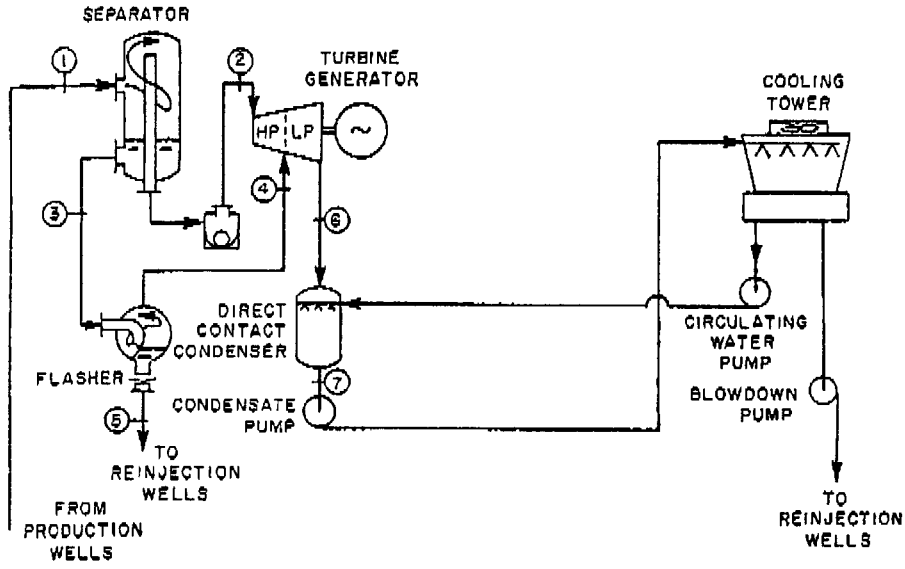

FIGURE 8.12.6 Schematic diagram of a dual-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Most successful flash systems are dual flash. The first flash is generally near the well-head pressure and the second flash near atmospheric pressure. The low-pressure flash is normally kept above atmospheric pressure to prohibit leakage of air into the system in the flasher. Some recent studies have indicated that for low-temperature resources, a subatmospheric second flash would produce a cost-effective system. Again, optimization of the two flash pressures is necessary to minimize the LEC. In cases in which the geofluid has a high dissolved solid content, flash crystallizers are used to remove the precipitated dissolved solids. The flashing process releases carbon dioxide dissolved in lowering the geofluid pH, which causes the precipitation of insoluble carbonates. The solubility of silica is temperature dependent; lowering the geofluid temperature causes the precipitation of silica.

None of the steam cycles depicted provides for the removal of the noncondensable gases from the condenser. This removal is typically accomplished with steam ejectors or compressors which continuously remove the small stream of vapor from the condenser. Some steam is lost in this process of removing the noncondensable gases.

Binary Systems — Liquid-Dominated Resources

Recent studies have shown that for resources below 200°C, current technology binary systems have lower LEC than flash steam plants for liquid-dominated resources. Figure 8.12.7 shows a typical binary system with an evaporative heat-rejection system. This type of heat-rejection system has been replaced by air-cooled condensers in most applications. In the areas where the geothermal resource exists, there is little excess water for makeup in the cooling tower, as shown in Figure 8.12.7. All of the cooled geofluid in a binary system is typically injected back into the reservoir. This provides an environmentally acceptable means of disposal of the fluid and, more important, provides a recharge of the reservoir to maintain the reservoir productivity.

The binary cycle is an attempt to reduce the scaling potential of the geofluid. Carbonates are precipitated when the pressure of the geofluid is reduced and carbon dioxide comes out of solution as the geofluid flashes. With downhole pumps in the wells, this can be eliminated by keeping the fluid pressurized. Some resources do not require pumps to maintain the flow and pressure necessary to eliminate flashing (artesian flow). Similarly, if the exit temperature of the geofluid remains above some minimum value, silica will not be precipitated. These two operational strategies limit the scaling in a binary plant. Any constraint imposed on the geofluid exit temperature will impact the design of the

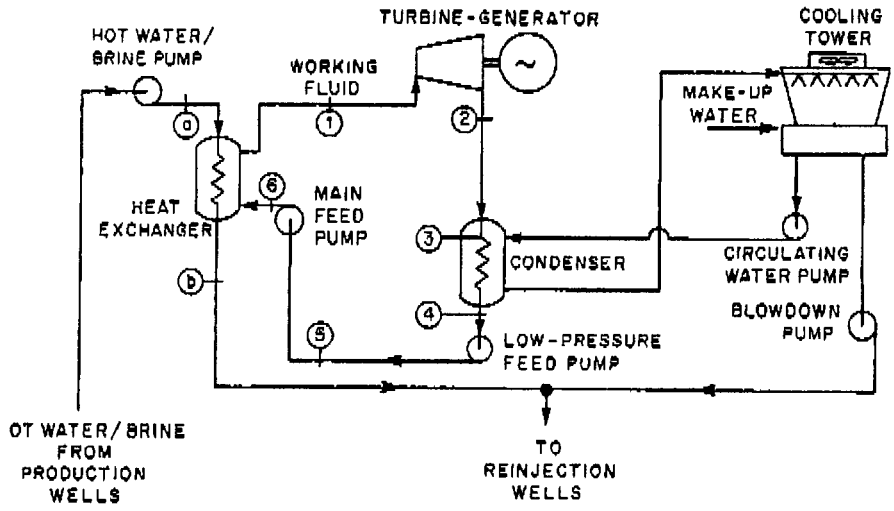

FIGURE 8.12.7 Schematic diagram of a binary plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

binary plant, affecting the selection of turbine inlet conditions as well as the possible choice of working fluid.

The binary cycle consists of a closed loop of a working fluid normally performing a Rankine cycle. Most existing binary cycles use isobutane, pentane, or isopentane as working fluids. Studies have indicated that mixtures of hydrocarbons, e.g., 96% isobutane/4% hexane, will produce better utilization of a 180°C resource and in some instances lower LEC.

The performance of the binary system depends on a number of factors. Some plant designs incorporate multiple or staged boiling cycles, where the working fluid flow is split and boiling occurs at multiple pressures. In these cycles, multiple or staged turbines are required. The advantage of these cycles is the fact that the working fluid heat-addition process more closely matches the sensible cooling of the liquid geofluid (as shown on the T-Q or T-h diagram). This lowers temperature differences through the cycle, reducing cycle irreversibilities and increasing performance. The same effect can be achieved by heating the working fluid at supercritical pressures (pressures above the critical pressure). While the supercritical cycle will have higher component, material, and pumping costs because of higher operating pressures, they have fewer components because they are less complex than multiple boiling cycles. (In many cases, the maximum pressure can be kept below 600 psi with hydrocarbons such as isobutane.) Lowering the mean temperature difference in heat exchangers tends to require larger units so that capital costs are increased. In general, the LEC is reduced because the effects of increased performance more than outweigh the increase in capital cost.

The choice of the working fluid for the power cycle will also impact the cycle performance. In general, as resource temperature decreases, the more volatile fluids will produce more power per unit mass of geofluid. Power cycles using the more volatile fluids typically operate at higher pressures and have higher associated material and equipment cost. These higher costs may offset the gains in performance and produce higher LECs in some cases.

Working fluid mixtures have been shown to provide superior performance to the single component or pure working fluids. This performance improvement is due to the nonisothermal phase changes of this type of fluid at constant-pressure (both boiling and condensing), which allows the working fluid to match more closely the sensible cooling of the geofluid. More importantly in the reduction of irreversibilities, the desuperheating and condensing process more closely matches the sensible heating of cooling water or air in the heat-rejection process.

One additional type of binary cycle that has been proposed uses an ammonia-water mixture for the working fluid. A great deal of recuperative preheat of the working fluid is accomplished by splitting the duty of the geofluid, turbine exhaust, and preheated liquid flows through a more complex heat-transfer train than is shown in Figure 8.12.7. These systems are known as **Kalina systems**. In general, these systems do not change the composition of the mixture in the cycle as the Kalina cycle for applications such as is the case for gas turbine bottoming.

There is some consideration of using a binary cycle as a bottoming cycle for a flash steam or direct steam system. Similarly, a binary cycle could be used to bottom another binary system, perhaps with a different working fluid.

Design Considerations

The selection of the working fluid in binary cycles imposes safety considerations to be considered in the design of the power plant. Equipment and facility designs must take into account the flammable characteristic of the hydrocarbon working fluids.

The selection of materials of construction for the piping and components exposed to the geofluid will be resource specific. Typically, carbon steel is used for piping and pressure vessels. Turbines that use the steam directly may have stainless steel components, although the use of stainless may be limited by the presence of chlorides and the potential for stress cracking. The standard design for heat exchangers in binary cycles is for the geofluid to be on the tube side. This facilitates the cleaning of the exchanger if scaling or fouling occurs on the surfaces exposed to the geofluid. If the geofluid has a high scaling potential, components and piping should be designed to allow for periodic cleaning.

Direct Use of the Geothermal Resource

A number of direct-use applications of the heat in a geothermal resource have been successfully implemented. These include

1. Space conditioning (heating with the resource or a secondary fluid and cooling with heat pumps);
2. Heating of greenhouses;
3. Aquaculture;
4. Process heating (drying vegetable products);
5. Ground coupled heat pumps.

Although the United States is one of the world leaders for the production of electrical power from geothermal energy, other nations take the lead for the direct use of this energy source. In Iceland, over 85% of the buildings are supplied with heat and domestic hot water from geothermal systems (Ragnorson, 1995).

Typical direct-use applications are either closed systems with produced fluids being injected back into the geothermal reservoir or systems where the produced water is pure enough for beneficial use or disposal to surface waterways. Experience has shown that it is usually worthwhile to inject as much of the cooled fluid as possible back into the reservoir to maintain pressure and production rates.

Defining Terms

Binary system: A binary system that uses thermal energy from the geofluid to vaporize a secondary working fluid in a Rankine cycle.

Direct steam system: A geothermal energy conversion system that utilizes steam directly from a geothermal well.

Flashed steam system: A geothermal energy conversion system that utilizes steam flashed from the liquid geofluid.

Geopressurized resource: Naturally occurring reservoirs of hot pressurized fluid created by convection of water through hot porous rock.

Hydrothermal resource: Artificial reservoirs created by injecting water into hot dry rock in the earth's core.

Kalina system: A binary system using a mixture of ammonia and water as the working fluid in the power cycle.

8.13 Direct Energy Conversion

Solar Photovoltaic Cells

Kitt C. Reinhardt

Introduction

Solar photovoltaic cells convert sunlight directly into electrical energy via the collection of solar photon-generated semiconductor charge carriers. The collection of charge carriers within the cell produces a voltage across the terminals of the cell, called the **photovoltaic effect**, that can drive an external electrical circuit or charge a storage battery. Photovoltaic cells are useful in both space and terrestrial power applications. Silicon, Si, photovoltaic cells have provided the main source of electrical power to virtually all Earth-bound satellites since the advent of the space program in the late 1950s. In the early 1970s, photovoltaics generated a significant amount of interest for use in terrestrial power systems when oil supplies to the industrial world were disrupted. Today, while photovoltaic power remains the primary energy source for most communication and surveillance satellites, issues concerning system efficiency, reliability, and cost currently prevent its widespread use in residential and power utility applications. For example, in the United States the average price for conventional utility electricity is 6¢/kWhr, compared with ~35¢/kWhr for terrestrial photovoltaic electricity (Zweibel, 1995). Thus, the cost of photovoltaic power must be reduced by a factor of ~6 for it to become economically viable. At present, photovoltaic power is generally only cost-competitive for use in remotely located systems where conventional power is cost-prohibitive, such as in remote water-pumping and communications stations, signal and emergency lighting, and for village power. Factors that influence photovoltaic system energy costs include cell panel efficiency, total system lifetime, and cost per unit area. The present discussion will focus on issues concerning photovoltaic cells and panels. Detailed literature on power conditioning electronics and energy storage systems can be found elsewhere. A large number of different photovoltaic cell designs have been demonstrated by researchers over the years. However, the most common and practical cell designs are fabricated using single-crystal Si. Consequently, Si will be used to describe basic principles of semiconductors and photovoltaic cell operation.

Introduction to Semiconductors

We begin with a description of the concept of covalent bonding, valence electrons, and energy bands, which relates to conduction in semiconductors (Sze, 1981). The crystalline structure of Si is diamond, where each Si atom in the lattice is covalently bonded to four equidistant nearest neighbors that lie at the corners of a tetrahedron. Each Si atom has four electrons in its outer orbit, called valence electrons, and each atom shares these electrons with its four neighbors to form four covalent bonds. The atomic configuration of the 14 electrons of Si is $1s^2 2s^2 2p^6 3s^2 3p^2$. At practical temperatures, only the $3s^2 3p^2$ valence electrons contribute to the electrical conductivity; the $1s^2 2s^2 2p^6$ core electrons are too tightly bounded to the nucleus to participate. In a simplified model, as N Si atoms are brought together at 0 K to form a crystal, two distinct and nearly continuous bands of electronic energy levels form that are separated by an energy gap called the semiconductor **band gap, E_g**. The resulting upper **conduction band** contains 4N states, as does the lower **valence band**. The 4N electrons that come from the Si $3s^2 3p^2$ states completely fill the 4N states in the valence band at 0 K, and the conduction band states are completely empty. Since there are no unoccupied states in the valence band for electrons to move and the conduction band is empty, Si is a perfect insulator at 0 K.

As the temperature of the crystal increases, electrons in the valence band gain sufficient thermal energy ($>E_g$) to be excited across the band gap into the conduction band, leaving holes (missing electrons) behind in the valence band. When current conduction in a semiconductor is dominated by thermally generated electrons and holes, it is called intrinsic. In this case, the resulting number of electrons per unit volume in the conduction band, n, equals the number of holes per volume in the valence band, p, that is $n = p = n_i$, where n_i is called the intrinsic carrier concentration. In the presence of an electric

field, intrinsic electrons and holes gain kinetic energy and conduct electricity. However, since at room temperature n_i for Si is only 1.45×10^{10} cm^{-3}, compared with a free-electron density of more than 10^{22} cm^{-3} in metals, Si behaves as a very good insulator, i.e., electrical conductivity, σ, is given by $\sigma = q(n\mu_n + p\mu_p)$, where q is the electronic charge and μ is the respective carrier mobility.

In order to increase the conductivity to values useful for solid-state devices, the level of n and p can be increased by purposely adding impurity atoms into the crystal, called doping, that liberate extra electrons or holes. In the case of Si, which is in column IV of the periodic table, and hence has four valence electrons for bonding, doping is achieved using either column III elements (boron, aluminum, gallium, or indium), which have three valence electrons, or column V elements (phosphorus, arsenic, or antimony), which have five valence electrons. When an arsenic atom with five valence electrons replaces (substitutes) an Si atom, four of its electrons are used to form covalent bonds with the four neighboring Si atoms. The fifth electron is loosely bound to the arsenic nucleus, and at room temperature is ionized and "donated" to the conduction band. Arsenic is therefore called a donor, and Si becomes an n-type (mostly electrons) semiconductor. Similarly, when a boron atom with three valence electrons substitutes for an Si atom, one of the boron four covalent bonds becomes deficient of one electron. Boron can then accept one electron from the valence band to satisfy the bond requirement, which creates a positively charged hole in the valence band. Boron is therefore called an acceptor, and Si becomes a p-type (mostly holes) semiconductor. In this way the electrical conductivity of semiconductors can be precisely controlled by varying the concentration of donor and acceptor impurities. In practical solid-state devices, typical values of n and p range between 10^{15} and 10^{19} cm^{-3}.

The p-n Junction Diode

The p-n junction is a basic structure used for solid-state device rectification, amplification, and switching, as well as for photocarrier collection in photovoltaic cells. A p-n junction is formed when a p-type semiconductor is metallurgically joined with an n-type semiconductor (Streetman, 1980). Before they are joined, the p-material has a large concentration of holes and very few electrons, whereas the converse is true for the n-material. Upon joining the two materials, holes instantaneously diffuse from the p-side into the n-side and electrons diffuse from the n-side into the p-side. The transport of these carriers constitutes a "diffusion" current from the p-side to n-side; electron current is opposite in direction to electron flow by convention. As shown in Figure 8.13.1, negative acceptor ions are left behind as holes leave the p-side of the junction, creating a negative space-charge region (SCR), and positive donor ions are left behind as electrons leave the n-side of the junction, creating a positive SCR. Consequently, an electric field directed from the positive SCR to the negative SCR results that opposes the further diffusion of electrons and holes; i.e., the electric field creates a drift component of current from the n-side to p-side that opposes the diffusion component. In the absence of any external fields a condition of equilibrium is established, and the net current flow across the junction is zero. As will be discussed, the p-n junction electric field is also responsible for separating and collecting photon-generated carriers in photovoltaic cells.

When a voltage is applied across a p-n junction, the balance between the electron and hole drift and diffusion currents is disturbed and a net current results. Under forward bias, a positive voltage is applied to the p-side relative to the n-side, and the electric field across the junction is reduced; i.e., the electric field associated with the applied voltage subtracts from the zero-bias field. The reduced field enhances hole diffusion from the p-side to the n-side and electron diffusion from the n-side to the p-side, thereby increasing the "positive" current; the transport of current from the p-side to the n-side is positive by convention. Conversely, under reverse bias a negative voltage is applied to the p-side relative to the n-side, and the electric field across the junction increases. Consequently, the diffusion component of current decreases relative to the drift component, and a net "negative" current results across the junction.

The dark current-voltage (I-V) characteristics for an Si p-n junction are generally well described by the ideal Shockley diode equation (Sze, 1981),

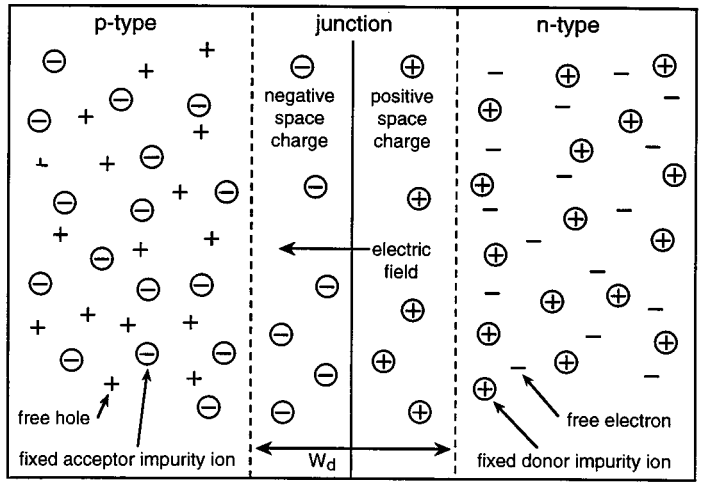

FIGURE 8.13.1 Schematic diagram illustrating an abrupt p-n junction with a unifiorm concentration of donor impurities in the n-region and acceptor impurities in the p-region.

$$I_D = I_o\left[\exp\left(qV/nkT\right) - 1\right] \tag{8.13.1}$$

where I_D is the junction dark current, I_o is the reverse saturation current, V is the forward-bias voltage, n is the diode ideality factor, and T is the absolute temperature. The value of n is ~1.0 when the current is dominated by carrier diffusion, but increases and approaches values of ~2 or greater when other current mechanisms become important, such as carrier recombination or tunneling. In high-quality Si p-n junction photovoltaic cells, the value of n is ~1.0 near the relevant operating voltage. The parameter I_o varies with T and E_g according to

$$I_o = qA\left[D_n n_p/L_n + D_p p_n/L_p\right] \propto T^3 \exp\left(-E_g/kT\right) \tag{8.13.2}$$

where A is the junction area and D_n and D_p, n_p and p_n, and L_n and L_p are the diffusion coefficients, minority carrier densities, and diffusion lengths for electrons and holes, respectively. The value of I_o decreases strongly as E_g increases, which, as will be shown, increases the photovoltage obtainable from a photovoltaic cell.

Cell Operation and Efficiency

Cell Operation. Photovoltaic energy conversion in a p-n junction is a two-step process where free electrons and holes (photocarriers) are generated in the semiconductor via the absorption of solar energy and then simultaneously collected across the junction (Fahrenbruch and Bube, 1983). Consider the schematic of a typical photovoltaic cell shown in Figure 8.13.2 which consists of a p-n junction formed very close to the top surface of the cell. Front metal ohmic contact grid fingers allow solar energy to pass into the absorber layers. The entire top surface is covered with an antireflection coating to minimize reflective losses, and the entire back surface is covered with an ohmic contact. The ohmic contacts form n and p region terminals that transfer (conduct) current from the semiconductor to the external circuit with a negligible amount of voltage drop.

When the photovoltaic cell is exposed to solar radiation, photons with energies greater than E_g (super-band-gap photons) are absorbed in the n and p layers, and free electrons and holes are generated via the breaking of covalent bonds. These electron-hole pairs, or **photocarriers**, are shown in Figure 8.13.1. The energy of the free photocarriers is converted directly into a current and voltage via photocarrier collection by the junction. The absorbed photons effectively contribute an energy E_g to the cell output,

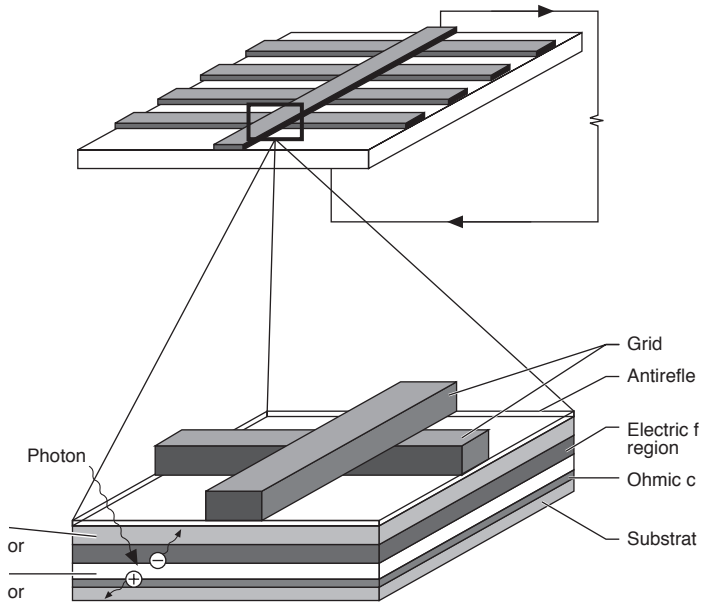

FIGURE 8.13.2 Schematic diagram of a typical p-n junction photovoltaic cell.

and energy greater than E_g is lost as heat. Photons with energies less than E_g (sub-band-gap photons) are transmitted through the cell. After generation, minority photocarriers, that is, holes on the n-side and electrons on the p-side, diffuse toward the edges of the junction due to a gradient of carriers that exists there. If the minority carriers are generated within a diffusion length, L, of the junction, they will reach it and be swept across it by the electric field of the junction. Hence, electrons are swept from the p-side to the n-side and holes from the n-side to the p-side, and thus they are separated. The minority carrier gradient present at the edges of the junction is due to the depletion of minority carriers that results from their transfer across the junction. The diffusion flux of minority carriers toward and across the junction constitutes a light-generated current, I_L, or photocurrent, that is directed from the n-side to the p-side of the cell. The build-up of positive holes on the p-side and negative electrons on the n-side gives rise to a **photovoltage** across the junction. The polarity of both the photovoltage and photocurrent is identical to that of a battery, and power is delivered from the junction to the external circuit.

Cell Efficiency. In order to derive the solar conversion efficiency, it is convenient to model the photovoltaic cell as an ideal p-n diode in parallel with a **light-generated** (constant) **current** source, I_L, as shown in the equivalent circuit of Figure 8.13.3. Parasitic series and shunt resistance losses, R_s and R_{sh}, respectively, are also shown, where R_s is due to ohmic contact and semiconductor resistances, and R_{sh} is due to defect-related carrier recombination and/or tunneling phenomena (Stirn, 1972). A qualitative expression for I_L is given by Tada et al. (1982):

$$I_L = qAG\left(L_n + W_d + L_p\right) \tag{8.13.3}$$

where G is the photocarrier generation rate in carriers/cm^3-sec due to solar photon absorption, which depends on E_g and the photon energy (wavelength) and intensity (concentration), and W_d is the sum of the negative and positive SCR widths. As mentioned, I_L is directed from the n-side to the p-side. In

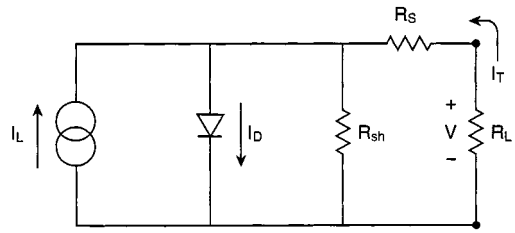

FIGURE 8.13.3 Schematic of equivalent circuit model for a p-n photovoltaic cell.

contrast, the dark diode current given by Equation (8.13.1) is directed oppositely from the p-side to the n-side. The **dark current** is due to the forward-bias photovoltage that appears across the cell p-n junction when it is illuminated. Thus, the dark current opposes the light current. In the ideal case, that is, when $R_s = 0$ and $R_{sh} = \infty$, the total forward current, I_T, is given by

$$I_T = I_D - I_L = I_o\left[\exp(qV/nkT) - 1\right] - I_L \tag{8.13.4}$$

A plot of dark and light current-voltage (I-V) curves resulting from Equations (8.13.1) and (8.13.4), respectively, is shown in Figure 8.13.4 for a typical p-n solar cell. Under illumination, the forward-bias dark I-V curve is displaced downward into the fourth quadrant by the **photocurrent**, $\boldsymbol{I_L}$. It is noted from Figure 8.13.3 that the voltage drop across the load resistance, R_L, is $V = -I_T R_L$. Under short-circuit conditions, that is, when the n and p terminals are tied to each other, R_L is negligible. The resulting voltage drop across the p-n junction will also be negligible, and from Equation (8.13.1), $I_D \approx 0$. As shown in Figure 8.13.4, the resultant current is termed the **short-circuit current**, $\boldsymbol{I_{sc}}$, or $I_T = -I_{sc} = -I_L$. As the value of R_L increases, a voltage appears across the junction, $V = -I_T R_L$, called the **photovoltage**, and I_D increases in accordance with Equation 8.13.1. Under this condition the cell is operating in the fourth quadrant of the I-V characteristic (i.e., the junction voltage is positive and the current is negative), and, consequently, the cell delivers power (product of the current and voltage) to R_L. As the value of R_L continues to increase, so too does V and I_D. When the value of R_L approaches infinity, that is, under open-circuit conditions, I_D approaches I_L and I_T goes to zero. The resulting **open-circuit voltage**, $\boldsymbol{V_{oc}}$, is shown in Figure 8.13.4. V_{oc} can be obtained by setting $I_T = 0$ in Equation (8.13.4) and solving for V. For $V \gg kT/q$,

$$V_{oc} = nkT/q \ln\left[I_L/I_o\right] \tag{8.13.5}$$

Thus, the operating point on the I-V curve in the fourth quadrant can be swept from (I_{sc}, 0) to (0, V_{oc}) by varying the value of R_L. When the optimum load is chosen (i.e., $R_L \approx V_{oc}/I_{sc}$), approximately 80% of the product $I_{sc}V_{oc}$ can be extracted as useful power as shown by the shaded maximum-power rectangle in Figure 8.13.4. Also shown in Figure 8.13.4 are the parameters I_m and V_m, which correspond to values of current and voltage, respectively, that yield the maximum cell power, P_m, where $P_m = I_m V_m$. The knee that appears at P_m is due to the parasitic effects of R_s and R_{sh}. The curvature of the knee at P_m is described by the **fill factor**, **FF**, where

$$\text{FF} = I_m V_m / I_{sc} V_{oc} \tag{8.13.6}$$

The photovoltaic cell **conversion efficiency**, η, is defined as

$$\eta = I_m V_m / P_{in} A$$

or

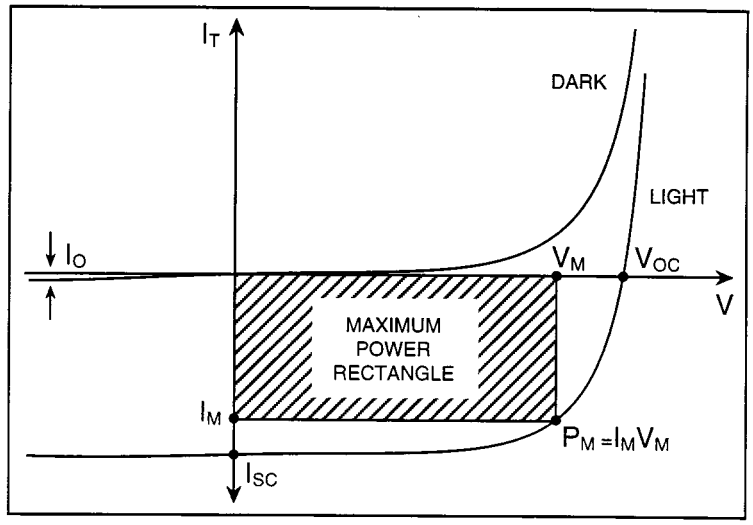

FIGURE 8.13.4 Typical dark and light current-voltage characteristics for a p-n photovoltaic cell.

$$\eta = FF\, I_{sc} V_{oc} / P_{\text{in}} \tag{8.13.7}$$

where P_{in} is the incident power in W/m^2 equal to the sum in energy of the incident photons per time per area. Values for V_{oc}, I_{sc}, FF, and η can be obtained in the laboratory under various air mass conditions from light *I-V* curves measured using a carefully controlled (calibrated) light source to illuminate the cell.

Cell Material vs. Efficiency

The optimum value of material E_g for solar photovoltaic conversion is ~1.0 to 1.5 eV. To understand how the choice of cell material affects conversion efficiency, an ideal expression can be derived using Equation 8.13.4 for the theoretical conversion efficiency. The output power can be expressed as (Henry, 1980)

$$P = IV = I_o V\left[\exp\left(qV/nkT\right) - 1\right] - I_L V \tag{8.13.8}$$

The maximum output power is obtained when $dP/dV = 0$, and an expression for I_m and V_m can be obtained from Equation (8.13.8) and multiplied to give P_m, where

$$P_m = I_m V_m \approx I_L\left[V_{oc} - kT/q \ln\left(qV_m/kT + 1\right) - kT/q\right] \tag{8.13.9}$$

In practical cells, values for V_m and V_{oc} are typically $^1/_2E_g/q$ to $^2/_3E_g/q$. Thus, for materials with $E_g \sim 1 - 2$ eV, the quantity in the large brackets of Equation (8.13.9) becomes ~V_{oc}, and the factors that determine I_L and V_{oc} also determine P_m. From Equations (8.13.2) and (8.13.5), it is clear that V_{oc} increases with E_g through the reduction in I_o. In contrast, as E_g increases, I_L decreases because a smaller portion of the solar spectrum is energetic enough to be absorbed; i.e., I_L is the product of q and the number of available photons with energy greater than E_g. Hence, for a given solar spectrum there is an optimum value of E_g that maximizes the product of V_{oc} and I_L. A plot of ideal AM1 conversion efficiency vs. E_g is shown in Figure 8.13.5 for "one sun" (925 W/m^2) and "1000 suns" (925 kW/m^2) concentrations (Henry, 1980). The efficiency curves were obtained using Equations (8.13.1) through (8.13.7) at 300 K. A maximum in efficiency occurs for $E_g \sim 1.0 - 1.5$ eV.

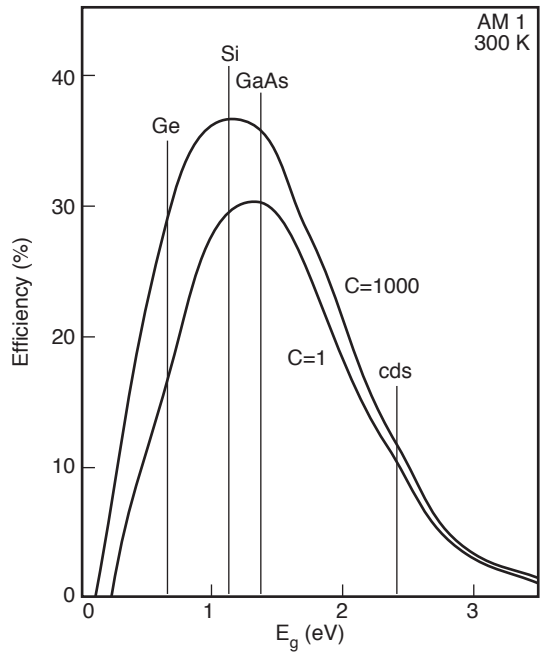

FIGURE 8.13.5 Theoretical AM1 efficiency vs. semiconductor band gap E_g for an ideal photovoltaic cell under 1 sun and 1000 suns concentrations.

Manufacture of Cells and Panels

There are basically five important solar cell design concepts, and each offers a trade-off between efficiency and cost: (1) Large-area single-crystal planar cells, typically 1 × 1 cm² to 6 × 6 cm², yield high efficiencies under normal light conditions, 2) single-crystal small-area concentrator cells, typically less than 1 × 1 cm², are potentially less costly and yield higher efficiencies under concentrated light, i.e., concentration ratios of 20 to 1000 are typical; (3) more-complex single-crystal multijunction cells yield the highest efficiencies measured to date, but are substantially more expensive; (4) cells made from polycrystalline materials are less expensive than single-crystalline cells, but are less efficient; and (5) cells made from thin film amorphous materials provide the lowest-cost approach yet, but are generally less efficient than polycrystalline cells.

A typical 15% 4 × 4 cm² photovoltaic cell produces only ~0.25 W under AM1.5 conditions. Therefore, individual cells must be electrically wired together to form larger submodules or panels to increase the total output power. The cells can be connected in series to increase the total voltage or in parallel to increase the current. The modular nature of photovoltaic power allows the design of systems that can deliver electrical power from a few watts to many megawatts. In terrestrial applications the cells are typically supported and held in place with a rigid substrate, i.e., typically aluminum, Plexiglas, fiberglass, or glass, and are encapsulated with glass or a polymeric material; in space applications the support structure may be rigid or flexible, and the cells are protected from the space environment with quartz cover slides. The electrical power generated by the cells is conducted to an electrical load or storage battery. Metal interconnects soldered to the ohmic contacts of the cells conduct electrical current from one cell to the next. Current is then conducted from the network of series- and parallel-connected cells by wires to a distribution terminal "bus" that transfers the power to either the load or battery.

Single-Crystal Cells. The p-n photovoltaic cells made from **single-crystal** Si dominate in space and terrestrial applications because of their high efficiency and reliability. The formation of single-crystal p-

type Si results from the selective cooling of pure molten Si to form large cylindrical crystal ingots, called boules, from which thin wafers are sliced and polished. The p-type impurities, usually boron, are added to the melt, to give the desired impurity concentration. A large-area p-n junction is then formed by diffusion of n-type impurity atoms, usually phosphorus. Front and back metal ohmic contacts and an antireflection coating are then formed using standard photolithography thermal evaporation or sputtering techniques (Sze, 1985). The resulting cell structure is shown in Figure 8.13.2, and typical cell areas range from 1 to 36 cm^2. Different semiconductors absorb sunlight more efficiently than others, described by a factor called the absorption coefficient. Si has a relatively small absorption coefficient compared with other materials, such as InP, GaAs, and amorphous-Si, and consequently requires an absorption layer thickness of ~100 μm to maximize conversion efficiency. Conventional Si cells have a thickness on the order of 250 μm, but can be chemically or mechanically polished to a thickness of 100 μm.

Single-crystal III-V photovoltaic cells, such as InP and GaAs, are made from elements in the III and V columns of the periodic table. The band gaps of these cells, 1.35 and 1.42 eV, respectively, are close to the optimum value. These materials involve the growth of single-crystal semiconductor layers upon a single-crystal semiconductor substrate. This technique is called epitaxy and it provides a method to produce both n-type and p-type layers to form the p-n junction. Epitaxial growth of n and p layers is required for InP and GaAs because diffusion of impurities at high temperatures is confounded by the high vapor pressure of the material. The formation of ohmic contacts and antireflection coating employ the same techniques as used for Si cells. The required absorption layer thickness for these cells is only a few microns because of their large absorption coefficients. However, issues concerning yield and mechanical strength limit their minimum thickness to ~100 μm The best reported efficiencies for single-crystal Si, GaAs, and InP cells under AM1.5 conditions are 24, 25, and 22%, respectively (Green et al., 1995).

Polycrystalline Cells. In the case of **polycrystalline** Si cells, molten Si is directly deposited into either cylindrical or rectangular ingots. As the material solidifies, individual crystalline regions form that are separated by grain boundaries which contain large numbers of structural defects. When the cell is illuminated, these defects capture a portion of the light-generated electron-hole pairs through recombination processes before they can reach the junction and be collected. Thus, the grain boundaries diminish the light-generated current and overall efficiency of the cell. However, polycrystalline silicon cells are sufficiently inexpensive to be commercially viable (Stone, 1993). An area that requires improvement is the slicing of polycrystalline ingots, where yields as low as 50% are common. An approach that eliminates the expense of sawing and polishing altogether is the growth of polycrystalline Si directly into the form of thin ribbons using a technique called edge-defined film-fed growth (EFG) (Fahrenbruch and Bube, 1983). In this approach, a carbon die with a slot-shaped aperture is immersed in a crucible of molten Si. The liquid Si wets the die and flows through the slot where it cools and is pulled to form a thin ribbon. This material also has high crystalline defect densities, but has good overall yields. An additional approach involves the growth of films of nearly single-crystal quality, where two parallel supporting dendrites form the boundaries of a web or ribbon pulled from a supercooled melt of Si. The best efficiency for polycrystalline Si cells under AM1.5 conditions is ~18%; that for Si cells grown by the EFG technique is 14%; and that for Si dendritic web cells is 15.5% (Stone, 1993). It is important to note that although these lower-cost films yield lower cell efficiencies compared with single-crystal cells, the cost of cells depends on the cost of the starting material and the cost per watt is more important than efficiency (Zweibel, 1995).

Thin Film Cells. Thin films cells provide an even lower-cost (and lower-efficiency) approach because they require a very small amount of semiconductor. An excellent review on thin film photovoltaic technologies, particularity on present and future cost issues, is given by Zweibel (1995). The general approach involves depositing only a few microns of material on a low-cost substrate using various vacuum deposition techniques, although a multitude of other deposition techniques have also been demonstrated. The top thin film cell candidates are amorphous Si, a-Si, cadmium telluride, CdTe, and copper indium diselenide, CIS (and related alloys). The highest reported thin film AM1.5 efficiencies

are 17% for CIS, followed by 15.8% for CdTe, and ~11% for a-Si (Zweibel, 1995). However, the relative level of maturity of each design for commercial application must be put into perspective. While the best CIS cell efficiency is quite high, the best CIS square foot panel efficiency reported back in 1988 was, and still is today, only 11%. Significant manufacturing problems have plagued the CIS cell, and currently it is still not commercially available. CdTe is believed to be the easiest of the thin film cells to fabricate, and probably represents the closest to large-scale commercialization. Two U.S. companies have publicly announced CdTe manufacturing plants, and commercial efficiencies are likely to be in the range of 6 to 8% in the first plants. The future of a-Si cells is currently believed to be limited if it cannot overcome a 10% efficiency at the module level. Development problems include electrochemical instability to light that results in a 20 to 40% degradation. However, it appears that the use of multijunction thin film a-Si layers may solve the problem, and modules of 7 to 9% are expected in the near term.

Concentrator Cells. Photovoltaic modules are typically either of the flat plate or concentrator configuration. Flat plate modules can be fixed with respect to the sun or mounted to track the sun in one or two axis. Concentrator modules use large-area mirrors or lenses to concentrate sunlight onto smaller-area cells. Concentrator cells operate at higher efficiencies. However, concentrator modules require one- or two-axis tracking which adds system complexity and cost that generally offsets the module efficiency and lower area cost benefits. The increase in conversion efficiency with illumination intensity is shown in the 1000-sun concentration curve of Figure 8.13.5. Values for I_L increase linearly with concentration through the factor G in Equation (8.13.3) and V_{oc} increases logarithmically with concentration through I_L in Equation (8.13.5). Under solar concentration of "20 suns" or greater, a significant amount of cell heating can occur. While J_{sc} increases slightly with increasing temperature, values of V_{oc} and FF drop strongly. Thus, on adequate heat sink or active cooling is required at high concentrations. The reported AM1.5 efficiency for Si cells increases from 24 to 26.5% under a concentration of 255; and that for GaAs cells increases from 25 to 27.6% under a concentration of 140 (Green et al., 1995).

Multijunction Cells. Another approach to increase photovoltaic cell efficiency is through the use of multijunction tandem cells. The simplest multijunction cell is a two-junction, two-terminal device. In this design, a high-band-gap (E_{g1}) p-n junction is vertically stacked (mechanically) or epitaxially grown atop a bottom lower-band-gap (E_{g2}) p-n junction as shown in Figure 8.13.6. The top junction absorbs photons with energy $\geq E_{g1}$, and the bottom junction absorbs photons with energy E, where $E_{g1} > E \geq E_{g2}$, that passed through the top cell. This increases the utilization of the solar spectrum, since the excess energy of the high-energy photons is not wasted. The values of E_{g1} and E_{g2} must be chosen to achieve maximum solar absorption and current matching; i.e., the two cells must generate equal currents when illuminated. The band gap combinations of ~0.7 and 1.4, 1.0 and 1.4, 1.1 and 1.4, and 1.4 and 1.9 eV are current matched, where E_g for GaSb, $CuInSe_2$, Si, GaAs, AlGaAs, and $GaInP_2$ are ~0.7, 1.0, 1.1, 1.4, and 1.9 eV, respectively. Multijunction concentrator cells have reported efficiencies in excess of 30% (Green, 1995).

Design of a Photovoltaic Generating System

A schematic diagram depicting the basic components of a typical photovoltaic power generation system is shown in Figure 8.13.7 (Pulfrey, 1978). The system includes a photovoltaic array that consists of many smaller submodules, each containing many hundreds or thousands of photovoltaic cells. The DC output power from the array is controlled by a power conditioning unit that contains an inverter for developing AC power and an input power tracking device to maintain the optimal array load to achieve maximum output power. Power is directly fed to the electrical load and/or storage system by the conditioning unit. The storage system is needed to save energy when power is generated in excess of the immediate demand, or when the load demand exceeds the immediate generation level. Total photovoltaic power system efficiency is the product of the efficiencies of the individual components. Typical efficiencies for the power conditioning unit (determined by the inverter) and energy storage system are about 95% and 50-80%, respectively. Thus, an array efficiency of 10% would result in a total system

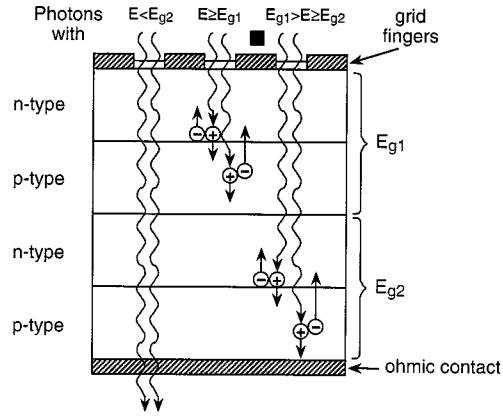

FIGURE 8.13.6 Schematic diagram of a multijunction (two-junction) photovoltaic cell under illumination.

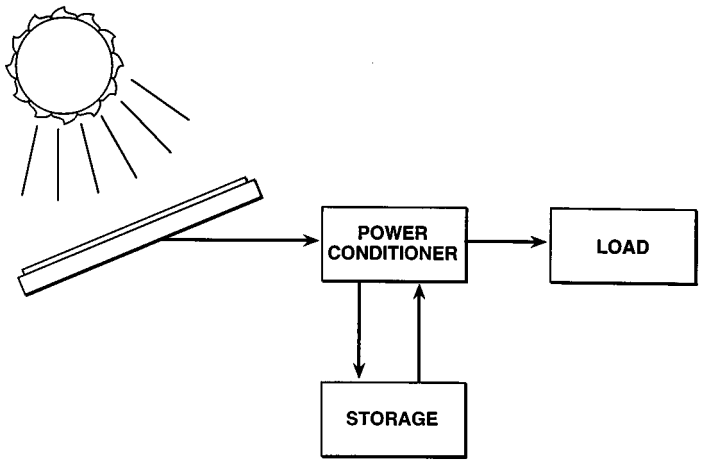

FIGURE 8.13.7 Schematic diagram depicting the basic components of a typical photovoltaic power system.

efficiency of about 5 to 8%, and a total system efficiency of 10% would require an array efficiency in excess of 13%.

Defining Terms

Band gap (E_g): The difference in energy between the energy level of the bottom of the conduction band and the energy level of the top of the valence band.

Conduction band: A range of allowable energy states in a solid in which electrons can move freely.

Conversion efficiency (η): The ratio of the available power output photovoltaic cell to the total incident radiant power.

Dark current: Any current that flows through the p-n junction in the absence of external irradiation.

Fill factor (ff): The ratio of the maximum photovoltaic cell output power to the product of the open-circuit voltage and short-circuit current.

Light-generated current (I_L): The electrical current obtained from an illuminated p-n junction resulting from the collection of photocarriers across the junction.

Open-circuit voltage (V_{oc}): The voltage obtained across the terminals of an illuminated p-n photovoltaic cell under open-circuit conditions.

Photocarriers: Electrons and holes generated within a semiconductor via the absorption of photon energy.

Photocurrent: Synonymous with light-generated current.

Photovoltaic effect: The production of a voltage difference across a p-n junction resulting from the absorption of photon energy.

Photovoltage: The voltage resulting from the photovoltaic effect.

Polycrystalline: A material characterized by an array or agglomerate of small single-crystal sections of various crystal orientations separated from one another by grain boundaries, which are localized regions of very severe lattice disruptions and dislocations.

Short-circuit current (I_{sc}): The electrical current measured through the terminals of an illuminated p-n photovoltaic cell under short-circuit conditions.

Single crystal: A material characterized by a perfect periodicity of atomic structure; the basic arrangement of atoms is repeated throughout the entire solid.

Valence band: A range of allowable energy states in a solid crystal in which lie the energies of the valence electrons that bind the crystal together.

Introduction

A *fuel cell* is an electrochemical device in which a fuel and an oxidant react in such a controlled manner that the chemical energy of reaction is converted directly into electrical energy. Ordinarily, a fuel reacts violently with an oxidant in a combustion reaction resulting in the release of heat of combustion. The heat of combustion can, then, be converted into electrical energy via mechanical work with the constraint of the second law of thermodynamics. The overall efficiency of the series of conversion processes is of the order of 40%. A fuel cell bypasses these processes resulting in potential efficiencies of the order of 80%. As an example, when hydrogen is burned in an atmosphere of oxygen it results in the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O + \Delta H \quad (\text{heat of reaction}) \tag{8.13.10}$$

In this reaction, two hydrogen atoms bond with an oxygen atom by sharing their electrons with the outermost orbit of oxygen, which becomes full, resulting in a stable structure.

The reactants H_2 and O_2 may be combined to form the same product (H_2O) by first stripping the electrons away from the hydrogen atoms and allowing the electrons to pass through an external circuit before combining with oxygen. Table 8.13.1 gives typical electrochemical reactions in fuel cells.

$$H_2 \rightarrow 2H^+ + 2e^- \quad (\text{electrons}) \tag{8.13.11}$$

$$2H^+ + O + 2e^- \rightarrow H_2O \tag{8.13.12}$$

Figure 8.13.8 shows a schematic of an arrangement that would allow the above reaction to proceed.

TABLE 8.13.1 Electrochemical Reactions in Fuel Cells

Fuel Cell	Anode Reaction	Cathode Reaction	Overall Reaction
Proton exchange	$H_2 \rightarrow 2H^+ + 2e^-$	$^1/_2O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Alkaline	$H_2 + 2(OH)^- \rightarrow 2H_2O + 2e^-$	$^1/_2O_2 + H_2O + 2e^- \rightarrow 2(OH)^-$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Phosphoric acid	$H_2 \rightarrow 2H^+ + 2e^-$	$^1/_2O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Molten carbonate	$H_2 + CO_3^- \rightarrow H_2O + CO_2 + 2e^-$ $CO + CO_3^- \rightarrow 2CO_2 + 2e^-$	$^1/_2O_2 + CO_2 + 2e^- \rightarrow CO_3^-$	$H_2 + {}^1/_2O_2 + CO_2$ (cathode) $\rightarrow H_2O + CO_2$ (anode)
Solid oxide	$H_2 + O^- \rightarrow H_2O + 2e^-$ $CO + O^- \rightarrow CO_2 + 2e^-$ $CH_4 + 4O^- \rightarrow 2H_2O + CO_2 + 8e^-$	$^1/_2O_2 + 2e^- \rightarrow O^-$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$ $CO + {}^1/_2O_2 \rightarrow CO_2$ $CH_4 + 2O_2 \rightarrow H_2O + CO_2$

In order for the above reactions to occur according to the schematic of Figure 8.13.8:

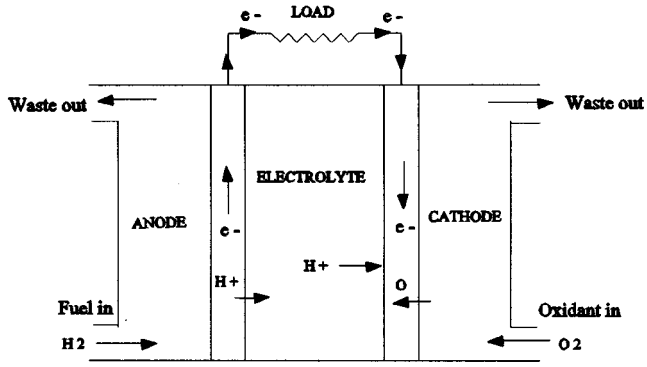

FIGURE 8.13.8 Conceptual schematic of a hydrogen fuel cell.

1. Electrodes must be porous to let the fuel and electrolyte penetrate.
2. The electrolyte must be permeable to H^+ and $(OH)^-$ ions.
3. Electrode materials must be catalysts for the reaction (Pt, Ni, etc.).

In 1839, William Grove, an English investigator, constructed a chemical battery in which he noticed that the water-forming reaction of hydrogen and oxygen generated an electrical current. However, it was not until 50 years later that two English chemists, Ludwig Mond and Carl Langer, developed a device they actually called a fuel cell (Angrist, 1982). There has been a strong resurgence in research and development of fuel cells in the last four decades.

Thermodynamic Performance

The energy released or needed in any chemical reaction (ΔH) is equal to the difference between the enthalpy of formation of the products and the reactants.

$$\Delta H = \sum (\Delta H)_{\text{products}} - \sum (\Delta H)_{\text{reactants}} \tag{8.13.13}$$

In an exothermic reaction the change in enthalpy of formation (ΔH) is negative. Table 8.13.2 gives values of ΔH for various compounds at 25°C at 1 atm. All naturally occurring elements have a ΔH value of zero.

TABLE 8.13.2 Enthalty of Formation ΔH^0 and Gibbs Free Energy ΔG^0 of Compounds at 1 atm and 298 K

Compound or Ion	Enthalpy of Formation, ΔH^0, J/kg · mol	Gibbs Free Energy ΔG^0, J/kg · mol
CO	-110.0×10^6	-137.5×10^6
CO_2	-394.0×10^6	-395.0×10^6
CH_4	-74.9×10^6	-50.8×10^6
Water	-286.0×10^6	-237.0×10^6
Steam	-241.0×10^6	-228.0×10^6
C, H_2, O_2	0	0
O(g)	$+249.2 \times 10^6$	$+231.8 \times 10^6$
H(g)	$+218.0 \times 10^6$	$+203.3 \times 10^6$

Source: Adapted from Wark, K., *Thermodynamics*, McGraw–Hill, New York, 1988. With permission.

In a combustion reaction all of the change in the enthalpy of formation (ΔH) is converted to heat and is, therefore, called the higher heating value (HHV).

$$-(\Delta H)_{\text{reaction}} = \text{HHV of fuel} \tag{8.13.14}$$

For example, for complete combustion of hydrogen according to the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \quad (\text{liquid}) \tag{8.13.15}$$

Change in the enthalpy of formation is

$$\Delta H = \Delta H_{H_2O} - \Delta H_{H_2} - \frac{1}{2}\left(\Delta H_{O_2}\right) = \left(-286 \times 10^6\right) - 0 - 0 = -286 \times 10^6 \ \text{J/kg} \cdot \text{mol } H_2 \tag{8.13.16}$$

In a fuel cell, most of ΔH can be converted to electricity directly. The part that cannot be converted to work directly gets converted into heat. The minimum amount that must be converted to heat is represented by reversible heat transfer $\int T\,dS$. If a fuel cell operates isothermally, the maximum amount of electrical work (W_e) produced is given by

$$W_e, \max = \Delta H - T\Delta S \tag{8.13.17}$$

In an irreversible reaction

$$W_e, \max < \Delta H - T\Delta S \tag{8.13.18}$$

Gibbs free energy, G, is given by:

$$G = H - TS \tag{8.13.19}$$

Therefore, in a reversible isothermal process

$$\Delta G = \Delta H - T\Delta S = W_e, \max \tag{8.13.20}$$

The actual electrical work in a fuel cell is given by

$$W_e \leq \Delta G \quad (\text{change in Gibbs free energy for the reaction}) \tag{8.13.21}$$

$$\Delta G_{\text{reaction}} = \sum (\Delta G)_{\text{products}} - \sum (\Delta G)_{\text{reactants}} \tag{8.13.22}$$

The electrical work, W_e, is associated with the work of electrons passing through an external resistance. 1 g · mol of electrons is equal to Avogadro's number (6.022×10^{23}) and the charge of these electrons is equal to 96,439 C which is called a **faraday** (F). If n g · mols of electrons are generated and E is the internal reversible cell voltage, then the maximum electrical work is given by

$$W_e, \max = \Delta G = -nFE \tag{8.13.23}$$

denoting values under standard conditions (25°C, 1 atm) by superscript 0, we have

$$\Delta G^0 = -nFE^0 \tag{8.13.24}$$

Values of G^0 for various compounds are given in Table 8.13.2. For fuel cell reactions as below:

$$aA + bB \rightarrow cC + dD \tag{8.13.25}$$

if the reactants (A and B) and the products (C and D) are assumed to be ideal gases with partial pressures P_A, P_B, P_C, and P_D the change in Gibbs free energy ΔG and the internal reversible cell voltage, E, are given by

$$\Delta G = \Delta G^0 + RT \ln \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b} \tag{8.13.26}$$

$$E = E^0 + RT \ln \frac{(P_A)^a (P_B)^b}{(P_C)^c (P_D)^d} \tag{8.13.27}$$

Equation 8.13.27 is also called the Nernst equation.

Table 8.13.3 gives Nernst equations for the electrochemical reactions listed in Table 8.13.1.

TABLE 8.13.3 Fuel Cell Reactions and the Corresponding Nernst Equations

Cell Reactions	Nernst Equation
$H_2 + {}^1/_2O_2 \rightarrow H_2O$	$E = E^0 + (RT/2F)\ln[P_{H_2}(P_{O_2})^{1/2}/P_{H_2O}]$
$H_2 + {}^1/_2O_2 + CO_2(c) \rightarrow H_2O + CO_2(a)$	$E = E^0 + (RT/2F)\ln[P_{H_2}(P_{O_2})^{1/2}(P_{CO_2})_c/(P_{H_2O}(P_{CO_2})_a]$
$CO + {}^1/_2O_2 \rightarrow CO_2$	$E = E^0 + (RT/2F)\ln[P_{CO}(P_{O_2})^{1/2}/P_{CO_2}]$
$CH_4 + 2O_2 \rightarrow H_2O + CO_2$	$E = E^0 + (RT/8F)\ln[P_{CH_4}(P_{O_2})^2/P_{H_2O}^2 P_{CO_2}]$

Note: (a) = anode; (c) = cathode; E = equilibrium potential.

Source: Hirschenhofer, J.H. et al., *Fuel Cells, A Handbook,* Gilbert/Commonwealth, Morgantown, WV, 1994. With permission.

The maximum conversion efficiency of a fuel cell is given by

$$\eta_{max} = \frac{W_e,max}{\Delta H} = \frac{\Delta G}{\Delta H} = 1 - \frac{T\Delta S}{\Delta H} = \frac{-nFE}{\Delta H} \tag{8.13.28}$$

As current is drawn through an external circuit, the actual voltage drop (V) will be less than the internal cell voltage (E). Therefore, the actual conversion efficiency of a fuel cell will be lower than above and may be calculated as

$$\eta_{actual} = \frac{-nFV}{\Delta H} = \frac{ItV}{\Delta H} \tag{8.13.29}$$

where I is the current drawn through an external circuit for a period of time, t.

Types of Fuel Cells

Fuel cells are primarily classified by type of electrolyte, since many other characteristics, particularly operating temperatures, are limited by the electrolyte properties (Hirschenhofer et al., 1994). Major fuel cells under active development at this time are the **phosphoric acid fuel cell (PAFC)**, the **molten carbonate fuel cell** (**MCFC**), the **solid oxide fuel cell** (**SOFC**), the **polymer electrolyte fuel cell** (**PEFC**), and the **alkaline fuel cell** (**AFC**).

Phosphoric Acid Fuel Cell. PAFC uses concentrated phosphoric acid (H_3PO_4) as the electrolyte, hydrogen as the fuel, and oxygen (from air) as the oxidant. Table 8.13.4 provides information on the electrodes and other materials for PAFC as well as other fuel cells.

The reactions take place at the porous electrodes on highly dispersed electrocatalyst Pt particles supported on carbon black and a polymeric binder, usually polytetrafluoroethylene (PTFE) (about 30 to 50% by weight) (Kinoshita et al., 1988; Hirschenhofer et al., 1994). A porous carbon paper substrate provides structural support for the electrocatalyst and serves as the current collector. A typical carbon paper electrode impregnated with the electrocatalyst has a porosity of about 60%, consisting of micropores of about 34 Å diameter and macropores of 3 to 50 μm diameter.

Dipolar plates (usually graphite) are used to separate the individual cells and electrically connect them in series in a fuel cell stack. In PAFC stacks, provisions are included to remove the waste heat, by liquids (usually water) or gases (usually air) which flow through channels provided in the cell stack.

Molten Carbonate Fuel Cells. MCFCs use as electrolytes mixtures of molten carbonates of lithium (Li_2CO_3), potassium (K_2CO_3), and sodium (Na_2CO_3) in proportions as shown in Table 8.13.4. The operating temperature of the cell (~650°C) is higher than the melting temperature of the carbonate electrolytes. Besides H_2 (fuel) and O_2 (oxidant from air) the cell uses CO_2 which transfers from the cathode to the anode according to the reactions in Table 8.13.1.

According to the reactions, 1 g · mol of CO_2 is transferred along with 2 g · mol of electrons ($2F$). The reversible potential for an MCFC, taking into account the transfer of CO_2, is given by the Nernst equation in Table 8.13.3.

It is usual practice to recycle the CO_2 generated at the anode to the cathode where it is consumed. An early process used to fabricate electrolyte structures involved hot processing mixtures of $LiAlO_2$ and alkali carbonates at temperatures slightly below the melting point of carbonates. These electrolyte structures had problems of void spaces, nonuniformity of microstructure, poor mechanical strength, and high iR drop. To overcome these problems, processes have been developed recently that include tape casting (Man et al., 1984; Hirschenhofer et al., 1994) and electrophoretic deposition (Baumgartner et al., 1985; Hirschenhofer et al., 1994).

Increasing the operating pressures results in enhanced cell voltages. Increasing the operating temperature above 550°C also enhances the cell performance. However, beyond 650°C the gains are diminished and the electrolyte loss and material corrosion are increased. Therefore, 650°C is about the optimum operating temperature.

Solid Oxide Fuel Cell. SOFCs offer a number of advantages over MCFCs for high-temperature operation, since there is no liquid electrolyte. Solid electrolyte allows flexibility in cell shape design based on application. Cells of several shapes, as shown in Figure 8.13.9, are being developed. Because of the high temperature of operation (~1000°C) carbon monoxide (CO) and hydrocarbons such as methane (CH_4) can be used as fuels. At 1000°C, these fuels can easily produce H_2 that is used at the anode by steam reforming and water-gas reactions as

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (\text{water-gas}) \tag{8.13.30}$$

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad (\text{steam reforming}) \tag{8.13.31}$$

Because of very high operating temperatures the choice of cell materials is limited by (1) chemical stability in oxidizing and reducing atmosphere; (2) chemical stability of contacting materials; and (3) conductivity and thermomechanical compatibility. A detailed description of the current status is given by Minh (1991; 1993) and Appleby and Foulkes (1989). Present SOFC designs make use of thin film wall concepts where films of electrodes, electrolyte, and interconnect material are deposited on each other and sintered to form cell structure. Electrochemical vapor deposition (EVD) is now used to deposit thin layers.

TABLE 8.13.4 Cell Components for Various Fuel Cells

Component	PAFC	MCFC	SOFC[b]	PEFC	AFC
Anode	• PTFE-bonded Pt/C • Vulcan XC-72[a] • 0.1 mg Pt/cm^2	• Ni-10 wt% Cr • 3–6 μm pore size • 50–70% initial porosity • 0.5–1.5 mm thickness • 0.1–1 m^2/g	• Ni/ZrO_2 cermet[c] (30 mol% Ni) • Deposit slurry • 12.5 × 10^{-6} cm/cm °C • ~150 μm thickness • 20–40% porosity	• 10% Pt thin film	• Dual Porosit Ni • 16 μm max pore on electrolyte side • 30 μm pore on gas side
Cathode	• PTFE-bonded Pt/c • Vulcan XC-72[a] • 0.5 mg Pt/cm^2	• Lithiated NiO • 7–15 μm pore size • 60–65% after lithiation and oxidation • 70–80% initial porosity • 0.5–0.75 mm thickness • 0.5 m^{2}g	• Sr-doped lanthanum manganite (10 mol% Sr) • Deposit slurry, sinter • ~1 mm thickness • 12 × 10^{-6} cm/cm °C expansion from room temperature to 1000°C[d] • 20–40% porosity	• 10% Pt thin film	• Porous lithinated NiO
Electrode support	• Carbon paper	—	—	• Carbon paper with Teflon coating on one side	
Electrolyte support	• PTFE-bonded SiC	• γ-$LiAlO_2$ • 0.1–12m^2/g • 0.5 mm thickness	—	—	—
Electrolyte[a]	• 100% H_3PO_4	• 62 Li-38 K • 50 Li-50 Na • 50 Li-50 K • Tape cast • 0.5 mm thickness	• Yttria-stabilized ZrO_2 (8 mol% Y) • EVD[d] • 10.5 × 10^{-6} cm/cm °C expansion from room temperature to 1000°C[d] • ~40 μm thickness	• Proton conducting membrane of perfluoro sulfonic acid polymer	• KOH (45% to 85%)

[a] Conductive oil furnace black, product of Cabot Corp. Typical properties: 002 d-spacing of 3.6 Å by X-ray diffusion, surface area of 220 m^2/g by nitrogen adsorption, and average particle size of 30 μm by electron microscopy.

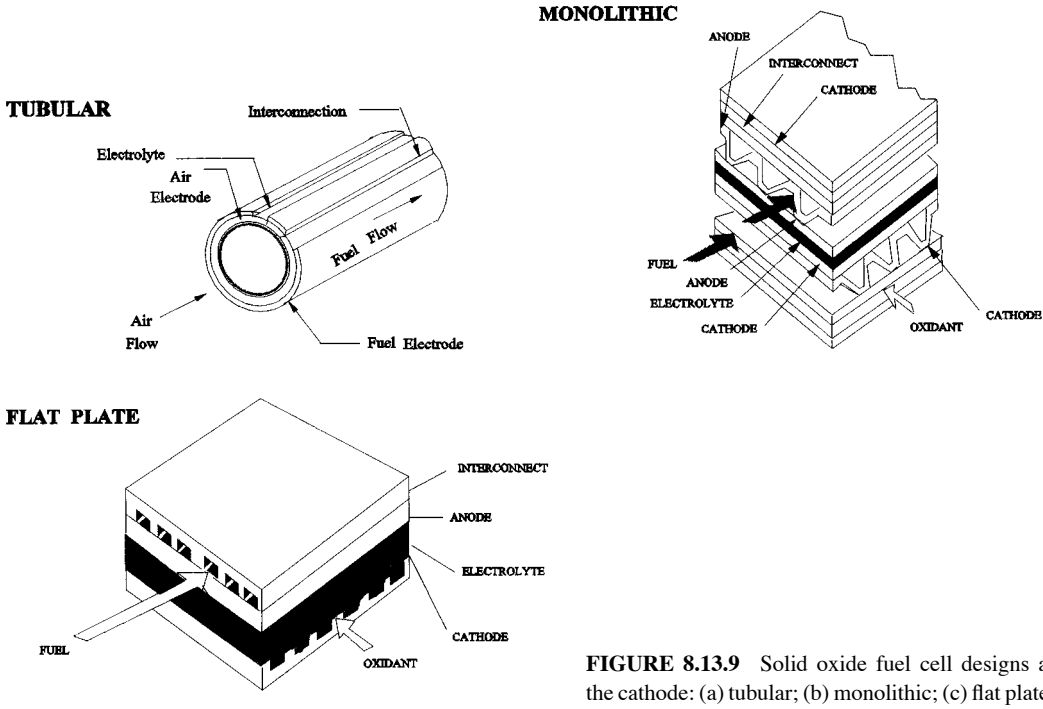

FIGURE 8.13.9 Solid oxide fuel cell designs at the cathode: (a) tubular; (b) monolithic; (c) flat plate.

Increasing pressure and temperature enhances the performance of SOFC.

Polymer Electrolyte Fuel Cell. The basic cell consists of a proton-conducting membrane such as perfluoro sulfonic acid polymer sandwiched between two Pt-impregnated porous electrodes. The backs of the electrodes are made hydrophobic by coating with Teflon®, which provides a path for gas to diffuse to the catalyst layer.

The electrochemical reactions for PEFC are similar to PAFC as given in Table 8.13.1.

The protons from the anode diffuse through the membrane with the help of water molecules soaked in the membrane. The cell operates at low temperature (80°C) and can have very high current densities. Therefore, the cell can be made very compact and can have fast start. There are no corrosive fluids (acids or alkalis) in the cell. Because of these attributes the cell is particularly suited for vehicle-power operation. Present research includes investigation of using methanol and natural gas as the fuel for the cell.

Alkaline Fuel Cell. Alkaline electrolytes have faster kinetics, which allows the use of non-noble metal electrocatalysts. However, AFCs suffer a drastic performance loss if CO_2 is present in the fuel or the oxidant, for example, air. Therefore, AFCs are restricted for use where pure H_2 and O_2 can be used. They have been used in the past in the space program.

Fuel Cell Performance

The performance of fuel cells is affected by the operating variables (e.g., temperature, pressure, gas composition, reactant utilization, and current density) and other factors that influence the reversible cell potential (impurities) and the magnitude of the irreversible voltage losses (polarization, contact resistance, exchange current).

The cell voltage (V_{cell}) is given by

$$V_{cell} = E - iR - \mu_p \tag{8.13.32}$$

where i is the current through the cell, R is the cell resistance, and μ_p is the polarization loss.

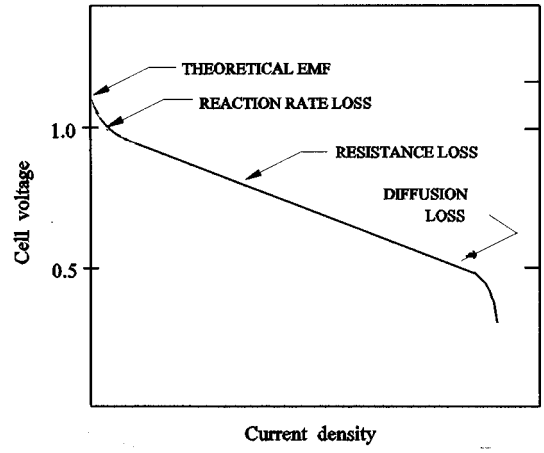

FIGURE 8.13.10 Losses affecting current-voltage characteristics.

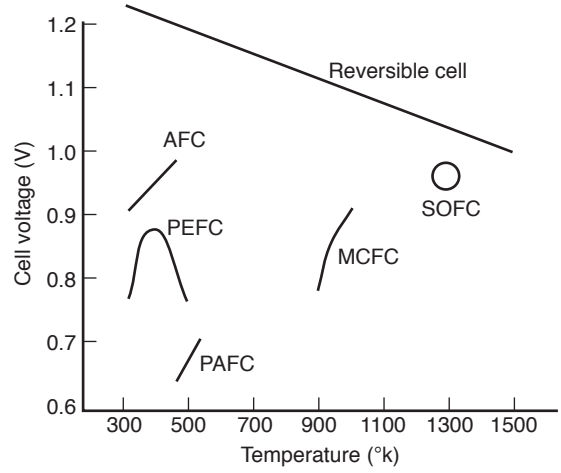

FIGURE 8.13.11 Dependence of the initial operating cell voltage of typical fuel cells on temperature. .

Current Density. Current density has a major impact on the cell voltage. Figure 8.13.10 shows how various losses affect the current-voltage characteristics.

Temperature and Pressure. Increase in pressure generally has a beneficial effect on the cell performance. Increased reactant pressure increases gas solubility and mass transfer rates. In addition, electrolyte loss due to evaporation is decreased.

Theoretically, the reversible potential of an H_2/O_2 fuel cell decreases with an increase in temperature. The practical effect of temperature is mixed, as shown in Figure 8.13.11.

Fuel Cell Power Systems

A general fuel cell power system consists of a fuel processor, fuel cell stack, power conditioner, and possibly a cogeneration or bottoming system to utilize the rejected heat. A schematic of a basic system is shown in Figure 8.13.12.

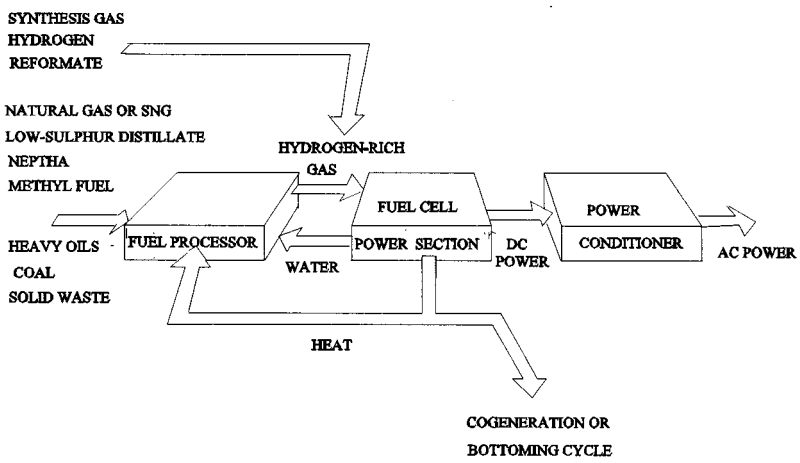

FIGURE 8.13.12 Basic fuel cell power system.

Fuel Processors. If pure hydrogen is available, no additional fuel processor is needed. However, in most applications hydrogen needs to be generated from other fuels, such as natural gas, methane, methanol, etc.

Natural Gas Processing. Natural gas is mostly methane (CH_4) with small amounts of other hydrocarbons. It can be converted to H_2 and CO in a steam-reforming reactor according to Equation (8.13.31). Fuels are typically steam reformed at temperatures of 760 to 980°C.

Liquid Fuel Processing. Liquid fuels such as distillate, naphtha, diesel oil, and fuel oil can be reformed by noncatalytic partial oxidation of the fuel by oxygen in the presence of steam with flame temperatures of 1300 to 1500°C.

Nomenclature

E = internal cell voltage
F = faraday, charge of 1 g-mol of electrons
G = Gibbs free energy
H = enthalpy
ΔH = heat of reaction, enthalpy of formation
I = current
n = number of g-mol
P = Pressure
R = gas constant
S = entropy
t = time
T = temperature
V = voltage drop
W_e = electrical work

Superscript

0 = values under standard conditions — 25°C, 1 atm

Defining Terms

Alkaline fuel cell (AFC): A fuel cell using KOH as the electrolyte.
Faraday: Change of 1 g · mol of electrons, which equals 96,439 C.
Molten carbonate fuel cell (MCFC): A fuel cell using molten carbonate as the electrolyte.

Phosphoric acid fuel cell (PAFC): A fuel cell using phosphoric acid as the electrolyte.
Polymer electrolyte fuel cell (PEFC): A fuel cell using Zerconia as the electrolyte.
Solid oxide fuel cell (SOFC): A fuel cell using potassium as the electrolyte.

Thermionic Energy Conversion

Mysore L. Ramalingam

Introduction

Thermionic energy conversion (TEC) is the process of converting heat directly to useful electrical work by the phenomenon of thermionic electron emission. This fundamental concept can be applied to a cylindrical version of the planar converter, considered the building block for space nuclear power systems (SNPS) at any power level. Space nuclear reactors based on TEC can produce power in the range of 5 kWe to 5 MWe, a spectrum that serves the needs of current users such as National Aeronautics and Space Administration (NASA), United States Air Force (USAF), United States Department of Energy (USDOE), and Ballistic Missile Defense Organization (BMDO). Electrical power in this range is currently being considered for commercial telecommunication satellites, navigation, propulsion, and planetary exploration missions.

The history of thermionic emission dates back to the mid-1700s when Charles Dufay observed that electricity is conducted in the space near a red-hot body. Although Thomas Edison requested a patent in the late 1800s, indicating that he had observed thermionic electron emission while perfecting his electric light system, it was not until the 1960s that the phenomenon of TEC was adequately described theoretically and experimentally (Hatsopoulos and Gryftopoulos, 1973). These pioneering activities have led to the development of thermionic SNPS that could potentially be augmented by Brayton and Stirling

cycle generators to produce additional power from waste heat in NASA manned lunar and martian exploration missions (Ramalingam and Young, 1993).

Principles of Thermionic Energy Conversion

Figure 8.13.13 represents a schematic of the essential components and processes in an elementary thermionic converter (TC). Electrons "boil-off" from the emitter material surface, a refractory metal such as tungsten, when heated to high temperatures (2000 K) by a **heat source**. The electrons then traverse the small interelectrode gap, to a colder (1000 K) collector surface where they condense, producing an output voltage that drives the current through the electrical load and back to the emitter. The flow of electrons through the electrical load is sustained by the temperature difference and the difference in **surface work functions** of the electrodes.

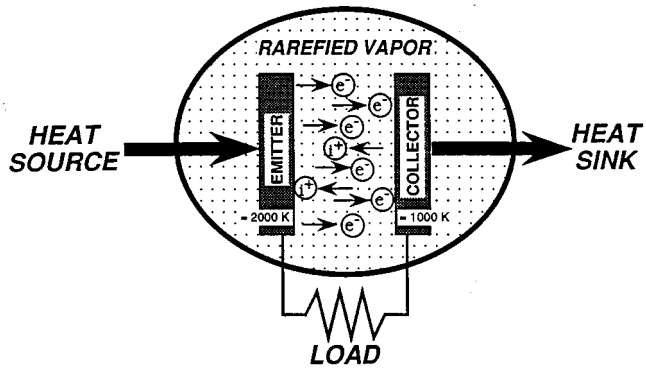

FIGURE 8.13.13 Schematic of an Elementary TEC.

Surface Work Function. In a simple form, the energy required to separate an electron from a metal surface atom and take it to infinity outside the surface is termed the electron work function or the work function of the metal surface. The force experienced by an electron as it crosses an interface between a metal and a rarefied vapor can be represented by the **electron motive**, Ψ, which is defined as a scalar quantity whose negative gradient at any point is a measure of the force exerted on the electron at that point (Langmuir and Kingdon, 1925). At absolute zero the kinetic energy of the **free electrons** would occupy quantum energy levels from zero to some maximum value called the Fermi level. Each energy level contains a limited number of free electrons, similar to the electrons contained in each electron orbit surrounding the nucleus of an atom. Fermi energy, μ, corresponds to the highest energy of all free electrons at absolute zero. At temperatures other than absolute zero some of the free electrons begin to experience energies greater than that at the Fermi level. Thus, the electron work function Φ, would be defined as

$$\Phi = \Psi_T - \mu \tag{8.13.33}$$

where Ψ_T represents the electron motive or energy at some temperature, T, above absolute zero.

Interelectrode Motive Distribution. Figure 8.13.14 provides a schematic representation of the electron motive distribution in the interelectrode space of a thermionic converter. Under ideal conditions of particle transport, the motive varies linearly from Ψ_{EM}, the motive just outside the emitter, to Ψ_{CO}, the motive outside the collector surface. The magnitudes of the Fermi energies of the emitter and collector relative to Ψ_{EM} and Ψ_{CO} are clearly indicated. The internal voltage drop of the converter is defined as;

$$\Delta V = \left(\Psi_{EM} - \Psi_{CO}\right)/e \tag{8.13.34}$$

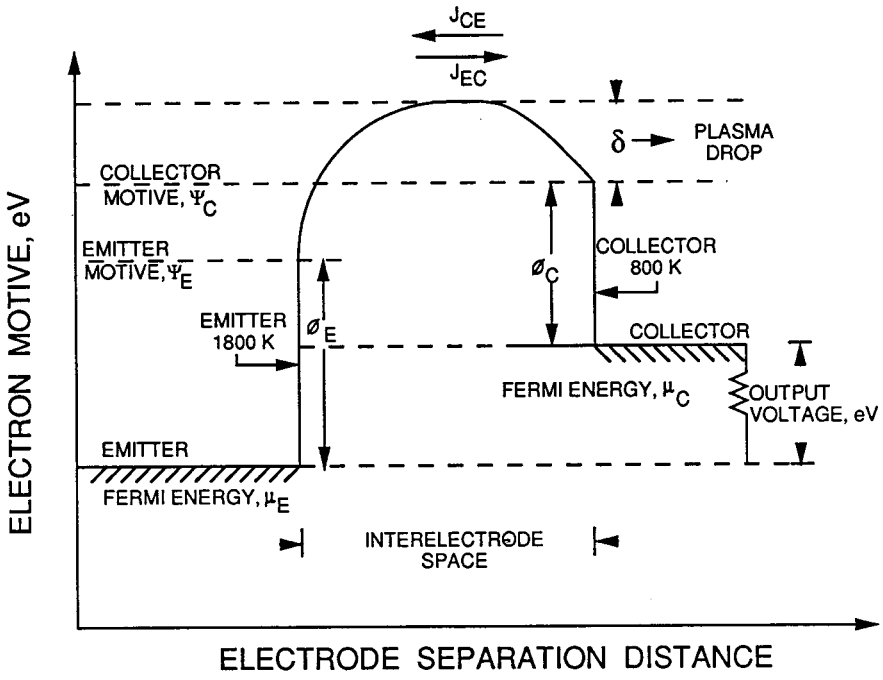

FIGURE 8.13.14 Electron motive distribution in the interelectrode gap.

In a conventional thermionic converter, the emitter and collector are not at the same temperature, but to a good approximation, the output voltage, neglecting **lead losses** and **particle interaction losses**, can be represented by the relationship.

$$V = \left(\mu_{CO} - \mu_{EM}\right)/e \tag{8.13.35}$$

Since a real thermionic converter has an ionizing medium to improve its performance, a similar motive distribution can be defined for the ions. It is sufficient to state that the ion interelectrode motive has a slope equal and opposite to the corresponding electron interelectrode motive. The ions are, therefore, decelerated when the electrons are accelerated and vice versa.

Electron Saturation Current. In the absence of a strong influence from an external electrical source, the electron current ejected from a hot metal at the emitter surface into the vacuum ionizing medium is termed the *electron saturation current*. As this quantity depends on the number of free electrons $N(\varepsilon_x)$, Fermi-Dirac statistics provide the means to compute the number of free electrons, $N(\varepsilon_x)\, d\varepsilon_x$, incident on a unit area within the metal in unit time with energies corresponding to the motion normal to the area, between ε_x and $\varepsilon_x + d\varepsilon_x$. For energies greater than the Fermi energy, the functional dependence of $N(\varepsilon_x)$ on ε_x is given by (Fowler, 1955)

$$N\left(\varepsilon_x\right) \approx \left[4\pi m_e kT/h^3\right]\left[\exp\left\{-\varepsilon_x - \mu/kT\right\}\right] \tag{8.13.36}$$

where m_e is the mass of the electron = 9.108×10^{-28} g and h is Planck's constant = 4.140×10^{-15} eV · sec.

The electron saturation current density, J_{sat}, for a uniform surface, is found by integrating $N(\varepsilon_x)$ in the range of ε_x from Ψ_T to infinity for all $\Psi_T - \mu > kT$, which is the case for almost all materials and practical temperatures. The result of the integration yields

$$J_{\text{sat}} = AT^2 \exp\left[-\left(\Psi_T - \mu\right)/kT\right] \tag{8.13.37}$$

or

$$J_{\text{sat}} = AT^2 \exp\left[-\left(\Phi\right)/kT\right] \tag{8.13.38}$$

where A is the Richardson constant ≈ 120 A/cm$^2 \cdot$ K^2.

Equation (8.13.38), which is the most fundamental and important relationship for the design of a thermionic converter, is called the Richardson-Dushmann equation (Richardson, 1912). On similar lines, the ion saturation current density for a converter with an ionizing medium is given by the relationship (Taylor and Langmuir, 1933):

$$f_{\text{iSat}} = ep_g \Big/ \left[\left(2\pi m_g kT_g\right)^{0.5}\left(1 + 2\exp\left\{\left(V_i - \Phi/kT\right)\right\}\right)\right] \tag{8.13.39}$$

where p_g, T_g, m_g, and V_i are the pressure, temperature, mass, and first ionization energy, respectively, of the ionizing medium.

Types of Thermionic Converters

Thermionic converters can be broadly classified as vacuum thermionic converters and vapor thermionic converters, depending on the presence of an ionizing medium in the interelectrode gap. In vacuum thermionic converters the interelectrode space is evacuated so that the space is free of particles other than electrons and the two electrodes are placed very close together, thereby neutralizing the negative space charge buildup on the electrode surface and reducing the total number of electrons in transit. Due to machining limitations, vacuum converters have been all but completely replaced by vapor-filled thermionic converters. In vapor-filled thermionic converters, the interelectrode space is filled with a rarefied ionizing medium at a vapor pressure generally on the order of 1 to 10 torr. The vapor generally used is cesium as it is the most easily ionized of all stable gases and this can be provided through an external two-phase reservoir or an internal graphite reservoir (Young et al., 1993). The vapor neutralizes the negative space charge effect by producing positive ions at the electrode surfaces and gets adsorbed on the surfaces, thereby altering the work function characteristics.

Converter Output Characteristics

Figure 8.13.15 represents the output current-voltage characteristics for various modes of operation of the vacuum and vapor-filled thermionic converters. Characteristics obtained by not considering particle interactions in the interelectrode gap are generally considered ideal output characteristics. The figure essentially displays three types of converter output current-voltage characteristics, an ideal characteristic, an ignited mode characteristic, and an unignited mode characteristic. For an ideal converter in the interelectrode space the net output current density consists of the electron current density, J_{EMCO} flowing from emitter to collector diminished by the electron current density J_{COEM} flowing from collector to emitter and the ion-current density $f_{i\text{EMCO}}$ flowing from emitter to collector. Thus,

$$J_{\text{net}} = J_{\text{EMCO}} - J_{\text{COEM}} - f_{i\text{EMCO}} \tag{8.13.40}$$

By expressing the individual terms as functions of ϕ, T, and V,

$$\begin{aligned} J_{\text{net}} = {} & AT_{\text{EM}}^2 \exp\left[-\left(\Phi_{\text{EM}}/kT_{\text{EM}}\right)\right] - AT_{\text{CO}}^2 \exp\left[-\left(\Phi_{\text{EM}} - eV\right)/kT_{\text{CO}}\right] \\ & - f_{\text{EMS}} \exp\left[-\left(\Psi_{\text{EM}} - \Psi_{\text{CO}}\right)kT_{\text{EM}}\right] \end{aligned} \tag{8.13.41}$$

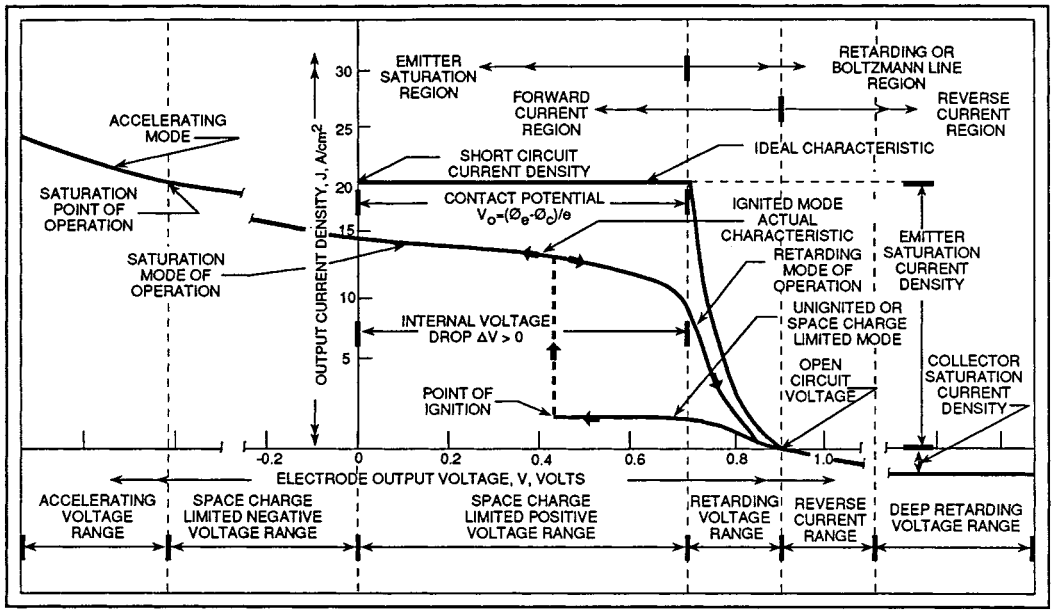

FIGURE 8.13.15 Thermionic diode output current density characteristics and nomenclature.

$$\text{for} \quad eV < \Phi_{EM} - \Phi_{CO}$$

Similar relationships can be generated for various types of thermionic converters.

Thermodynamic Analysis

In thermodynamic terms a thermionic converter is a heat engine that receives heat at high temperature, rejects heat at a lower temperature, and produces useful electrical work while operating in a cycle analogous to a simple vapor cycle engine. Based on the application of the first law of thermodynamics to the control volumes around the emitter (Houston, 1959; Angrist, 1976),

$$\text{Energy In} = \text{Energy Out} \tag{8.13.42}$$

i.e.,

$$q_{CB} + q_{JH} + q_{HS} = q_{EC} + q_{WB} + q_{CD} + q_{RA} \tag{8.13.43}$$

where, by using the terminology in Figure 8.13.14, each of the terms in Equation (8.13.43) can be elaborated as follows:

(a) Energy supplied by back emission of the collector:

$$q_{CB} = J_{COEM}\left[\Phi_{CO} + \delta + V + \left(2kT_{CO}/e\right)\right] \tag{8.13.44}$$

(b) Energy supplied by joule heating of lead wires and plasma:

$$q_{JH} = 0.5\left[J_{EMCO} - J_{COEM}\right]^2\left(R_{LW} + R_{PL}\right) \tag{8.13.45}$$

(c) Energy dissipated by electron cooling:

$$q_{EC} = J_{EMCO}\left[\Phi_{CO} + \delta + V - \Phi_{EM} + \left(2kT_{EM}\right)/e\right] \tag{8.13.46}$$

(d) Energy dissipated due to phase change by electron evaporation:

$$q_{WB} = J_{EM}\Phi_{EM} \tag{8.13.47}$$

(e) Energy dissipated by conduction through the lead wires and plasma:

$$q_{CD} = \Delta T\left[\left(K_{LW}A_{LW}/A_eL_{LW}\right) + \left(K_{PL}A_{PL}/A_eL_{IG}\right)\right] \tag{8.13.48}$$

Here, K represents thermal conductivity, LW = lead wires, PL = plasma, and IG = interelectrode gap.

(f) Energy dissipated by radiation from emitter to collector:

$$q_{RA} = 5.67 \times 10^{-12}\left(T_{EM}^2 - T_{CO}^4\right)\left(\varepsilon_{EM}^{-1} + \varepsilon_{CO}^{-1} - 1\right)^{-1} \tag{8.13.49}$$

Substitution for the various terms in Equation (8.13.42) yields q_{Hs}, the energy supplied to the emitter from the heat source.

The thermal efficiency of the thermionic converter is now expressed as

$$\eta_{TH} = \left[V\left(J_{EMCO} - J_{COEM}\right)/q_{HS}\right] \tag{8.13.50}$$

Design Transition to Space Reactors — Concluding Remarks

All the fundamentals discussed so far for a planar thermionic converter can be applied to a cylindrical version which then becomes the building block for space power systems at any power level. In a thermionic reactor, heat from the nuclear fission process produces the temperatures needed for thermionic emission to occur. The design of a thermionic SNPS is a user-defined compromise between the required output power and the need to operate reliably for a specified lifetime. Based on the type of contact the emitter has with the nuclear fuel, the power systems can be categorized as “in-core” or “out-of-core” power systems. At this stage it suffices to state that the emitter design for in-core systems is extremely complex because of its direct contact with the hot nuclear fuel.

Defining Terms

Electron motive: A scalar quantity whose negative gradient at any point is a measure of the force exerted on an electron at that point.

Free electrons: Electrons available to be extracted from the emitter for thermionic emission.

Heat source: Electron bombardment heating of the emitter.

Lead losses: Voltage drop as a result of the built-in resistance of the leads and joints.

Particle interaction losses: Voltage drop in the interelectrode gap as a result of particle collisions and other interactions.

Surface work function: A measure of the electron-emitting capacity of the surface.

Thermionic energy conversion: Energy conversion from heat energy to useful electrical energy by thermionic electron emission.

Thermoelectric Power Conversion

Jean-Pierre Fleurial

Introduction

The advances in materials science and solid-state physics during the 1940s and 1950s resulted in intensive studies of thermoelectric effects and related applications in the late 1950s and through the mid-1960s (Rowe and Bhandari, 1983). The development of semiconductors with good thermoelectric properties made possible the fabrication of thermoelectric generators and refrigerators. Being solid-state devices, thermoelectric systems offer some unique advantages, such as high reliability, long life, small-size and no-vibrations refrigerators, and can be used in a wide temperature range, from 200 to 1300 K. However, because of their limited conversion efficiencies, these devices have remained confined to specialized applications. As the following sections will emphasize, the performance of those devices is closely associated with the magnitude of the **dimensionless figure of merit**, *ZT*, of the thermoelectric semiconductor.

ZT represents the relative magnitude of electrical and thermal cross-effect transport in materials. State-of-the-art thermoelectric materials, known since the early 1960s, have been extensively developed. Although significant improvements of the thermoelectric properties of these materials have been achieved, a maximum *ZT* value close to 1 is the current approximate limit over the whole 100 to 1500 K temperature range (Figure 8.13.16). To expand the use of thermoelectric devices to a wide range of applications will require improving *ZT* by a factor of two to three. There is no theoretical limitation on

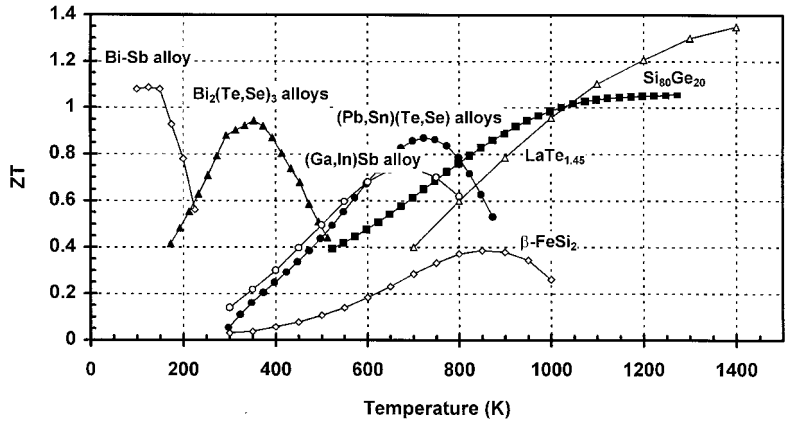

FIGURE 8.13.16 Typical temperature variations of *ZT* of state-of-the-art n-type thermoelectric alloys.

the value of *ZT*, and new promising approaches are now focusing on the investigation of totally different materials and the development of novel thin film heterostructure.

Thermoelectric Effects

Thermoelectric devices are based on two transport phenomena: the Seebeck effect for power generation and the Peltier effect for electronic refrigeration. If a steady temperature gradient is applied along a conducting sample, the initially uniform charge carrier distribution is disturbed as the free carriers located at the high-temperature end diffuse to the low-temperature end. This results in the generation of a back emf which opposes any further diffusion current. The open-circuit voltage when no current flows is the Seebeck voltage. When the junctions of a circuit formed from two dissimilar conductors (n- and p-type semiconductors) connected electrically in series but thermally in parallel are maintained at different temperatures T_1 and T_2, the open-circuit voltage V developed is given by $V = S_{pn}(T_1 - T_2)$, where S_{pn} is the Seebeck coefficient expressed in $\mu V \cdot K^{-1}$.

The complementary Peltier effect arises when an electrical current I passes through the junction. A temperature gradient is then established across the junctions and the corresponding rate of reversible heat absorption $\dot{Q}$ is given by $\dot{Q} = \Pi_{pn} I$, where Π_{pn} is the Peltier coefficient expressed in $W \cdot A^{-1}$ or V. There is actually a third, less-important phenomenon, the Thomson effect, which is produced when an electrical current passes along a single conducting sample over which a temperature gradient is maintained. The rate of reversible heat absorption is given by $\dot{Q} = \beta I(T_1 - T_2)$, where β is the Thomson coefficient expressed in $V \cdot K^{-1}$. The three coefficients are related by the Kelvin relationships:

$$S_{pn} = \frac{\Pi_{pn}}{T} \quad \text{and} \quad \frac{dS_{pn}}{dT} = \frac{\beta_p - \beta_n}{T} \tag{8.13.51}$$

Thermoelectric Applications

The schematic of a thermoelectric device, or module, on Figure 8.13.17, illustrates the three different modes of operation: power generation, cooling, and heating. The *thermoelectric module* is a standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each side (typically alumina). The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples and can operate in a wide range of currents, voltages, powers, and efficiencies. Complex, large-scale thermoelectric systems can be easily designed and built by assembling various numbers of these modules connected in series or in parallel depending on the type of applications.

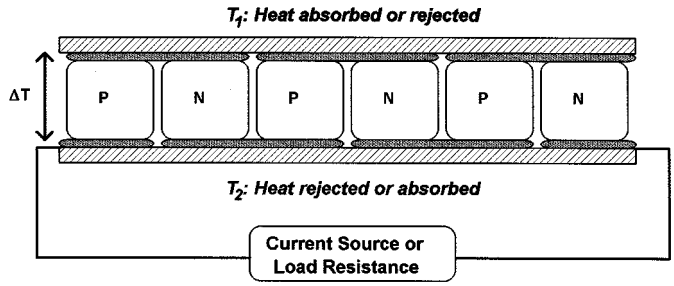

FIGURE 8.13.17 Schematic of a thermoelectric module.

Power Generation. When a temperature gradient is applied across the thermoelectric device, the heat absorbed at the hot junction (Figure 8.13.17, hot side $T_h - T_1$ and cold side, $T_c - T_2$) will generate a current through the circuit and deliver electrical power to the load resistance R_L (Harman and Honig, 1967). The conversion efficiency η of a thermoelectric generator is determined by the ratio of the electrical energy, supplied to the load resistance, to the thermal energy, absorbed at the hot junction, and is given by

$$\eta = \frac{R_L I^2}{S_{\text{pn}} I T_h + K\left(T_h - T_c\right) - \frac{1}{2} RI^2} \tag{8.13.52}$$

where K is the thermal conductance in parallel and R is the electrical series resistance of one p-n thermoelectric couple. The electrical power P_L generated can be written as

$$P_L = \frac{S_{\text{pn}}\left(T_h - T_c\right)^2 R_L}{\left(R_L + R\right)^2} \tag{8.13.53}$$

The thermoelectric generator can be designed to operate at maximum power output, by matching the load and couple resistances, $R_L = R$. The corresponding conversion efficiency is

$$\eta_P = \frac{T_h - T_c}{\frac{3}{2} T_h + \frac{1}{2} T_c + \frac{1}{4} Z_{\text{pn}}^{-1}} \tag{8.13.54}$$

where Z_{pn} is the figure of merit of the p-n couple given by

$$Z_{\text{pn}} = \frac{S_{\text{pn}}^2}{RK} \tag{8.13.55}$$

The figure of merit can be optimized by adjusting the device geometry and minimizing the RK product. This results in Z_{pn} becoming independent of the dimensions of the **thermoelectric legs**. Moreover, if the p- and n-type legs have similar transport properties, the figure of merit, $Z_{\text{pn}} = Z$, can be directly related to the Seebeck coefficient S, electrical conductivity σ or resistivity ρ, and thermal conductivity λ of the thermoelectric material:

$$Z = \frac{S^2}{\rho\lambda} = \frac{S^2\sigma}{\lambda} \tag{8.13.56}$$

The maximum performance η_{max} of the generator is obtained by optimizing the load-to-couple-resistance ratio, leading to the maximum energy conversion efficiency expressed as

$$\eta_{max} = \frac{T_h - T_c}{T_h} \frac{\sqrt{1 + Z_{pn} T_{av}} - 1}{\sqrt{1 + Z_{pn} T_{av}} + \frac{T_c}{T_h}} \tag{8.13.57}$$

It must be noted that the maximum efficiency is thus the product of the Carnot efficiency, less than unity, and of a material-related efficiency, increasing with increasing Z_{pn} values as illustrated in Figure 8.13.18.

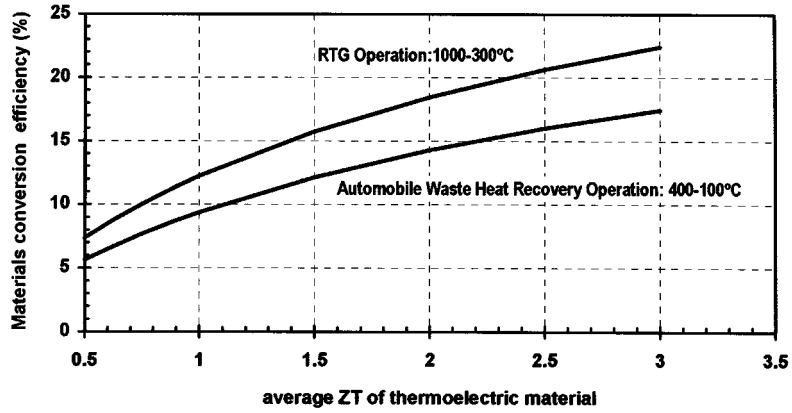

FIGURE 8.13.18 Maximum conversion efficiency η_{max} as a function of the average material figure of merit *ZT,* calculated using Equation (8.13.57) for two systems operating in different temperature ranges: the radioisotope generator (RTG) used for deep space missions and an automobile waste heat recovery generator.

Refrigeration. When a current source is used to deliver electrical power to a thermoelectric device, heat can be pumped from T_1 to T_2 and the device thus operates as a refrigerator (Figure 8.13.17, hot side $T_h = T_2$ and cold side, $T_c = T_1$). As in the case of a thermoelectric generator the operation of a thermoelectric cooler depends solely upon the properties of the p-n thermocouple materials expressed in terms of the figure of merit Z_{pn} and the two temperatures T_c and T_h (Goldsmid, 1986). The conversion efficiency or **coefficient of performance**, COP, of a thermoelectric refrigerator is determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source and is given by

$$\text{COP} = \frac{S_{pn} T_c I - \frac{1}{2} RI^2 - K\left(T_h - T_c\right)}{S_{pn}\left(T_h - T_c\right) I + RI^2} \tag{8.13.58}$$

There are three different modes of operation which are of interest to thermoelectric coolers. A thermoelectric cooler be designed to operate at maximum cooling power, Qc_{max}, by optimizing the value of the current:

$$I_{Qc_{max}} = \frac{S_{pn} T_c}{R} \quad \text{and} \quad Qc_{max} = \frac{1}{2} \frac{\left(ST_c\right)^2}{R} - K\left(T_h - T_c\right) \tag{8.13.59}$$

Similarly, the conditions required for operating at maximum efficiency, COP_{max}, across a constant temperature gradient, are determined by differentiating Equation (8.13.58) with respect to I, with the solution:

$$I_{COP_{max}} = \frac{K(T_h - T_c)_c}{S_{pn} T_{av}} \left(1 + \sqrt{1 + Z_{pn} T_{av}}\right) \tag{8.13.60}$$

$$COP_{max} = \frac{T_c}{T_h - T_c} \frac{\sqrt{1 + Z_{pn} T_{av}} - \frac{T_h}{T_c}}{\sqrt{1 + Z_{pn} T_{av}} + 1} \tag{8.13.61}$$

By reversing the input current to the device, the thermoelectric refrigerator can become a heat pump, with T_1 being the hot junction temperature. The expression of the maximum conversion efficiency of the heat pump is very similar to Equation (8.13.61) because of the following relationship:

$$\left(COP_{max}\right)^{\text{heat pump}} = 1 + \left(COP_{max}\right)^{\text{refrigerator}} \tag{8.13.62}$$

The maximum COP expression in Equation (8.13.61) is similar to the one derived for the conversion efficiency η of a thermoelectric generator in Equation (8.13.57). However, there is a major difference between the COP_{max} and η_{max} parameters. Clearly, η_{max} increases with increasing ΔT values but is limited by the Carnot efficiency (Equation 8.13.54) which is less than 1, while COP_{max} in Equation (8.13.52) increases with decreasing ΔT values and can reach values much larger than 1. Figure 8.13.19 represents the variations of the COP_{max} of a thermoelectric cooling device optimized for working voltage and geometry as a function of average ZT values and temperature differences (hot junction temperature at 300 K). The average ZT value for current state-of-the-art commercially available materials (Bi_2Te_3-based alloys) is about 0.8. For example, it can be seen that a COP_{max} of 4 is obtained for a $(T_h - T_c)$ difference of 10 K, meaning that to pump 8 W of thermal power only 2 W of electrical power needs to be provided to the thermoelectric cooling device. This also means that 10 W of thermal power will be rejected at the hot side of the cooler.

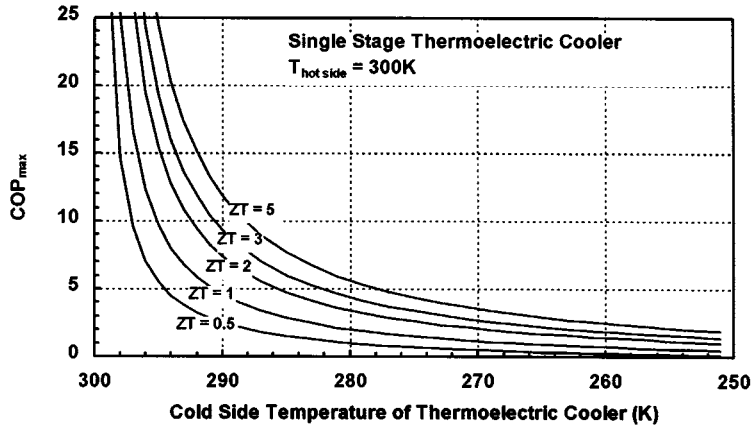

FIGURE 8.13.19 Maximum material coefficient of performance COP_{max} of a single-stage thermoelectric cooler calculated using Equation (8.13.61) as a function of the cold-side temperature (hot-side temperature of 300 K). Curves corresponding to various values of the average material figure of merit are displayed.

The operation of a thermoelectric refrigerator at maximum cooling power necessitates a substantially higher input current than the operation at maximum efficiency. This is illustrated by calculating the variations of the maximum COP and cooling power with the input current and temperature difference which have been plotted in Figures 8.13.20 and 8.13.21. The calculation was based on the properties of a thermoelectric cooler using state-of-the-art Bi_2Te_3-based alloys, and the arbitrary units are the same for both graphs. It can be seen that $I_{COP_{max}}$ increases while $I_{Qc_{max}}$ decreases with increasing ΔT. Also, it is possible to operate at the same cooling power with two different current values.

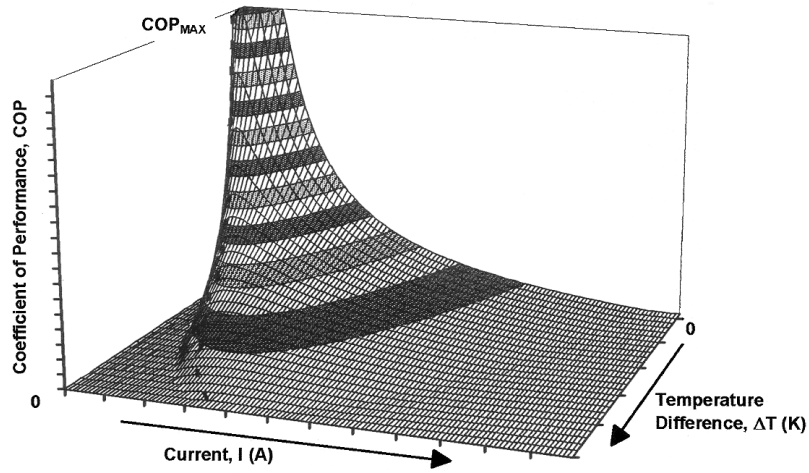

FIGURE 8.13.20 Three-dimensional plot of the variations of the COP of a thermoelectric cooler as a function of the operating current and the temperature difference.

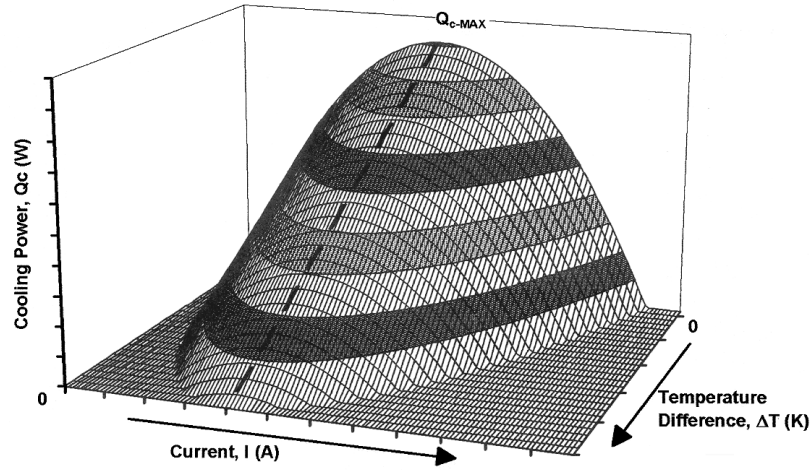

FIGURE 8.13.21 Three-dimensional plot of the variations of the cooling power of a thermoelectric cooler as a function of the operating current and the temperature difference.

Finally, the third problem of interest for thermoelectric coolers is to determine the maximum temperature difference, ΔT_{max}, that can be achieved across the device. As shown on Figure 8.13.21, by operating at maximum cooling power and extrapolating Equation (8.13.59) to $Qc_{max} = 0$, ΔT_{max} is given by

$$\Delta T_{max} = \frac{1}{2} Z_{pn} T_c^2 \quad \text{and} \quad T_{c\,min} = \frac{\sqrt{1 + 2Z_{pn} T_h} - 1}{Z_{pn}} \tag{8.13.63}$$

where $T_{c\,min}$ corresponds to the lowest cold-side temperature achievable. If the cooler operates at a ΔT close to ΔT_{max} or higher, it becomes necessary to consider a cascade arrangement with several **stages**. The COP of an n-stage thermoelectric cooler is optimized if the COP of each stage, COP_i, is the same, which requires $\Delta T_i / T_{i-1}$ to be the same for each stage. The overall maximum COP is then expressed as

$$COP_{max} = \frac{1}{\left(\prod_{i=1}^{n} \left(1 + \frac{1}{COP_i} \right) - 1 \right)} \tag{8.13.64}$$

Additional Considerations

When considering the operation of an actual thermoelectric device, several other important parameters must be considered. The thermal and electrical contact resistances can substantially degrade the device performance, in particular for short lengths of the thermoelectric legs. For example, the conversion efficiency of a radioisotope generator system is about 20% lower than the value calculated in Figure 8.13.18 for the thermoelectric materials only. The electrical contact resistance arises from the connection (see Figure 8.13.17) of all the legs in series. Typical values obtained for actual generators and coolers are 10 to 25 $\mu\Omega \cdot cm^2$. The thermal contact resistance is generated by the heat-transfer characteristics of the ceramic plates and contact layers used to build the thermoelectric module. The heat exchangers and corresponding heat losses should also be taken into account.

In addition, the transport properties of the thermoelectric materials vary with temperature, as illustrated in Figure 8.13.16. When a thermoelectric device is operating across a wide temperature range, these variations should be factored in the calculation of its performance.

Nomenclature

COP	coefficient of performance
COP_{max}	maximum coefficient of performance
COP_i	coefficient of performance of the *i*th stage of a multistage thermoelectric cooler
I	current intensity
$I_{COP_{max}}$	current intensity required to operate a thermoelectric cooler at maximum conversion efficiency
$I_{Qc_{max}}$	current intensity required to operate a thermoelectric cooler at maximum cooling power
K	thermal conductance
Q	rate of reversible heat absorption
R	electrical resistance
R_L	load resistance
P_L	electrical power delivered to the load resistance
S	Seebeck coefficient
S_{pn}	Seebeck coefficient of a p-n couple of thermoelements
T_1	temperature
T_2	temperature
T_{av}	average temperature across the thermoelectric device
T_c	cold-side temperature of a thermoelectric device
$T_{c\,min}$	minimum cold-side temperature which can be achieved by a thermoelectric cooler
T_h	hot-side temperature of a thermoelectric device
V	voltage; open-circuit voltage
Z	thermoelectric figure of merit

Z_{pn} thermoelectric figure of merit of a p-n couple of thermoelements
ZT dimensionless thermoelectric figure of merit
β Thomson coefficient
β_p Thomson coefficient for the p-type thermoelement
β_n Thomson coefficient for the n-type thermoelement
ΔT temperature difference across a thermoelectric device
ΔT_{max} maximum temperature difference which can be achieved across a thermoelectric cooler
η thermoelectric conversion efficiency
η_{max} maximum thermoelectric conversion efficiency
λ thermal conductivity
Π_{pr} Peltier coefficient
ρ electrical resistivity

Defining Terms

Coefficient of performance: Electrical to thermal energy conversion efficiency of a thermoelectric refrigerator, determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source.

Dimensionless figure of merit: The performance of a thermoelectric device depends solely upon the properties of the thermoelectric material, expressed in terms of the dimensionless figure of merit *ZT*, and the hot-side and cold-side temperatures. *ZT* is calculated as the square of the Seebeck coefficient times the absolute temperature divided by the product of the electrical resistivity to the thermal conductivity. The best *ZT* values are obtained in heavily doped semiconductors, such as Bi_2Te_3 alloys, PbTe alloys, and Si-Ge alloys.

Stage: Multistage thermoelectric coolers are used to achieve larger temperature differences than possible with a single-stage cooler composed of only one module.

Thermoelectric leg: Single thermoelectric element made of n-type or p-type thermoelectric material used in fabricating a thermoelectric couple, the building block of thermoelectric modules. The geometry of the leg (cross-section-to-length ratio) must be optimized to maximize the performance of the device.

Thermoelectric module: Standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each. The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples.

Magnetohydrodynamic Power Generation

William D. Jackson

Introduction

The discipline known as magnetohydrodynamics (MHD) deals with the interactions between electrically conducting fluids and electromagnetic fields. First investigated experimentally by Michael Faraday in 1832 during his efforts to establish the principles of electromagnetic induction, application to energy conversion yields a heat engine which has its output in electrical form and, therefore, qualifies as a direct converter. This is generally referred to as an MHD generator, but could be better described as an electromagnetic turbine as it operates on a thermodynamic cycle similar to that of a gas turbine.

The operating principle is elegantly simple, as shown in Figure 8.13.22. A pressurized, electrically conducting fluid flows through a transverse magnetic field in a channel or duct. Electrodes located on the channel walls parallel to the magnetic field and connected through an external circuit enable the motionally induced "Faraday electromotive force" to drive an electric current through the circuit and thus deliver power to a load connected into it. Taking the fluid velocity as **u** and the magnetic flux density as **B**, the intensity of the motionally induced field is **u** × **B**. The current density, **J**, in the channel for a scalar conductivity σ is then given by Ohm's law for a moving conductor as

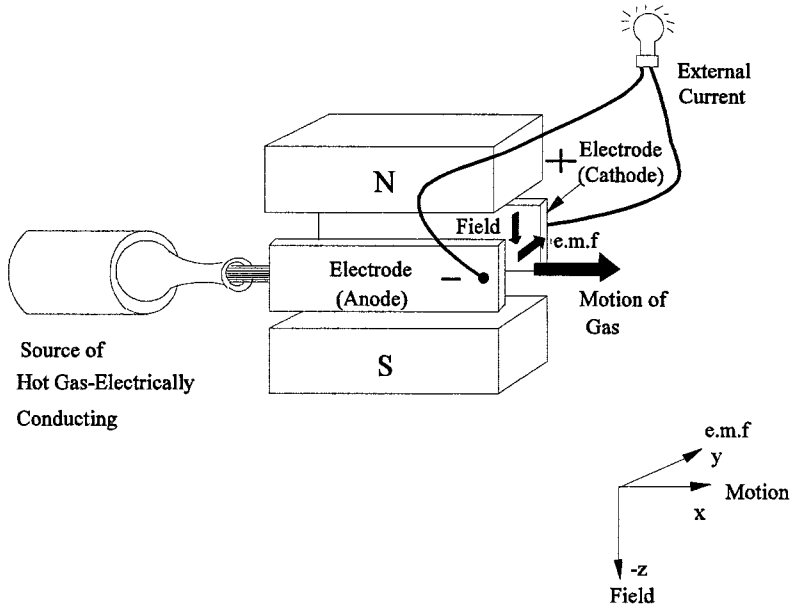

FIGURE 8.13.22 Principle of electromagnetic turbine or MHD generator.

$$\mathbf{J} = \sigma[\mathbf{E} + \mathbf{u} \times \mathbf{B}]$$

By taking the coordinates of Figure 8.13.22 and assuming that the quantities are constant, the power density flow from the MHD generator is, using **E** · **J**

$$w_e = \sigma u_x^2 B^2 k(1-k)$$

where $k = Ez/u \times B$ is the "loading factor" relating loaded electric field to open circuit induction and is used in the same manner as the regulation of an electrical machine is applied to its terminal voltage.

It is instructive at this point to determine the power density of an MHD generator using values representative of the most commonly considered type of MHD generator. Combustion gas with $\sigma = 10$ S/m, a flow velocity of 800 m/sec and an applied field of 5 T for maximum power transfer ($k = 0.5$) yields w_e as 40 MW/m^3. This value is sufficiently attractive to qualify MHD generators for bulk power applications. An intensive, worldwide development effort to utilize this and other MHD generator properties has been conducted since the late 1950s. However, this has not yet led to any significant application of MHD generators. To understand how this has come about and what still needs to be accomplished to make MHD attractive will now be summarized.

Electrical Conductivity Considerations

Two approaches have been followed to obtain adequate ionization and, therefore, conductivity in the working fluid. What may be termed the mainline approach to achieving electrical conductivity is to add a readily ionizable material to "seed" the working fluid. Alkali metals with ionization potentials around 4 V are obvious candidates, although a lower value would be highly desirable. A potassium salt with an ionization potential of 4.09 eV has been widely used because of low cost but cesium with a 3.89-eV value is the preferred seed material when the running time is short or the working fluid is recycled. There are two methods of ionization:

1. Thermal ionization in which recombination ensures a common temperature for electrons, ions, and neutrals; the mass action law (Saha equation) is followed; and the heat of ionization in electron volts is the ionization potential; and
2. Extrathermal or nonequilibrium ionization where electrons and heavy particles are at different temperatures and the concept of entwined fluids (electron, ion, and neutral gases) is involved.

The former is applicable to diatomic combustion gases while the latter occurs in monatomic (noble) gases but is also observed in hydrogen. Only a small amount of seed material is required and is typically around 1% of the total mass flow for maximum conductivity.

The existence of mutually perpendicular **E** and **B** fields in an MHD generator is of major significance in that the electrons are now subjected to the Hall effect. This causes electrons and, therefore, electric currents to flow at an angle with respect to the **E** field in the collision-dominated environment of the MHD generator. The presence of a significant Hall effect requires that the electrical boundary conditions on the channel be carefully selected and also introduces the possibility of working fluid instabilities driven by force fluctuations of electrical origin. A further source of fluctuations and consequent loss of conductivity occurs when nonequilibrium ionization is employed due to current concentration by Joule heating. This latter effect is controlled by operating only in a regime where, throughout the channel, complete ionization of the seed material is achieved.

Generator Configurations and Loading

The basic consequence of the Hall effect is to set up **E** fields in both transverse and axial directions in the generator channel and these are generally referred to as the Faraday and Hall fields, respectively. The direction of the Faraday field depends on the magnetic field; the Hall field depends on the Hall parameter and is always directed toward the upstream end of the channel. These considerations, in turn, lead to the MHD generator having the characteristics of a gyrator — a two-terminal pair power-producing device in which one terminal pair (Faraday) is a voltage source and the other (Hall) is a current source dependent in this case on the Hall parameter. Electric power can be extracted from either the Faraday or Hall terminals, or both.

This has resulted in several electrical boundary conditions being utilized with the axial flow channel as shown in Figure 8.13.23. These are most readily understood by treating each anode-cathode pair as a generating cell. The segmented Faraday configuration (Figure 8.13.23a) is then simply a parallel operation of cells which leads to the apparently inconvenient requirement of separate loading of individual

cells: the Hall connection (Figure 8.13.23b) utilizes a single load by series connection but depends on the Hall parameter for its performance; and the diagonal connection (Figure 8.13.23c) connects the cells in series-parallel and so avoids Hall parameter dependence while retaining the single load feature. In all three linear configurations, the channel walls are electrically segmented to support the Hall field, and experience has shown that this must be sufficiently finely graded so that no more than 50 V is supported by the interelectrode gaps to avoid electrical breakdown.

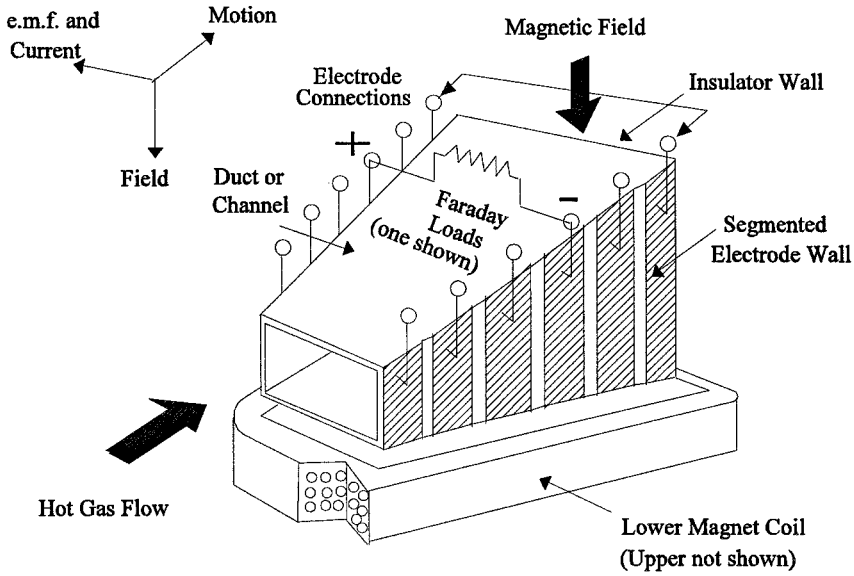

FIGURE 8.13.23 Basic Faraday linear MHD generator.

The MHD generator is a linear version of the homopolar machine originally demonstrated by Faraday and is, as a practical matter, confined to DC generation. Accordingly, some form of DC-AC conversion using power electronics is required for the vast majority of applications. The single load feature loses significance in this situation as the "power conditioning" can readily be arranged to combine (consolidate) the individual cell outputs before conversion to the required AC system conditions. Indeed, to maximize power extraction while limiting interelectrode voltages and controlling electrode currents (to ensure adequate lifetime), the power conditioning is arranged to extract power from both Faraday and Hall terminal pairs.

An alternative geometry is to set up a radial flow (usually but not necessarily outward) with the disk configuration of Figure 8.13.23d. The result is a Hall generator, which is generally favored for nonequilibrium ionization as it avoids the inevitable nonuniformities associated with electrode segmentation with their proclivity for promoting ionization instabilities. A measure of Faraday performance is achievable through the introduction of swirl, and additional ring electrodes enable power conditioning to control (and optimize) the radial electric field.

Components

An MHD generator per se requires several components to make up a complete powertrain. In addition to the power conditioning needed for DC-AC conversion these include a magnet, seed injector, combustor with fuel and oxidizer supply or an input heat exchanger, nozzle, compressor, diffuser, exhaust gas-cleaning system (for once-through systems), and controls. The need to accommodate a channel between the poles of a magnet qualifies the MHD generator as a large-air-gap machine.

Systems

Power systems incorporating MHD generators are either of the once-through (open-cycle) or working fluid recycle (closed-cycle) type, and the complete MHD system described in the previous section can either be stand-alone or incorporated into a more complex configuration such as a binary cycle. In the latter case, the high-temperature operation of the MHD unit makes it a topping cycle candidate and it is in this mode that MHD has received most system consideration. An MHD generator operated directly on ionized combustion gas is usually associated with an open cycle while nonequilibrium ionization with seeded noble gases and LMMHD are invariably considered for closed-cycle operation. An exception is nonequilibrium ionization in cesium-seeded hydrogen which has received some attention for open-cycle operation.

Heat Sources, Applications, and Environmental Considerations

A heat source capable of providing from 1000 K for LMMHD to over 3000 K for open-cycle systems for power production is a candidate. Rocket motor fuels, all fossil fuels, high-temperature nuclear reactors cooled with hydrogen and biomass are suitable for open cycles, while closed cycles can be driven through a heat exchanger by any of these combustion sources. A high-temperature nuclear reactor, probably helium cooled, is also a feasible source for MHD and in the early stages of development of the process received much attention. With the abandonment of efforts to develop commercial reactors to operate at temperatures above 1200 K, attention has focused on high-energy fuels for pulse power (few seconds) operation and coal for utility power generation.

While the debate over the role of fossil energy in the long-term electricity generation scenario continues, it is established that coal is a major resource which must be utilized at maximim efficiency to limit CO_2 production and must be combusted in a manner which reduces SO_2 and NO_x effluents to acceptable levels. The use of MHD generators significantly advances all of these objectives. Briefly, it was first observed that the "electromagnetic turbine" has the major advantage that it cannot only provide the highest efficiency of any known converter from the Carnot viewpoint but that its operation is not adversely affected by coal slag and ash. Indeed, slag provides an excellent renewable coating for the channel walls and increases lifetime.

System calculations have shown that, when coupled as a topping cycle to the best available steam plant technology, a thermal efficiency with coal and full environmental control is 52.5%. When coupled into a ternary cycle with either a gas turbine or fuel cells and a steam turbine, efficiencies upward of 60% are possible.

Technology Status

A pulse-type MHD generator was successfully built and operated by Avco (now Textron Defense Industries) in 1963 and a complete natural gas-fired pilot plant with a nominal 20-MW MHD generator was commissioned in the U.S.S.R. on the northern outskirts of Moscow in 1971. In the decade of the 1980s, development was focused on coal firing as a result of the oil crises of the 1970s and in the U.S. progressed to the point where the technology base was developed for a demonstration plant with a 15-MW MHD generator.

Future Prospects

The two particular attributes of the MHD generator are its rapid start-up to multimegawatt power levels for pulse power applications and its ability to provide a very high overall thermal efficiency for power plants using coal while meeting the most stringent environmental standards. The first has already been utilized in crustal exploration, and the second must surely be utilized when coal is the fuel of choice for electric power production. In the meantime, MHD has been established as a viable technology on which further development work will be conducted for advanced applications such as the conversion system for thermonuclear fusion reactors.

Further Information

The following proceedings series contain a full and complete record of MHD generator and power system development:

1. *Proceedings of the Symposia for the Engineering Aspects of Magnetohydrodynamics*, held annually in the U.S. since 1960 (except for 1971 and 1980).
2. *Proceedings of 11 International Conferences on Magnetohydrodynamic Electrical Power Generation*, held in 1962, 1964, 1966, 1968, 1971 , 1975, 1980, 1983, 1986, 1989, and 1992. The 12th conference will be held in Yokahama, Japan in October 1996.

8.14 Ocean Energy Technology

Desikan Bharathan and Federica Zangrando

The ocean contains a vast renewable energy potential in its waves and tides, in the temperature difference between cold, deep waters and warm surface waters, and in the salinity differences at river mouths (SERI, 1990; WEC, 1993; Cavanagh et al., 1993). Waves offer a power source for which numerous systems have been conceived. Tides are a result of the gravity of the sun, the moon, and the rotation of the Earth working together. The ocean also acts as a gigantic solar collector, capturing the energy of the sun in its surface water as heat. The temperature difference between warm surface waters and cold water from the ocean depths provides a potential source of energy. Other sources of ocean energy include ocean currents, salinity gradients, and ocean-grown biomass.

The following sections briefly describe the status and potential of the various ocean energy technologies, with emphasis placed on those with a near-term applicability.

Ocean Thermal Energy Conversion

Ocean thermal energy conversion (OTEC) technology is based on the principle that energy can be extracted from two reservoirs at different temperatures (SERI, 1989). A temperature difference as little as 20°C can be exploited effectively to produce usable energy. Temperature differences of this magnitude prevail between ocean waters at the surface and at depths up to 1000 m in many areas of the world, particularly in tropical and subtropical latitudes between 24° north and south of the equator. Here, surface water temperatures typically range from 22 to 29°C, while temperatures at a depth of 1000 m range from 4 to 6°C. This constitutes a vast, renewable resource, estimated at 10^{13} W, for potential baseload power generation.

Recent research has been concentrated on two OTEC power cycles, namely, **closed-cycle** and **open-cycle**, for converting this thermal energy to electrical energy (Avery and Wu, 1994). Both cycles have been demonstrated, but no commercial system is yet in operation. In a closed-cycle system, warm seawater is used to vaporize a working fluid such as ammonia flowing through a heat exchanger (evaporator). The vapor expands at moderate pressures and turns a turbine. The vapor is condensed in another heat exchanger (condenser) using cold seawater pumped from the ocean depths through a cold-water pipe. The condensed working fluid is pumped back to the evaporator to repeat the cycle. The working fluid remains in a closed system and is continuously circulated. In an open cycle system, the warm seawater is "flash" evaporated in a vacuum chamber to make steam at an absolute pressure of about 2.4 kPa. The steam expands through a low-pressure turbine coupled to a generator to produce electricity. The steam exiting the turbine is condensed by using cold seawater pumped from the ocean depths through a cold-water pipe. If a surface condenser is used, condensed steam provides desalinated water.

Effluent from either a closed cycle or an open cycle system can be further processed to enhance production of desalinated water through a flash evaporator/condenser system in a second stage.

For combined production of power and water, these systems are estimated to be competitive with conventional systems in several coastal markets.

Tidal Power

The energy from tides is derived from the kinetic energy of water moving from a higher to a lower elevation, as for hydroelectric plants. High tide can provide the potential energy for seawater to flow into an enclosed basin or estuary that is then discharged at low tide (Ryan, 1980). Electricity is produced from the gravity-driven inflow or outflow (or both) through a turbogenerator. The tidal resource is variable but quite predictable, and there are no significant technical barriers for deployment of this technology. Because costs are strongly driven by the civil works required to dam the reservoir, only a few sites around the world have the proper conditions of tides and landscape to lend themselves to this technology.

Although it has benefited from some recent developments in marine and offshore construction that significantly reduce construction time and costs, the economics of tidal power production still does not make it competitive with conventional energy systems.

The highest tides in the world can reach above 17 m, as in the Bay of Fundy between Maine and Nova Scotia, where it is projected that up to 10,000 MW could be produced by tidal systems in this bay alone. A minimum tidal range (difference between mean high and low tides) of 5 m is required for plants using conventional hydroelectric equipment (horizontal axial-flow water turbines housed in underwater bulbs or Straflo turbines). More recently, low-head hydroelectric power equipment has proved adaptable to tidal power and new systems for 2-m heads have been proposed.

There are a few tidal power stations operating in France, the former U.S.S.R., China, and Canada. The largest and longest-operating plant is the 240-MW tidal power station on the Rance River estuary in northern France (Banal and Bichon, 1981), which has operated with 95% availability since 1968. The 400-kW tidal plant in Kislaya Bay on the Barents Sea in the former U.S.S.R. has been operating since 1968; at this favorable site only a 50-m-wide dam was needed to close the reservoir. The 20-MW Canadian plant at Annapolis on the Bay of Fundy uses a Straflo turbine generator and has operated reliably since 1984. A number of small-bulb and Straflo turbine generator plants of up to 4 MW are also installed on the China coastline.

Wave Power

Waves contain significant power which can be harnessed by shore-mounted or offshore systems, the latter having larger incident power on the device but requiring more costly installations. A myriad of wave-energy converter concepts have been devised, transforming wave energy into other forms of mechanical (rotative, oscillating, or relative motion), potential, or pneumatic energy, and ultimately into electricity; very few have been tested at sea.

The power per unit frontal length of the wave is proportional to wave height squared and to wave period, with their representative values on the order of 2 m and 10 sec. The strong dependence on wave height makes the resource quite variable, even on a seasonal and a yearly average basis. The northeastern Pacific and Atlantic coasts have average yearly incident wave power of about 50 kW/m, while near the tip of South America the average power can reach 100 kW/m. Japan, on the other hand, receives an average of 15 kW/m. Waves during storms can reach 200 kW/m, but these large waves are unsafe for operation because of their severity, and they impose significant constraints and additional costs on the system. Overall, the amount of power that could be harvested from waves breaking against world coastlines is estimated to be on the order of the current global consumption of energy. However, total installed capacity amounts to less than 1 MW worldwide.

A commonly deployed device is the oscillating water column (OWC), which has so far been mounted on shore but is also proposed for floating plants. It consists of an air chamber in contact with the sea so that the water column in the chamber oscillates with the waves. This motion compresses the air in the chamber, which flows in and out of a Wells turbine. This turbine can be self-rectifying, i.e., it uses the airflow in both directions, and it consists of a simple rotor, with symmetrical airfoil blades attached tangentially to a central disk. Inertial energy storage (flywheels) is often used to even out the variable pneumatic energy delivered by the air.

Two of the largest wave-energy power plants were built at Toftestallen, near Bergen, Norway. A Norwegian company, Norwave A.S., built a 350-kW tapered channel (Tapchan) device in 1984, which survived a severe storm in 1989 (the 500 kW multi-resonant OWC plant built by Kvaerner Brug A.S. did not). The channel takes advantage of the rocky coastline to funnel waves through a 60-m-wide opening into a coastal reservoir of 5500 m^2, while maintaining civil engineering costs to a minimum. Wave height increases as the channel narrows over its 60-m length, and the rising waves spill over the 3-m-high channel walls, filling the reservoir. Continuous wave action maintains the reservoir level at a relatively constant elevation above sea level, providing potential energy for a low-head hydroelectric Kaplan turbogenerator. Estimates by Norwave to rebuild an identical plant at this site suggested capital

costs of $3500/kW installed, and energy costs of 8¢/kWhr, at a plant capacity factor of 25% (ASCE, 1992). In recent efforts, the National Institute of Ocean Technology has installed a 150-kW wave-energy conversion device in the southern tip of India.

Concluding Remarks

Among the many ocean energy prospects, OTEC, tides, and tapered channel wave-energy converters offer the most near-term potential and possess applicability for a large variety of sites. To realize their potential, additional research and development is required.

Defining Terms

Ocean thermal energy conversion (OTEC): A system that utilizes the temperature difference between the seawater at the surface and at depths.

Closed-cycle OTEC: Uses a working fluid in a closed cycle.

Open-cycle OTEC: Uses steam flashed from the warm seawater as the working fluid which is condensed and exhausted.

In the past two decades, several cycles which combine the gas turbine and the steam turbine have become available with good fuel utilization compared with other available power plants. The first ones in the 1970s had net plant efficiencies of about 40% with the most recent ones achieving net plant efficiencies of over 55%.

One way to utilize the energy available in gas turbine exhaust gases is as the energy source for a steam power plant. This is called a *combined cycle* and uses components from two systems which have independently proved themselves. The combined cycle power plant usually consists of one or more gas turbine engines exhausting into a heat-recovery steam generator (HRSG) where the energy is transferred from the exhaust gases to the water in the steam power plant.

The simplest arrangement for a combined cycle power plant is the single-pressure system as illustrated in Figure 8.15.1. It consists of the HRSG, a turbine, condenser, and pump. In this simplified configuration, it is assumed that no additional fuel is burned between the gas turbine and the HRSG.

The gases leaving the gas turbine engine enter the HRSG at state 4 and leave the HRSG at state 5. The water in the steam cycle portion of the combined cycle enters the HRSG economizer as a subcooler liquid (state a). The temperature of the water is increased in the economizer until it is a saturated liquid (state m). This is the point where the minimum temperature difference between the water in the steam cycle and the exhaust gases occurs and is called the *pinch point*. Typical pinch point values range from 10 to 30°C; the smaller the pinch point difference, the larger the required heat-transfer surface area. From state m to state v, the water is changed from a saturated liquid to a saturated vapor. From state v to state d, the water is superheated where it has its maximum temperature. A typical temperature-heat transfer diagram for this single-pressure steam turbine combined cycle is illustrated in Figure 8.15.2.

One should note that there is a significant difference between the desired feedwater conditions of a combined cycle power plant and a conventional steam power plant. In a combined cycle power plant, it is desirable to have the temperature of the water at as low a temperature as possible as it enters the HRSG to permit the maximum amount of energy to be transferred from the exhaust gases to the water

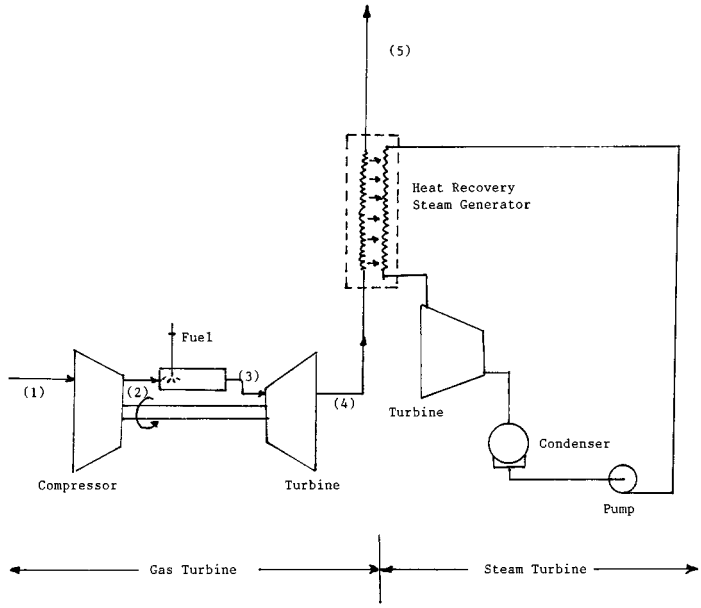

FIGURE 8.15.1 Combined cycle power plant with no supplementary firing.

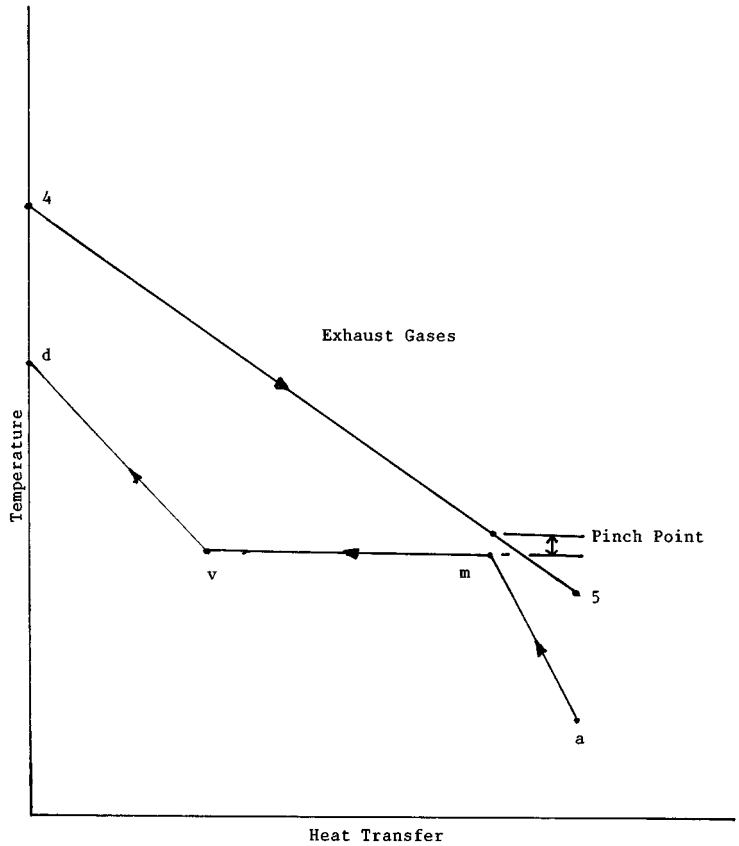

FIGURE 8.15.2 Typical temperature-heat transfer diagram for a single-pressure combined cycle power plant.

since the more energy transferred, the greater the amount of power produced by the steam turbine and the higher the combined cycle thermal efficiency or the lower the heat rate. In a conventional steam cycle power plant, the higher the feedwater temperature as it enters the steam generator (boiler), the higher the cycle thermal efficiency. Conventional steam cycle power plants achieve the higher feedwater temperature by the use of feedwater heaters.

Table 8.15.2 lists net plant output, heat rate, and net plant efficiency values for several combined cycles. One should observe for the units listed in Table 8.15.2 that

1. The size varies widely from a low of 22,800 kW to a high of 711,000 kW;
2. The heat rates vary from 7880 to 5885 Btu/kWhr. These compare with heat rate values for the gas turbines listed in Table 8.15.1 that vary from a high of 12,544 Btu/kWhr to a low of 8980 Btu/kWhr.
3. The net plant efficiency varies from a low of 42.8% to a high of 57.0%;
4. The fraction of the total net plant output from the steam turbine power plant in most cases ranges from 35 to 39%.

Source: 1995 Handbook, Gas Turbine World, Southport, CT, 1995. With permission.

One should keep in mind that only a few of the combined cycle plants currently available are listed in Table 8.15.2. The ones listed are intended to illustrate the range in net plant output and heat rate values and should not be interpreted as a list of all units currently available.

The amount of energy transferred in the HRSG is dependent on the steam pressure. This is illustrated in Figure 8.15.3. In this comparison, it is assumed in both cases that the steam exit temperature is the same and that the exhaust gas HRSG inlet temperature and flow rate are the same. One observes that the pressure of the water dictates the temperature at which evaporation occurs. The higher the evaporation temperature (and therefore steam pressure), the lower the mass flow rate of the steam, and therefore the lower the power generated by the steam power plant. It is obvious that the lower the steam pressure, the lower the flue gas temperature.

The output of an unfired single-pressure combined cycle power plant is determined by the gas turbine selected since this fixes the temperature and mass flow rate of the exhaust gases. One way to increase the steam cycle output is to introduce supplementary firing in the exhaust duct between the gas turbine exit and HRSG inlet. This is shown schematically in Figure 8.15.4. The advantages of adding supplementary firing are

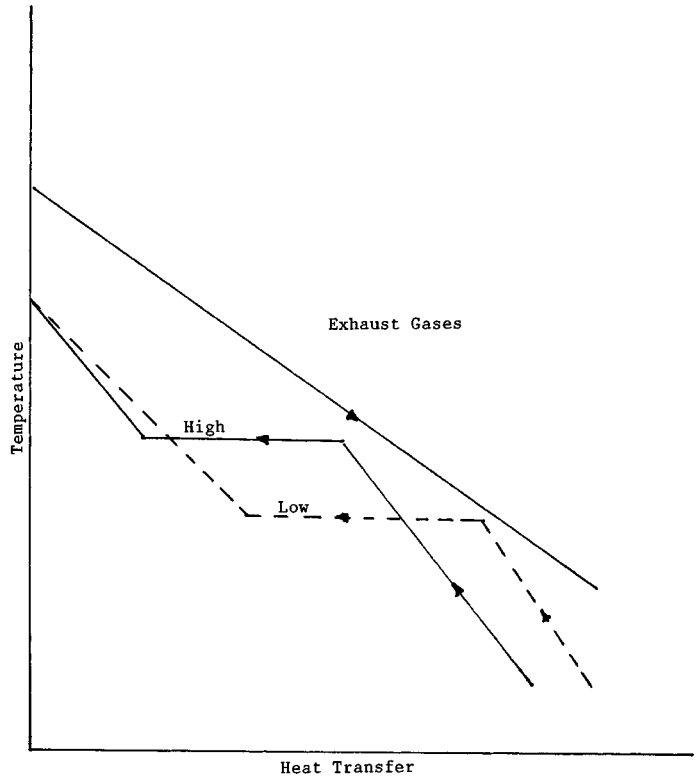

FIGURE 8.15.3 Effect of steam cycle pressure on energy transferred for a single-pressure combined cycle power plant.

1. The total output from the combined cycle will increase with a higher fraction of the output coming from the steam turbine cycle;
2. The temperature at the inlet to the HRSG can be controlled. This is important since the temperature and mass flow rate at the exit from the gas turbine are very dependent on the ambient temperature.

Figure 8.15.5 illustrates the effect on the temperature of the exhaust gases at the exit from the HRSG for unfired and supplementary fired combined cycles with the same pinch point temperature.

Combined cycle power plants with a single-pressure steam turbine do not maximize utilization of the energy in the exhaust gases. The ideal temperature-heat transfer diagram would be one where the temperature difference in the HRSG between the water (steam) and the exhaust gases is a constant.

One way to approach this constant temperature difference and improve the utilization of the energy in the exhaust gases is to use multipressures in the steam power plant cycle. Systems which have been used are

1. A dual pressure nonreheat cycle;
2. A dual-pressure reheat cycle; and
3. A triple-pressure reheat cycle.

Each system listed above has advantages and disadvantages. As new gas turbine engines enter the market with increased turbine inlet temperatures and component efficiencies, exhaust temperature from the gas turbine increases. This allows for higher superheated steam temperatures and improved combined cycle power plant efficiencies. This means that each design must be analyzed so that the selected design yields the most economical system.

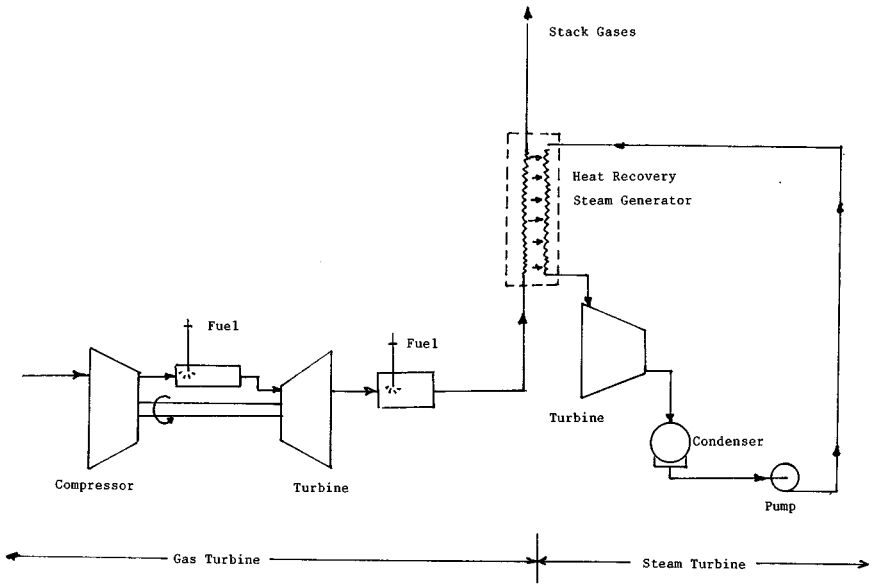

FIGURE 8.15.4 Combined cycle power plant with supplementary firing.

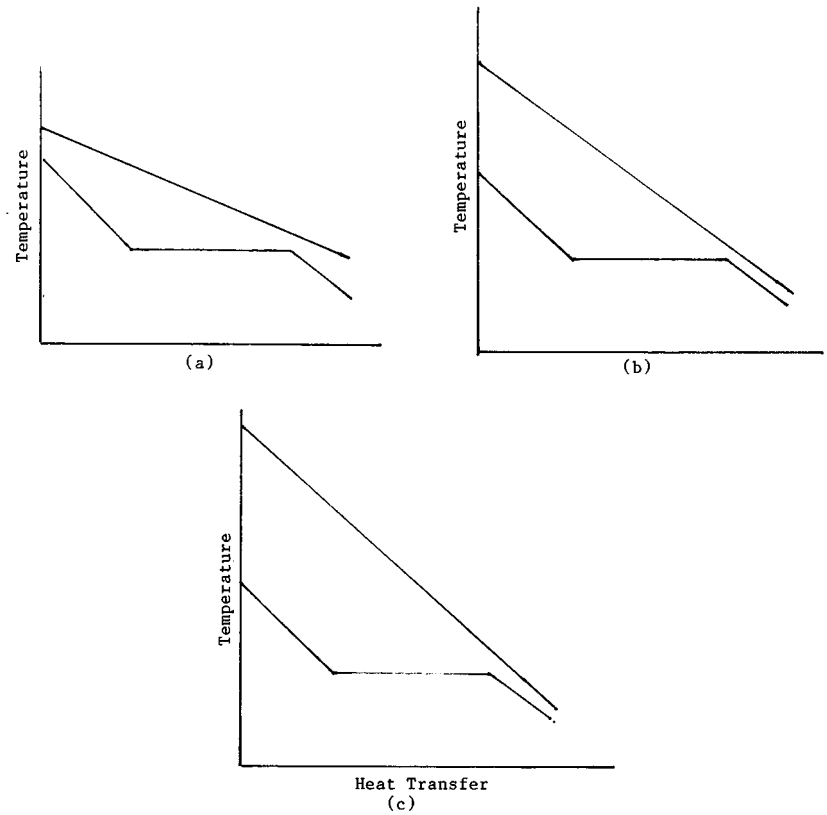

FIGURE 8.15.5 Effect of supplementary firing on exit temperature for same pinch point temperature difference. (a) No supplementary firing; (b), (c) supplementary firing.

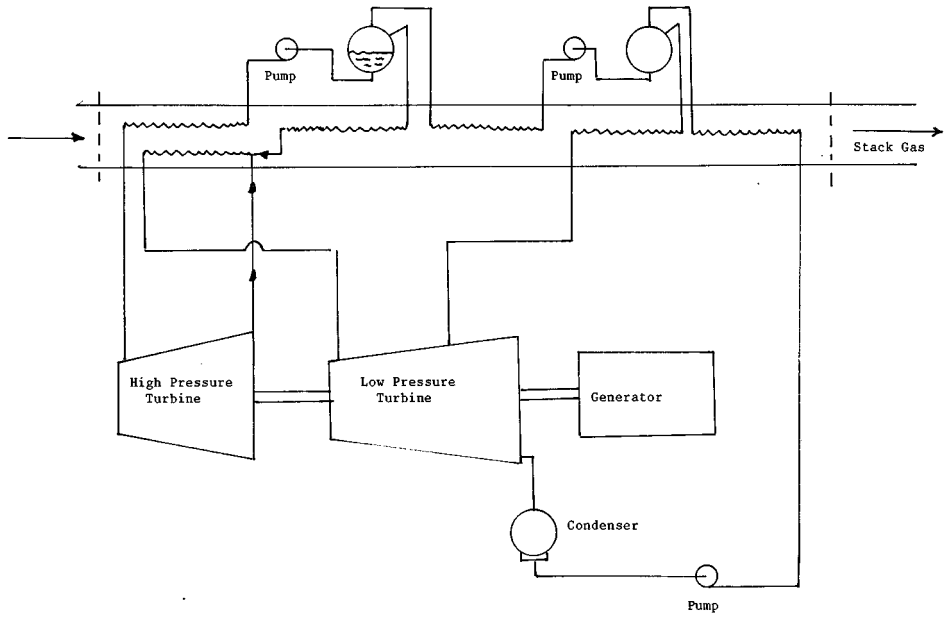

FIGURE 8.15.6 Schematic diagram for a three-pressure steam turbine combined cycle with superheating and reheat.

A simplified schematic diagram for a three-pressure combined cycle power plant is shown in Figure 8.15.6. This arrangement results in a high quality at the exit from the low-pressure steam turbine.

8.16 EMERGY Evaluation and Transformity

Howard T. Odum

EMERGY (spelled with an "m") evaluation is a method of energy analysis that puts all inputs and products on a common basis of what was previously required directly and indirectly to make each from one form of energy.

> EMERGY is the available energy of one kind previously used up directly and indirectly to make a service or product.

Its unit is the *emjoule,* defined to measure availability already used up. If average solar insolation at the earth's surface is chosen as the common base for the convenience of evaluating environmental and technological energy flows, then evaluations are made in units of solar emjoules, abbreviated sej.

In every energy transformation, available energy is used up to produce a smaller amount of energy of another kind. The EMERGY of one kind required directly and indirectly to make one unit of energy of another kind is defined as *transformity* (Odum, 1988).

> Solar transformity is the solar EMERGY of the inputs divided by the energy of the output.

$$\text{energy (J)} \times \text{transformity (sej/J)} = \text{EMERGY (sej)}$$

If all energy flows are expressed in solar EMERGY, then all kinds of energy may be compared according to their solar transformity. The more successive energy transformations there are, the higher the transformity. The higher the transformity, the more energy flows have converged in the process. Since many energy flows of one kind are usually required to support a smaller energy flow of another type, it is appropriate to describe the converging process as an *energy hierarchy.* The more transformations there are, the higher the transformity and the higher the position in a universal energy hierarchy. Figure 8.16.1 shows an environmental food chain with more energy flow but lower quality units (lower transformity) on the left and small total energy flow through high transformity units on the right. A land example is sunlight-grass-sheep-people. An aquatic series is sunlight-phytoplankton-zooplankton-small fish-large fish.

In environment, engineering, and economics the selective process of self organization generates higher quality energy capable of amplifying other processes. Thus observed transformitites are a measure of energy quality. Tables of solar transformity have been prepared based on previous EMERGY analysis (Odum, 1996). See sample in Table 8.16.1

Empower is the EMERGY used per unit time, for the United States about 8.5 E24 solar emjoules per year, a measure of the nation's processing of real wealth. By dividing the gross economic product ($6.5 trillion per year) the *EMERGY/money ratio* results (1.3 trillion solar emjoules per dollar). This is real wealth buying power of a dollar.

After an EMERGY evaluation is made, the solar EMERGY of each item can be divided by the *EMERGY*/money ratio to determine the *emdollars*, the buying power contributed by that item.

> *Emdollars are defined as the dollars of gross economic product due to that much real wealth measured as EMERGY.*

Because it puts all forms of available energy on a common basis, EMERGY may be the correct way to evaluate useful work. If real wealth comes from work, maximizing EMERGY production and use maximizes the real wealth of an economy. Selecting alternatives to maximize empower and emdollars is a new tool for engineering design and public policy.

Many energy analysis procedures add available energy as an exergy sum. However, EMERGY evaluation recognizes that each form of energy is different in its quality and the quantity of energy of other kinds required to make it. As shown in the EMERGY evaluation example (Table 8.16.2), each energy value is multiplied by its transformity so as to convert all items to solar EMERGY.

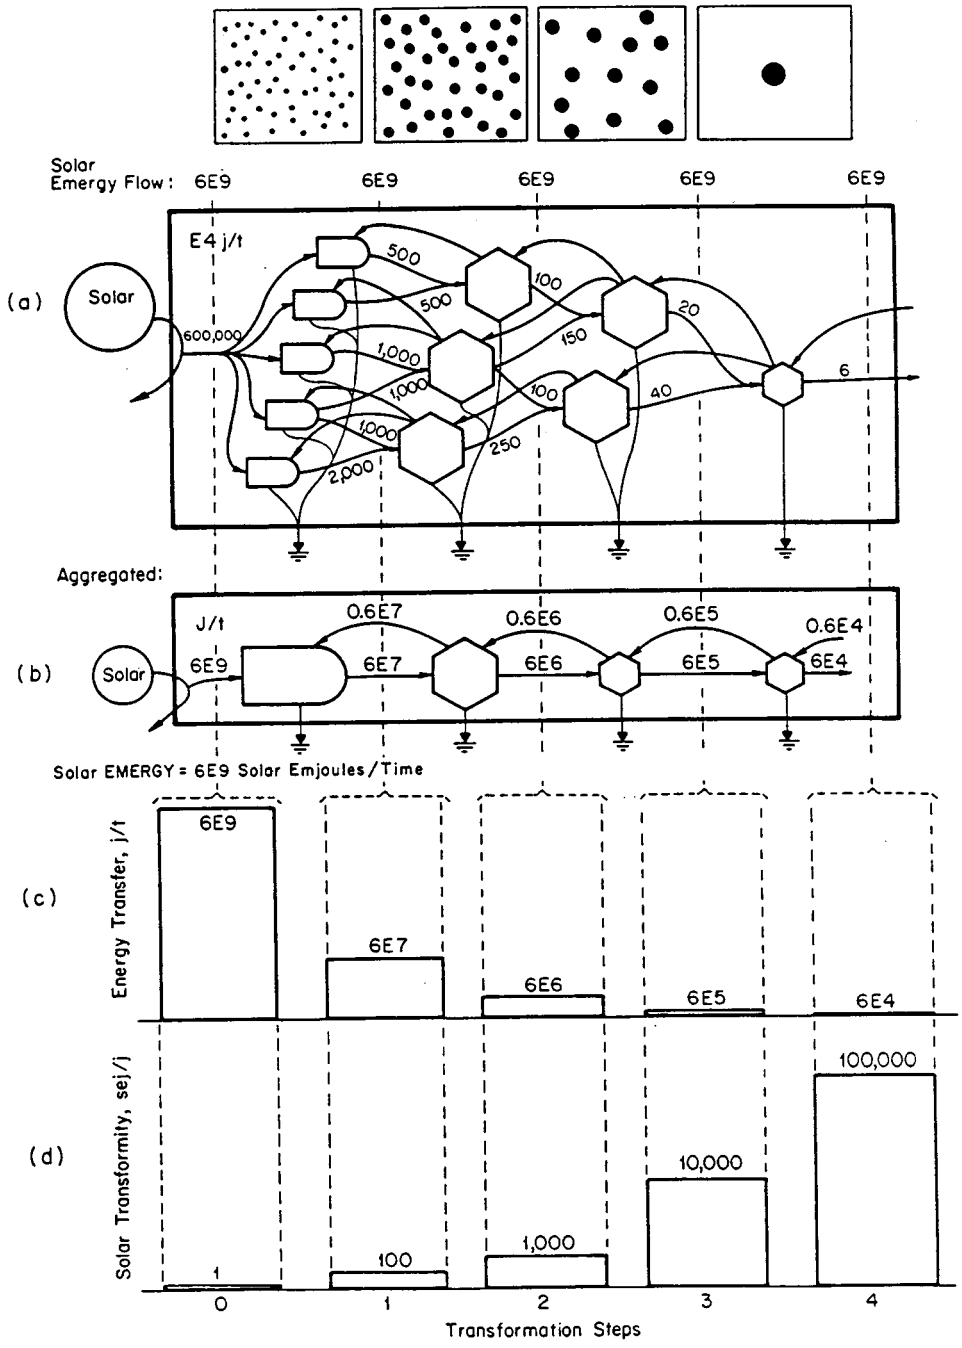

FIGURE 8.16.1 Energy transformation hierarchy: (a) spatial view of units, their sizes, and territories; (b) systems diagram of energy flow web; (c) web aggegated into an energy transformation chain; (d) energy flows between hierarchical levels; (e) transformitites of flows between levels.

TABLE 8.16.1 Typical Solar Transformities

Form of Energy	Solar Transformity sej/J
Solar insolation	1
Chemical energy in rain transpired over land#	18,000
Mined coal	40,000
Electric power	174,000
Human service, college graduate	343,000,000

sej/J = solar emjoules per Joule

Gibbs energy relative to sea water salt concentration in leaves, the main energy basis for land plants.

TABLE 8.16.2 EMERGY Evaluation of Lignite Processing in Texas*

Note	Item	Data Units/Day J, G, or $	Solar EMERGY/Unit sej/unit	Solar Empower E17 sej/day	Em$ 1995$ Thsd $/yr#
1	Diverted env. product.	7.10 E11 J	1.5 E4/J	0.11	8.5
2	Topsoil lost	5.04 E12 J	6.3 E4/J	3.18	244
3	Fuel used	6.38 E10 J	5.0 E4/J	0.032	2.5

6	Goods & service costs	2.8 E5 $	2.2 E12/$	6.2	477
				6.2	477
7	Sum of inputs			10.8	830
8	Lignite yield	2.0 E14 J	3.68 E4/J	73.6	5661

* Analysis of Big Brown Plant, Fairfield, Texas (Odum et al., 1987, revised).

Solar empower in Column 5 divided by 1.3 E12 sej/$ for U.S.A., 1995. Net EMERGY ratio = Yield/Inputs = 73.6/10.8 = 6.8

An Example of EMERGY Evaluation, Lignite

The evaluation procedure starts with an aggregated systems diagram to relate inputs, outputs, and main processes. This is used to identify line items in an evaluation table. An example is the analysis of lignite processing at the Big Brown Mine in Fairfield, Texas. Line items for the EMERGY evaluation in Table 8.16.2 were identified from the summarizing systems diagram in Figure 8.16.2. The net EMERGY ratio relates the EMERGY yield to the EMERGY required for the processing. The net EMERGY ratio of 6.8 (Table 8.16.2) means that 6.8 times more real wealth was contributed to the economy than required in the processing. The operation contributed 5.6 million emdollars per day to the economy as lignite yield, almost 12 times more than the economic value of $477,000 dollars per day.

Defining Terms

EMERGY: Available energy of one kind previously required directly and indirectly to make a product or service (unit: emjoules). Example: solar emjoules (abbreviation: sej).

Transformity: EMERGY per unit available energy (units: emjoules per joule). Example: solar emjoules per joule (abbreviation: sej/J).

Empower: EMERGY flow per unit time (units: emjoules per time). Example: solar emjoules per year (abbreviation: sej/yr).

Emdollars: EMERGY divided by EMERGY/money ratio. (abbreviation Em$).

Net EMERGY ratio: Yield EMERGY/EMERGY of purchased inputs.

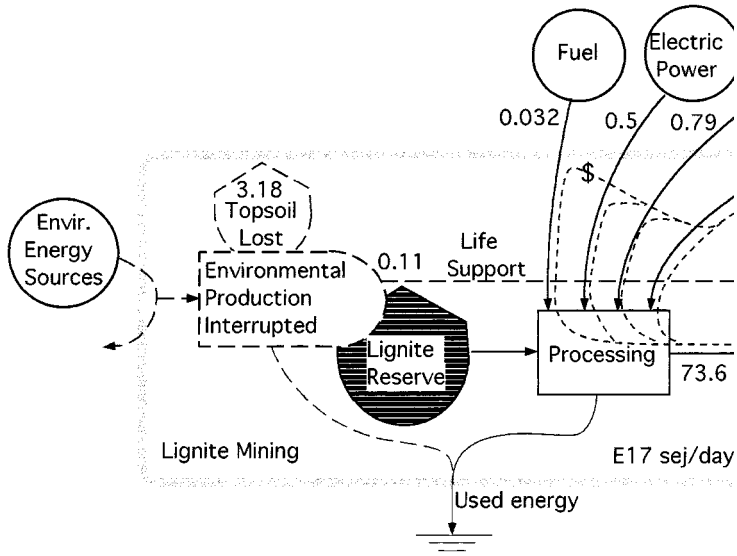

FIGURE 8.16.2 Energy systems diagram and emergy flows of a lignite mining operation evaluated in Table 8.16.2.

9.1 Introduction

Air-Conditioning

Air-conditioning is a process that simultaneously conditions air; distributes it combined with the outdoor air to the conditioned space; and at the same time controls and maintains the required space's temperature, humidity, air movement, air cleanliness, sound level, and pressure differential within predetermined limits for the health and comfort of the occupants, for product processing, or both.

The acronym HVAC&R stands for heating, ventilating, air-conditioning, and refrigerating. The combination of these processes is equivalent to the functions performed by air-conditioning.

Because I-P units are widely used in the HVAC&R industry in the U.S., I-P units are used in this chapter. A table for converting I-P units to SI units is available in Appendix X of this handbook.

Air-Conditioning Systems

An *air-conditioning* or *HVAC&R system* consists of components and equipment arranged in sequential order to heat or cool, humidify or dehumidify, clean and purify, attenuate objectionable equipment noise, transport the conditioned outdoor air and recirculate air to the conditioned space, and control and maintain an indoor or enclosed environment at optimum energy use.

The types of buildings which the air-conditioning system serves can be classified as:

- Institutional buildings, such as hospitals and nursing homes
- Commercial buildings, such as offices, stores, and shopping centers

- Residential buildings, including single-family and multifamily low-rise buildings of three or fewer stories above grade
- Manufacturing buildings, which manufacture and store products

Types of Air-Conditioning Systems

In institutional, commercial, and residential buildings, air-conditioning systems are mainly for the occupants' health and comfort. They are often called *comfort air-conditioning systems*. In manufacturing buildings, air-conditioning systems are provided for product processing, or for the health and comfort of workers as well as processing, and are called *processing air-conditioning systems*.

Based on their size, construction, and operating characteristics, air-conditioning systems can be classified as the following.

Individual Room or Individual Systems. An individual air-conditioning system normally employs either a single, self-contained, packaged room air conditioner (installed in a window or through a wall) or separate indoor and outdoor units to serve an individual room, as shown in Figure 9.1.1. "Self-contained, packaged" means factory assembled in one package and ready for use.

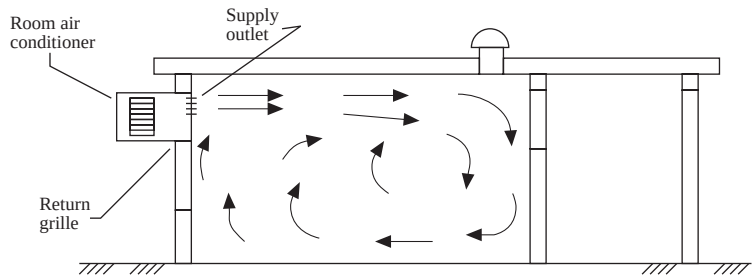

FIGURE 9.1.1 An individual room air-conditioning system.

Space-Conditioning Systems or Space Systems. These systems have their air-conditioning—cooling, heating, and filtration—performed predominantly in or above the conditioned space, as shown in Figure 9.1.2. Outdoor air is supplied by a separate outdoor ventilation system.

Unitary Packaged Systems or Packaged Systems. These systems are installed with either a single self-contained, factory-assembled packaged unit (PU) or two split units: an indoor air handler, normally with ductwork, and an outdoor condensing unit with refrigeration compressor(s) and condenser, as shown in Figure 9.1.3. In a packaged system, air is cooled mainly by direct expansion of refrigerant in coils called DX coils and heated by gas furnace, electric heating, or a heat pump effect, which is the reverse of a refrigeration cycle.

Central Hydronic or Central Systems. A central system uses chilled water or hot water from a central plant to cool and heat the air at the coils in an air handling unit (AHU) as shown in Figure 9.1.4. For energy transport, the heat capacity of water is about 3400 times greater than that of air. Central systems are built-up systems assembled and installed on the site.

Packaged systems are comprised of only air system, refrigeration, heating, and control systems. Both central and space-conditioning systems consist of the following.

Air Systems. An air system is also called an air handling system or the air side of an air-conditioning or HVAC&R system. Its function is to condition the air, distribute it, and control the indoor environment according to requirements. The primary equipment in an air system is an AHU or air handler; both of these include fan, coils, filters, dampers, humidifiers (optional), supply and return ductwork, supply outlets and return inlets, and controls.

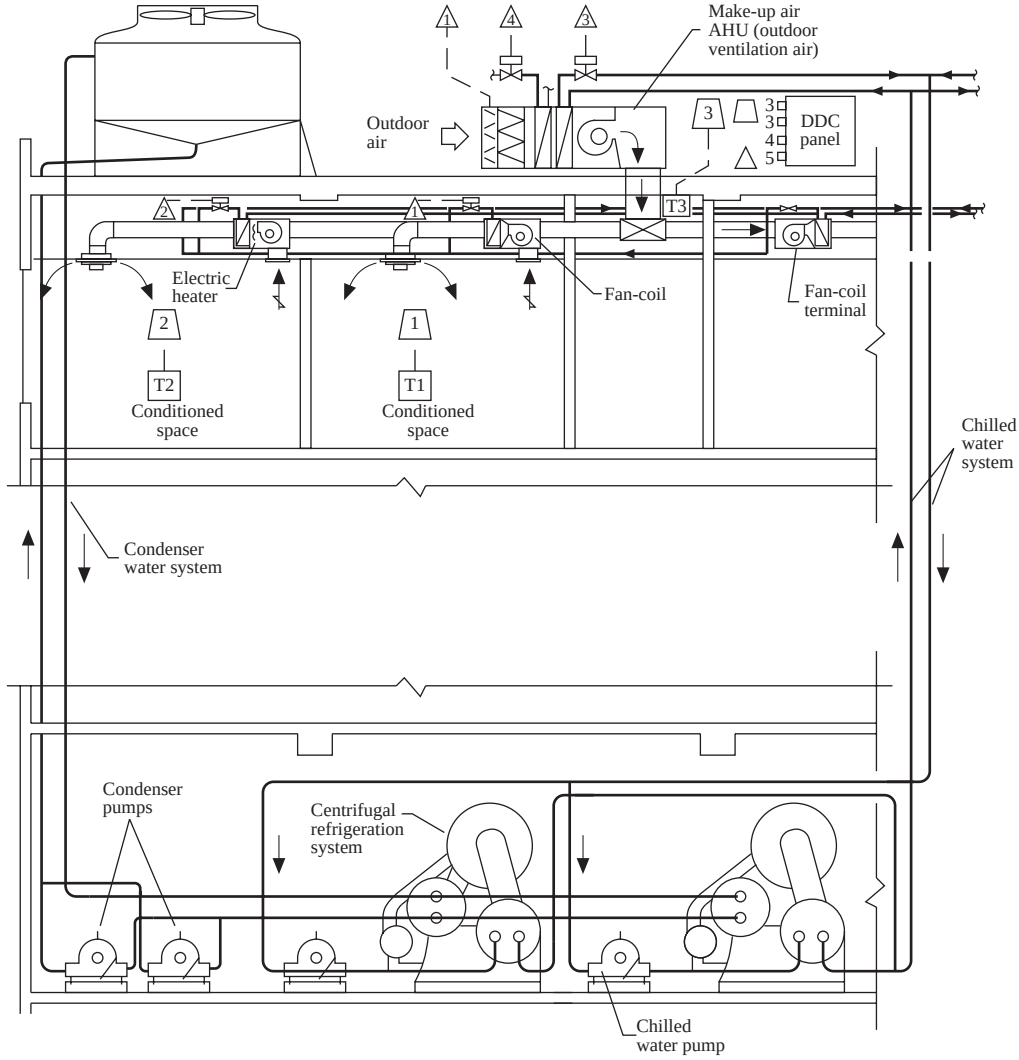

FIGURE 9.1.2 A space-conditioning air-conditioning system (fan-coil system).

Water Systems. These systems include chilled water, hot water, and condenser water systems. A water system consists of pumps, piping work, and accessories. The water system is sometimes called the water side of a central or space-conditioning system.

Central Plant Refrigeration and Heating Systems. The refrigeration system in the central plant of a central system is usually in the form of a chiller package with an outdoor condensing unit. The refrigeration system is also called the refrigeration side of a central system. A boiler and accessories make up the heating system in a central plant for a central system, and a direct-fired gas furnace is often the heating system in the air handler of a rooftop packaged system.

Control Systems. Control systems usually consist of sensors, a microprocessor-based direct digital controller (DDC), a control device, control elements, personal computer (PC), and communication network.

Based on Commercial Buildings Characteristics 1992, Energy Information Administration (EIA) of the Department of Energy of United States in 1992, for commercial buildings having a total floor area

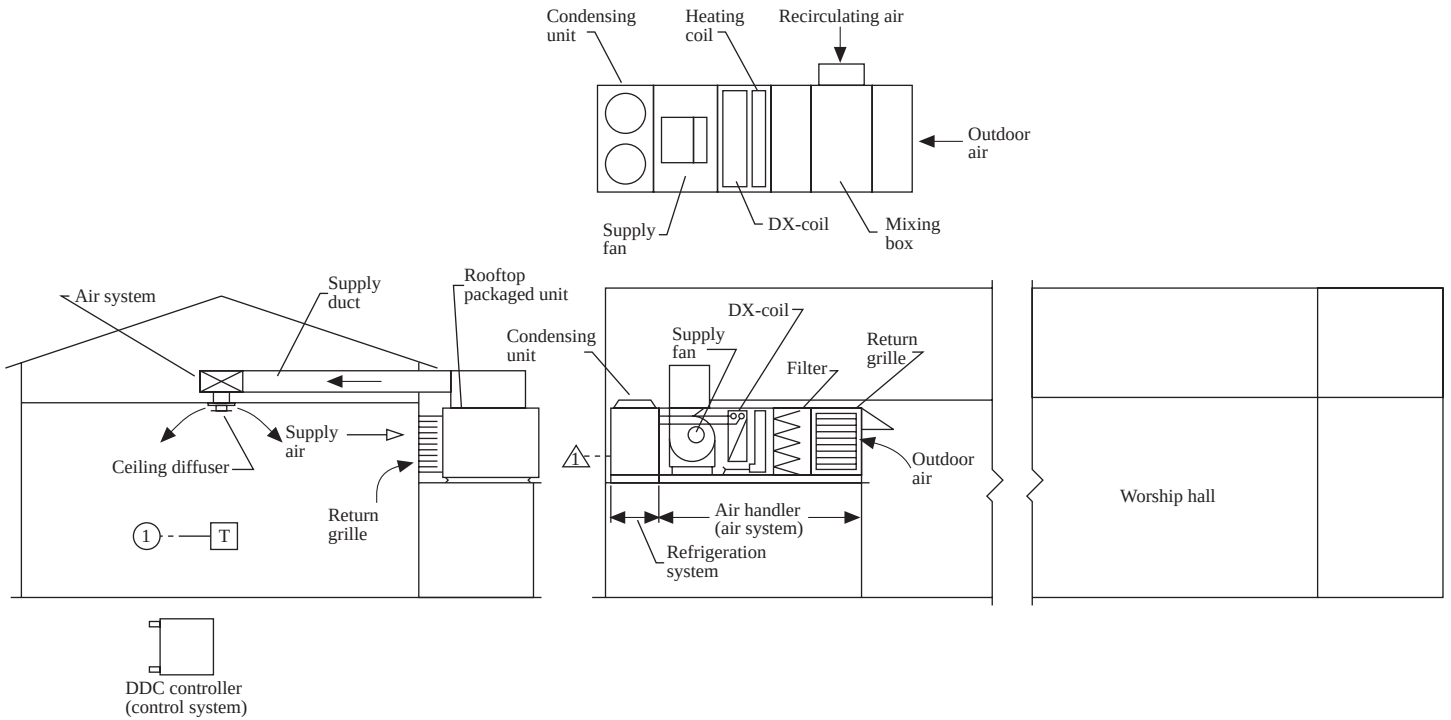

FIGURE 9.1.3 A packaged air-conditioning system.

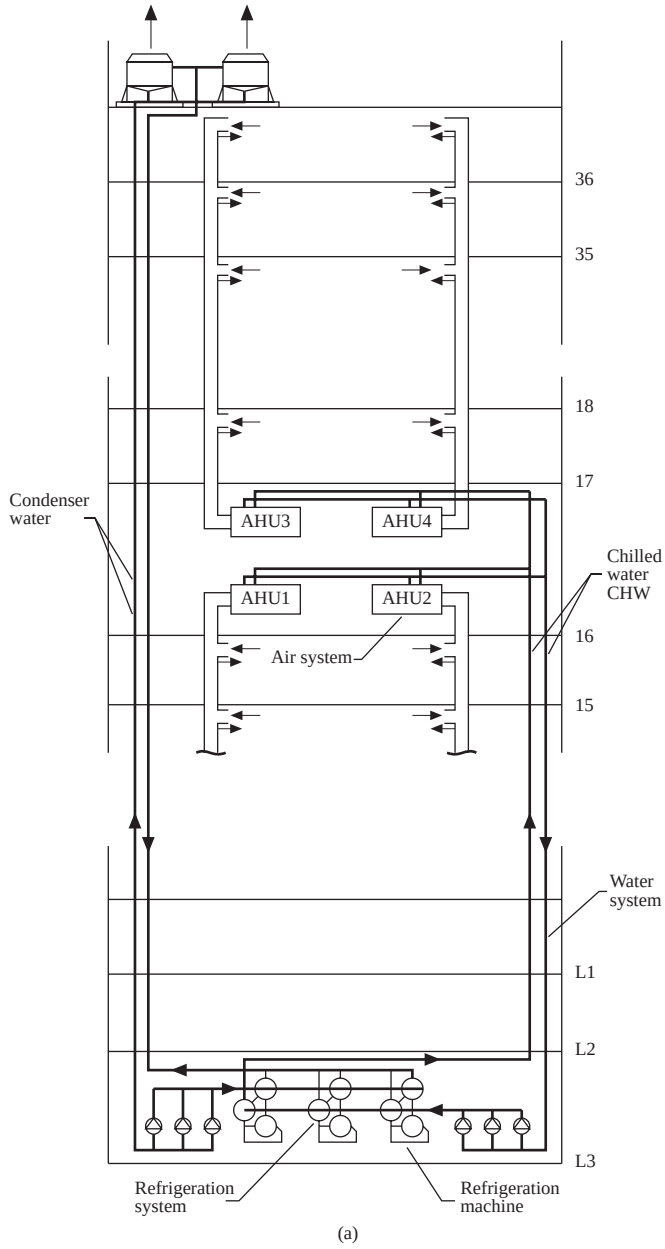

FIGURE 9.1.4a A central air-conditioning system: schematic diagram.

of 67,876 million ft², of which 57,041 million ft² or 84% is cooled and 61,996 million ft² or 91% is heated, the air-conditioning systems for cooling include:

Individual systems	19,239 million ft²	(25%)
Packaged systems	34,753 million ft²	(49%)
Central systems	14,048 million ft²	(26%)

Space-conditioning systems are included in central systems. Part of the cooled floor area has been counted for both individual and packaged systems. The sum of the floor areas for these three systems therefore exceeds the total cooled area of 57,041 million ft².

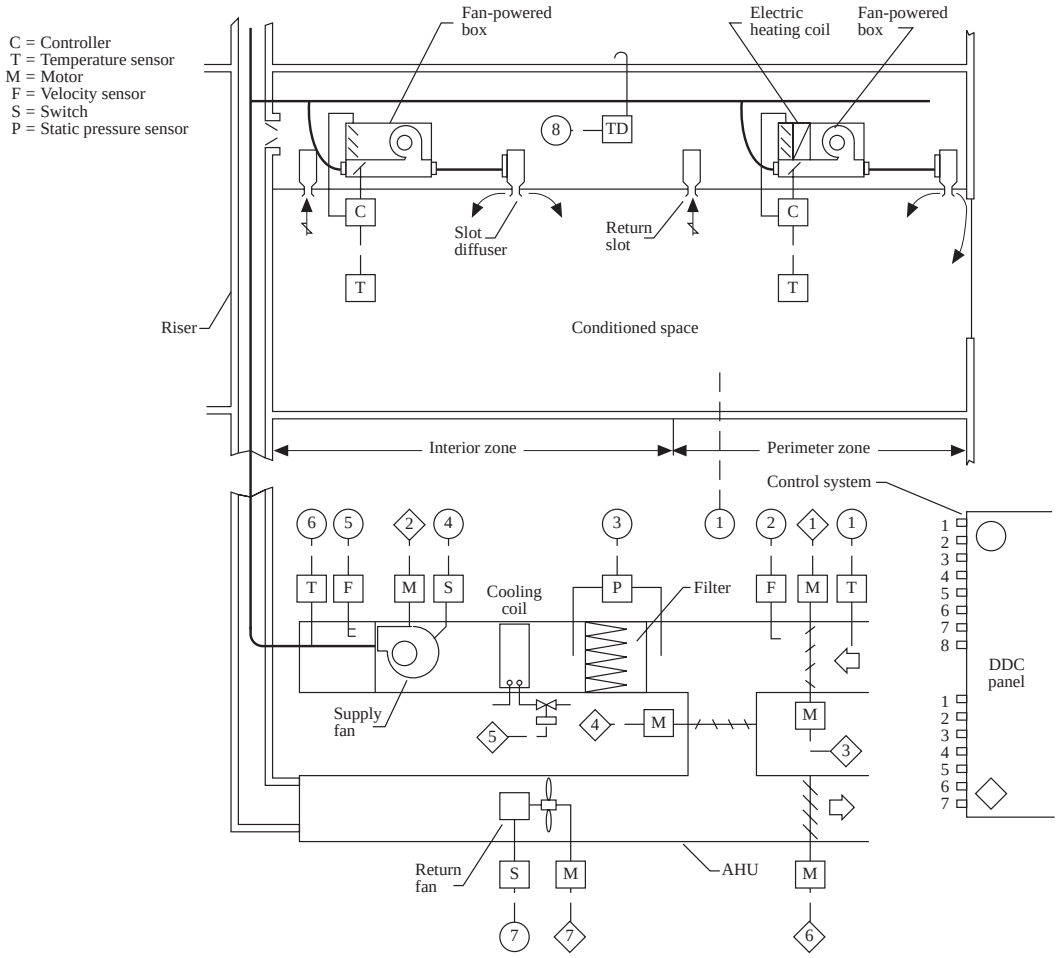

FIGURE 9.1.4b A central air-conditioning system: air and control systems for a typical floor.

Air-Conditioning Project Development and System Design

The goal of an air-conditioning/HVAC&R system is to provide a healthy and comfortable indoor environment with acceptable indoor air quality, while being energy efficient and cost effective.

ASHRAE Standard 62-1989 defines *acceptable indoor air quality* as "air in which there are no known contaminants at harmful concentrations as determined by cognizant authorities and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction."

The basic steps in the development and use of an air-conditioning project are design, installation, commissioning, operation, and maintenance. There are two types of air-conditioning projects: *design-bid* and *design-build*. A design-bid project separates the design (engineering consultant) and installation (contractors) responsibilities. In a design-build project, the design is also done by the installation contractor. A design-build project is usually a small project or a project having insufficient time to go through normal bidding procedures.

In the building construction industry, air-conditioning or HVAC&R is one of the *mechanical services*; these also include plumbing, fire protection, and escalators.

Air-conditioning design is a process of selecting the optimum system, subsystem, equipment, and components from various alternatives and preparing the drawings and specifications. Haines (1994) summarized this process in four phases: gather information, develop alternatives, evaluate alternatives,

and sell the best solution. Design determines the basic operating characteristics of a system. After an air-conditioning system is designed and constructed, it is difficult and expensive to change its basic characteristics.

The foundation of a successful project is teamwork and coordination between designer, contractor, and operator and between mechanical engineer, electrical engineer, facility operator, architect, and structural engineer.

Field experience is helpful to the designer. Before beginning the design process it is advisable to visit similar projects that have operated for more than 2 years and talk with the operator to investigate actual performance.

Mechanical Engineer's Responsibilities

The normal procedure in a design-bid construction project and the mechanical engineer's responsibilities are

1. Initiation of a project by owner or developer
2. Organizing a design team
3. Determining the design criteria and indoor environmental parameters
4. Calculation of cooling and heating loads
5. Selection of systems, subsystems, and their components
6. Preparation of schematic layouts; sizing of piping and ductwork
7. Preparation of contract documents: drawings and specifications
8. Competitive biddings by various contractors; evaluation of bids; negotiations and modifications
9. Advice on awarding of contract
10. Monitoring, supervision, and inspection of installation; reviewing shop drawings
11. Supervision of commissioning
12. Modification of drawings to the as-built condition; preparation of the operation and maintenance manual
13. Handing over to the property management for operation

Design Documents

Drawings and *specifications* are legal documents of a construction contract. The designer conveys the owner's or developer's requirements to the contractor through these documents. Drawings and specifications complement each other.

Drawings should clearly and completely show, define, and present the work. Adequate plan and sectional views should be drawn. More often, isometric drawings are used to show the flow diagrams for water or the supply, return, and exhaust air.

Specifications include the legal contract between the owner and the contractor, installer, or vendor and the technical specifications, which describe in detail what kind of material and equipment should be used and how they are to be installed.

Most projects now use a format developed by the Construction Specifications Institute (CSI) called the Masterformat for Specifications. It includes 16 divisions. The 15000 Mechanical division is divided into the following:

Section No.	Title
15050	Basic Mechanical Materials and Methods
15250	Mechanical Insulation
15300	Fire Protection
15400	Plumbing
15500	Heating, Ventilating, and Air-Conditioning
15550	Heat Generation
15650	Refrigeration
15750	Heat Transfer
15850	Air Handling

Section No.	Title
15880	Air Distribution
15950	Controls
15990	Testing, Adjusting, and Balancing

Each section includes general considerations, equipment and material, and field installation. Design criteria and selected indoor environmental parameters that indicate the performance of the HVAC&R system must be clearly specified in the general consideration of Section 15500.

There are two types of specifications: the performance specification, which depends mainly on the required performance criteria, and the or-equal specification, which specifies the wanted vendor. Specifications should be written in simple, direct, and clear language without repetition.

Computer-Aided Design and Drafting

With the wide acceptance of the PC and the availability of numerous types of engineering software, the use of *computer-aided drafting* (CAD) and *computer-aided design and drafting* (CADD) has increased greatly in recent years. According to the 1994 CADD Application and User Survey of design firms reported in *Engineering Systems* (1994[6]), "15% of the design firms now have a computer on every desk" and "Firms with high productivity reported that they perform 95% on CADD." Word processing software is widely used to prepare specifications.

Drafting software used to reproduce architectural drawings is the foundation of CADD. Automated CAD (AutoCAD) is the leading personal computer-based drafting tool software used in architectural and engineering design firms.

In "Software Review" by Amistadi (1993), duct design was the first HVAC&R application to be integrated with CAD.

- Carrier Corp. DuctLINK and Softdesk HVAC 12.0 are the two most widely used duct design software. Both of them convert the single-line duct layout drawn with CAD to two-dimensional (2D) double-line drawings with fittings, terminals, and diffusers.
- Tags and schedules of HVAC&R equipment, ductwork, and duct fittings can be produced as well.
- DuctLINK and Softdesk can also interface with architectural, electrical, and plumbing drawings through AutoCAD software.

Software for piping system design and analysis can also be integrated with CAD. The software developed at the University of Kentucky, KYCAD/KYPIPE, is intended for the design and diagnosis of large water piping systems, has extensive hydraulic modeling capacities, and is the most widely used. Softdesk AdCADD Piping is relative new software; it is intended for drafting in 2D and 3D, linking to AutoCAD through design information databases.

Currently, software for CADD for air-conditioning and HVAC&R falls into two categories: engineering and product. The engineering category includes CAD (AutoCAD integrated with duct and piping system), load calculations and energy analysis, etc. The most widely used software for load calculations and energy analysis is Department of Energy DOE-2.1D, Trane Company's TRACE 600, and Carrier Corporation's softwares for load calculation, E20-II Loads.

Product categories include selection, configuration, performance, price, and maintenance schedule. Product manufacturers provide software including data and CAD drawings for their specific product.

Codes and Standards

Codes are federal, state, or city laws that require the designer to perform the design without violating people's (including occupants and the public) safety and welfare. Federal and local codes must be followed. The designer should be thoroughly familiar with relevant codes. HVAC&R design codes are definitive concerning structural and electrical safety, fire prevention and protection (particularly for gas- or oil-fired systems), environmental concerns, indoor air quality, and energy conservation.

Conformance with *ASHRAE Standards* is voluntary. However, for design criteria or performance that has not been covered in the codes, whether the ASHRAE Standard is followed or violated is the vital criterion, as was the case in a recent indoor air quality lawsuit against a designer and contractor.

For the purpose of performing an effective, energy-efficient, safe, and cost-effective air-conditioning system design, the following ASHRAE Standards should be referred to from time to time:

- ASHRAE/IES Standard 90.1-1989, Energy Efficient Design of New Buildings Except New Low-Rise Residential Buildings
- ANSI/ASHRAE Standard 62-1989, Ventilation for Acceptable Indoor Air Quality
- ANSI/ASHRAE Standard 55-1992, Thermal Environmental Conditions for Human Occupancy
- ASHRAE Standard 15-1992, Safety Code for Mechanical Refrigeration

9.2 Psychrometrics

Moist Air

Above the surface of the earth is a layer of air called the *atmosphere*, or *atmospheric air*. The lower atmosphere, or homosphere, is composed of moist air, that is, a mixture of dry air and water vapor.

Psychrometrics is the science of studying the thermodynamic properties of moist air. It is widely used to illustrate and analyze the change in properties and the thermal characteristics of the air-conditioning process and cycles.

The composition of dry air varies slightly at different geographic locations and from time to time. The approximate composition of dry air by volume is nitrogen, 79.08%; oxygen, 20.95%; argon, 0.93%; carbon dioxide, 0.03%; other gases (e.g., neon, sulfur dioxide), 0.01%.

The amount of water vapor contained in the moist air within the temperature range 0 to 100°F changes from 0.05 to 3% by mass. The variation of water vapor has a critical influence on the characteristics of moist air.

The equation of state for an ideal gas that describes the relationship between its thermodynamic properties covered in Chapter 2 is

$$pv = RT_R \tag{9.2.1}$$

or

$$pV = mRT_R \tag{9.2.2}$$

where p = pressure of the gas, psf (1 psf = 144 psi)
v = specific volume of the gas, ft^3/lb
R = gas constant, $ftlb_f/lb_m$ °R
T_R = absolute temperature of the gas, °R
V = volume of the gas, ft^3
m = mass of the gas, lb

The most exact calculation of the thermodynamic properties of moist air is based on the formulations recommended by Hyland and Wexler (1983) of the U.S. National Bureau of Standards. The psychrometric charts and tables developed by ASHRAE are calculated and plotted from these formulations. According to Nelson et al. (1986), at a temperature between 0 and 100°F, enthalpy and specific volume calculations using ideal gas Equations (9.2.1) and (9.2.2) show a maximum deviation of 0.5% from the results of Hyland and Wexler's exact formulations. Therefore, ideal gas equations are used in the development and calculation of psychrometric formulations in this handbook.

Although air contaminants may seriously affect human health, they have little effect on the thermodynamic properties of moist air. For thermal analysis, moist air may be treated as a binary mixture of dry air and water vapor.

Applying Dalton's law to moist air:

$$p_{at} = p_a + p_w \tag{9.2.3}$$

where p_{at} = atmospheric pressure of the moist air, psia
p_a = partial pressure of dry air, psia
p_w = partial pressure of water vapor, psia

Dalton's law is summarized from the experimental results and is more accurate at low gas pressure. Dalton's law can also be extended, as the Gibbs-Dalton law, to describe the relationship of internal energy, enthalpy, and entropy of the gaseous constituents in a mixture.

Humidity and Enthalpy

The *humidity ratio* of moist air, w, in lb/lb is defined as the ratio of the mass of the water vapor, m_w to the mass of dry air, m_a, or

$$w = m_w / m_a = 0.62198 p_w / \left(p_{at} - p_w\right) \tag{9.2.4}$$

The *relative humidity* of moist air, φ, or RH, is defined as the ratio of the mole fraction of water vapor, x_w, to the mole fraction of saturated moist air at the same temperature and pressure, x_{ws}. Using the ideal gas equations, this relationship can be expressed as:

$$\varphi = x_w / x_{ws}\big|_{T,p} = p_w / p_{ws}\big|_{T,p} \tag{9.2.5}$$

and

$$x_w = n_w / \left(n_a + n_w\right); \quad x_{ws} = n_{ws} / \left(n_a + n_{ws}\right)$$

$$x_a + x_w = 1 \tag{9.2.6}$$

where p_{ws} = pressure of saturated water vapor, psia
T = temperature, °F
n_a, n_w, n_{ws} = number of moles of dry air, water vapor, and saturated water vapor, mol

Degree of saturation μ is defined as the ratio of the humidity ratio of moist air, w, to the humidity ratio of saturated moist air, w_s, at the same temperature and pressure:

$$\mu = w / w_s\big|_{T,p} \tag{9.2.7}$$

The difference between φ and μ is small, usually less than 2%.

At constant pressure, the difference in specific enthalpy of an ideal gas, in Btu/lb, is $\Delta h = c_p \Delta T$. Here c_p represents the specific heat at constant pressure, in Btu/lb. For simplicity, the following assumptions are made during the calculation of the *enthalpy* of moist air:

1. At 0°F, the enthalpy of dry air is equal to zero.
2. All water vapor is vaporized at 0°F.
3. The enthalpy of saturated water vapor at 0°F is 1061 Btu/lb.
4. The unit of the enthalpy of the moist air is Btu per pound of dry air and the associated water vapor, or Btu/lb.

Then, within the temperature range 0 to 100°F, the enthalpy of the moist air can be calculated as:

$$\begin{aligned} h &= c_{pd} T + w\left(h_{g0} + c_{ps} T\right) \\ &= 0.240 T + w(1061 + 0.444 T) \end{aligned} \tag{9.2.8}$$

where c_{pd}, c_{ps} = specific heat of dry air and water vapor at constant pressure, Btu/lb°F. Their mean values can be taken as 0.240 and 0.444 Btu/lb°F, respectively.
h_{g0} = specific enthalpy of saturated water vapor at 0°F.

Moist Volume, Density, Specific Heat, and Dew Point

The specific *moist volume v*, in ft^3/lb, is defined as the volume of the mixture of dry air and the associated water vapor when the mass of the dry air is exactly 1 lb:

$$v = V/m_a \tag{9.2.9}$$

where V = total volume of the moist air, ft^3. Since moist air, dry air, and water vapor occupy the same volume,

$$v = R_a T_R / p_{at}(1 + 1.6078w) \tag{9.2.10}$$

where R_a = gas constant for dry air.

Moist air density, often called *air density* ρ, in lb/ft^3, is defined as the ratio of the mass of dry air to the total volume of the mixture, or the reciprocal of the moist volume:

$$\rho = m_a/V = 1/v \tag{9.2.11}$$

The *sensible heat of moist air* is the thermal energy associated with the change of air temperature between two state points. In Equation (9.2.8), $(c_{pd} + wc_{ps})T$ indicates the sensible heat of moist air, which depends on its temperature T above the datum 0°F. *Latent heat of moist air*, often represented by wh_{fg0}, is the thermal energy associated with the change of state of water vapor. Both of them are in Btu/lb. Within the temperature range 0 to 100°F, if the average humidity ratio w is taken as 0.0075 lb/lb, the *specific heat of moist air* c_{pa} can be calculated as:

$$c_{pa} = c_{pd} + wc_{ps} = 0.240 + 0.0075 \times 0.444 = 0.243 \text{ Btu/lb °F} \tag{9.2.12}$$

The *dew point temperature* T_{dew}, in °F, is the temperature of saturated moist air of the moist air sample having the same humidity ratio at the same atmospheric pressure. Two moist air samples of similar dew points T_{dew} at the same atmospheric pressure have the same humidity ratio w and the same partial pressure of water vapor p_w.

Thermodynamic Wet Bulb Temperature and Wet Bulb Temperature

The *thermodynamic wet bulb temperature* of moist air, T^*, is equal to the saturated state of a moist air sample at the end of a constant-pressure, ideal adiabatic saturation process:

$$h_1 + \left(w_s^* - w_1\right)h_w^* = h_s^* \tag{9.2.13}$$

where h_1, h_s^* = enthalpy of moist air at the initial state and enthalpy of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, Btu/lb

w_1, w_s^* = humidity ratio of moist air at the initial state and humidity ratio of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, lb/lb

h_w^* = enthalpy of water added to the adiabatic saturation process at temperature T^*, Btu/lb

An *ideal adiabatic saturation process* is a hypothetical process in which moist air at initial temperature T_1, humidity ratio w_1, enthalpy h_1, and pressure p flows over a water surface of infinite length through a well-insulated channel. Liquid water is therefore evaporated into water vapor at the expense of the sensible heat of the moist air. The result is an increase of humidity ratio and a drop of temperature until the moist air is saturated at the thermodynamic wet bulb temperature T^* during the end of the ideal adiabatic saturation process.

The thermodynamic wet bulb temperature T^* is a unique fictitious property of moist air that depends only on its initial properties, T_1, w_1, or h_1.

A sling-type *psychrometer*, as shown in Figure 9.2.1, is an instrument that determines the temperature, relative humidity, and thus the state of the moist air by measuring its dry bulb and wet bulb temperatures. It consists of two mercury-in-glass thermometers. The sensing bulb of one of them is dry and is called the dry bulb. Another sensing bulb is wrapped with a piece of cotton wick, one end of which dips into a water tube. This wetted sensing bulb is called the wet bulb and the temperature measured by it is called the *wet bulb temperature* T'.

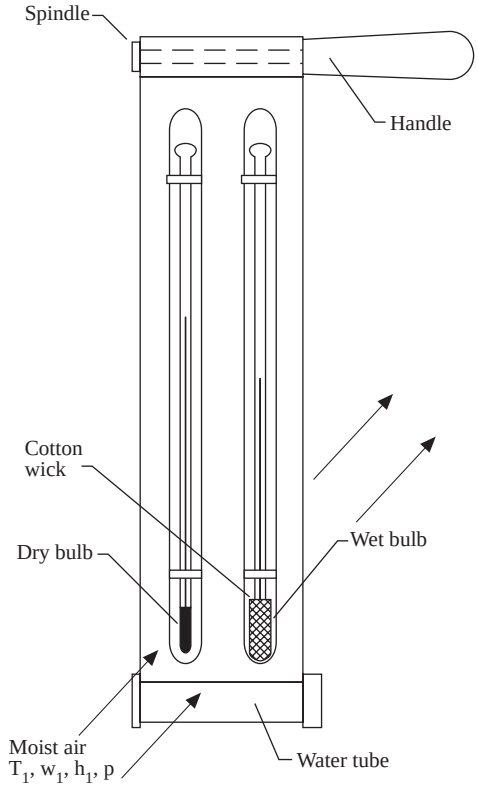

FIGURE 9.2.1 A sling psychrometer.

When unsaturated moist air flows over the surface of the wetted cotton wick, liquid water evaporates from its surface. As it absorbs sensible heat, mainly from the surrounding air, the wet bulb temperature drops. The difference between the dry and wet bulb temperatures is called *wet bulb depression* $(T - T')$. Turning the handle forces the surrounding air to flow over the dry and wet bulbs at an air velocity between 300 to 600 fpm. Distilled water must be used to wet the cotton wick.

At steady state, if heat conduction along the thermometer stems is neglected and the temperature of the wetted cotton wick is equal to the wet bulb temperature of the moist air, as the sensible heat transfer from the surrounding moist air to the cotton wick exactly equals the latent heat required for evaporation, the heat and mass transfer per unit area of the wet bulb surface can be evaluated as:

$$h_c(T - T') + h_r(T_{ra} - T) = h_d(w'_s - w_1) \tag{9.2.14}$$

where h_c, h_r = mean conductive and radiative heat transfer coefficient, Btu/hr ft²°F
h_d = mean convective mass transfer coefficient, lb/hr ft²

T = temperature of undisturbed moist air at a distance from the wet bulb, °F
T_{ra} = mean radiant temperature (covered later), °F
w_1, w'_s = humidity ratio of the moist air and the saturated film at the interface of cotton wick and surrounding air, lb/lb
h'_{fg} = latent heat of vaporization at the wet bulb temperature, Btu/lb

The humidity ratio of the moist air is given by:

$$w_1 = w'_s - K'(T - T')\left(1 + \left\{h_r(T_{ra} - T')/\left[h_c(T - T')\right]\right\}\right)$$

$$K' = c_{pa}\,\mathrm{Le}^{0.6667}/h'_{fg} \tag{9.2.15}$$

where K' = wet bulb constant, which for a sling psychrometer = 0.00218 1/°F
Le = Lewis number

The wet bulb temperature T' depends not only on its initial state but also on the rate of heat and mass transfer at the wet bulb. Therefore, the thermodynamic wet bulb temperature is used in ASHRAE psychrometric charts.

According to Threlkeld (1970), for a sling psychrometer whose wet bulb diameter is 1 in. and for air flowing at a velocity of 400 fpm over the wet bulb, if the dry bulb temperature is 90°F and the measured wet bulb temperature is 70°F, the difference between the measured wet bulb and the thermodynamic wet bulb $(T' - T^*)/(T^* - T')$ is less than 1%.

Psychrometric Charts

A *psychrometric chart* is a graphical presentation of the thermodynamic properties of moist air and various air-conditioning processes and air-conditioning cycles. A psychrometric chart also helps in calculating and analyzing the work and energy transfer of various air-conditioning processes and cycles.

Psychrometric charts currently use two kinds of basic coordinates:

1. *h*-*w* charts. In *h*-*w* charts, enthalpy *h*, representing energy, and humidity ratio *w*, representing mass, are the basic coordinates. Psychrometric charts published by ASHRAE and the Charted Institution of Building Services Engineering (CIBSE) are *h*-*w* charts.
2. *T*-*w* charts. In *T*-*w* charts, temperature *T* and humidity ratio *w* are basic coordinates. Psychrometric charts published by Carrier Corporation, the Trane Company, etc. are *T*-*w* charts.

Figure 9.2.2 shows an abridged ASHRAE psychrometric chart. In the ASHRAE chart:

- A normal temperature chart has a temperature range of 32 to 120°F, a high-temperature chart 60 to 250°F, and a low-temperature chart –40 to 50°F. Since enthalpy is the basic coordinate, temperature lines are not parallel to each other. Only the 120°F line is truly vertical.
- Thermodynamic properties of moist air are affected by atmospheric pressure. The standard atmospheric pressure is 29.92 in. Hg at sea level. ASHRAE also published charts for high altitudes of 5000 ft, 24.89 in. Hg, and 7500 ft, 22.65 in. Hg. Both of them are in the normal temperature range.
- Enthalpy *h*-lines incline downward to the right-hand side (negative slope) at an angle of 23.5° to the horizontal line and have a range of 12 to 54 Btu/lb.
- Humidity ratio *w*-lines are horizontal lines. They range from 0 to 0.28 lb/lb.
- Relative humidity φ-lines are curves of relative humidity 10%, 20%, ... 90% and a saturation curve. A saturation curve is a curve of the locus of state points of saturated moist air, that is, φ = 100%. On a saturation curve, temperature *T*, thermodynamic wet temperature bulb T^*, and dew point temperature T_{dew} have the same value.

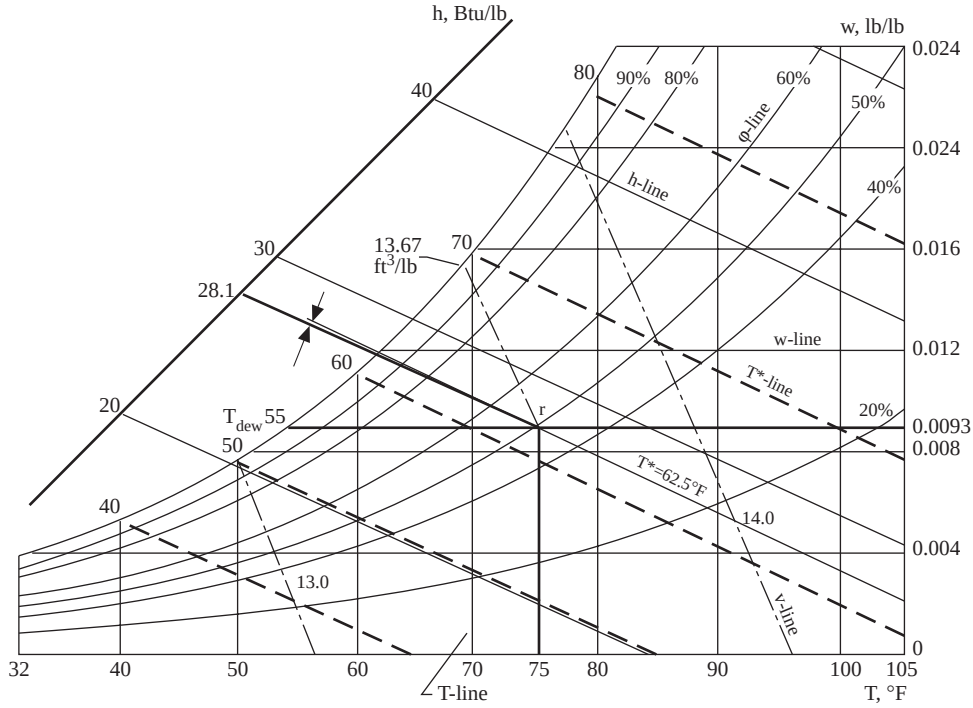

FIGURE 9.2.2 The abridged ASHRAE psychrometric chart and the determination of properties as in Example 9.2.1.

- Thermodynamic wet bulb T^*-lines have a negative slope slightly greater than that of the h-lines. A T^*-line meets the T-line of the same magnitude on the saturation curve.
- Moist volume v-lines have a far greater negative slope than h-lines and T^*-lines. The moist volume ranges from 12.5 to 15 ft^3/lb.

Moist air has seven independent thermodynamic properties or property groups: h, T, φ, T^*, p_{at}, $\rho - v$, and $w - p_w - T_{dew}$. When p_{at} is given, any additional two of the independent properties determine the state of moist air on the psychrometric chart and the remaining properties.

Software using AutoCAD to construct the psychrometric chart and calculate the thermodynamic properties of moist air is available. It can also be linked to the load calculation and energy programs to analyze the characteristics of air-conditioning cycles.

Refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993) and *ASHRAE Handbook, Fundamentals* (1993) for details of psychrometric charts and psychrometric tables that list thermodynamic properties of moist air.

Example 9.2.1

An air-conditioned room at sea level has an indoor design temperature of 75°F and a relative humidity of 50%. Determine the humidity ratio, enthalpy, density, dew point, and thermodynamic wet bulb temperature of the indoor air at design condition.

Solution

1. Since the air-conditioned room is at sea level, a psychrometric chart of standard atmospheric pressure of 14.697 psi should be used to find the required properties.
2. Plot the state point of the room air at design condition r on the psychrometric chart. First, find the room temperature 75°F on the horizontal temperature scale. Draw a line parallel to the 75°F

temperature line. This line meets the relative humidity curve of 50% at point *r*, which denotes the state point of room air as shown in Figure 9.2.2.

3. Draw a horizontal line toward the humidity ratio scale from point *r*. This line meets the ordinate and thus determines the room air humidity ratio $\varphi_r = 0.0093$ lb/lb.
4. Draw a line from point *r* parallel to the enthalpy line. This line determines the enthalpy of room air on the enthalpy scale, $h_r = 28.1$ Btu/lb.
5. Draw a line through point *r* parallel to the moist volume line. The perpendicular scale of this line indicates $v_r = 13.67$ ft^3/lb.
6. Draw a horizontal line to the left from point *r*. This line meets the saturation curve and determines the dew point temperature, $T_{dew} = 55$°F.
7. Draw a line through point *r* parallel to the thermodynamic wet bulb line. The perpendicular scale to this line indicates that the thermodynamic wet bulb temperature $T^* = 62.5$°F.

9.3 Air-Conditioning Processes and Cycles

Air-Conditioning Processes

An *air-conditioning process* describes the change in thermodynamic properties of moist air between the initial and final stages of conditioning as well as the corresponding energy and mass transfers between the moist air and a medium, such as water, refrigerant, absorbent or adsorbent, or moist air itself. The energy balance and conservation of mass are the two principles used for the analysis and the calculation of the thermodynamic properties of the moist air.

Generally, for a single air-conditioning process, heat transfer or mass transfer is positive. However, for calculations that involve several air-conditioning processes, heat supplied to the moist air is taken as positive and heat rejected is negative.

The *sensible heat ratio* (SHR) of an air-conditioning process is defined as the ratio of the change in absolute value of sensible heat to the change in absolute value of total heat, both in Btu/hr:

$$\text{SHR} = \left|q_{\text{sen}}\right| \Big/ \left|q_{\text{total}}\right| = \left|q_{\text{sen}}\right| \Big/ \left(\left|q_{\text{sen}}\right| + \left|q_1\right|\right) \tag{9.3.1}$$

For any air-conditioning process, the sensible heat change

$$q_{\text{sen}} = 60\,\mathring{V}_s\,\rho_s c_{\text{pa}}\left(T_2 - T_1\right) = 60\,\mathring{m}_a\,c_{\text{pa}}\left(T_2 - T_1\right) \tag{9.3.2}$$

where $\mathring{V}_s$ = volume flow rate of supply air, cfm
ρ_s = density of supply air, lb/ft^3
T_2, T_1 = moist air temperature at final and initial states of an air-conditioning process, °F

and the mass flow rate of supply air

$$\mathring{m}_s = \mathring{V}_s\,\rho_s \tag{9.3.3}$$

The latent heat change is

$$q_1 \approx 60\,\mathring{V}_s\,\rho_s\left(w_2 - w_1\right)h_{\text{fg.58}} = 1060 \times 60\,\mathring{V}_s\,\rho_s\left(w_2 - w_1\right) \tag{9.3.4}$$

where w_2,w_1 = humidity ratio at final and initial states of an air-conditioning process, lb/lb.

In Equation (9.3.4), $h_{\text{fg58}} \approx 1060$ Btu/lb represents the latent heat of vaporization or condensation of water at an estimated temperature of 58°F, where vaporization or condensation occurs in an air-handling unit or packaged unit. Therefore

$$\text{SHR} = \mathring{m}_a\,c_{\text{pa}}\left(T_2 - T_1\right) \Big/ \left[\mathring{m}_a\,c_{\text{pa}}\left(T_2 - T_1\right) + \mathring{m}_a\left(w_2 - w_1\right)h_{\text{fg.58}}\right] \tag{9.3.5}$$

Space Conditioning, Sensible Cooling, and Sensible Heating Processes

In a *space conditioning process*, heat and moisture are absorbed by the supply air at state *s* and then removed from the conditioned space at the state of space air *r* during summer, as shown by line *sr* in Figure 9.3.1, or heat or moisture is supplied to the space to compensate for the transmission and infiltration losses through the building envelope as shown by line *s′r′*. Both processes are aimed at maintaining a desirable space temperature and relative humidity.

The space cooling load q_{rc}, in Btu/hr, can be calculated as:

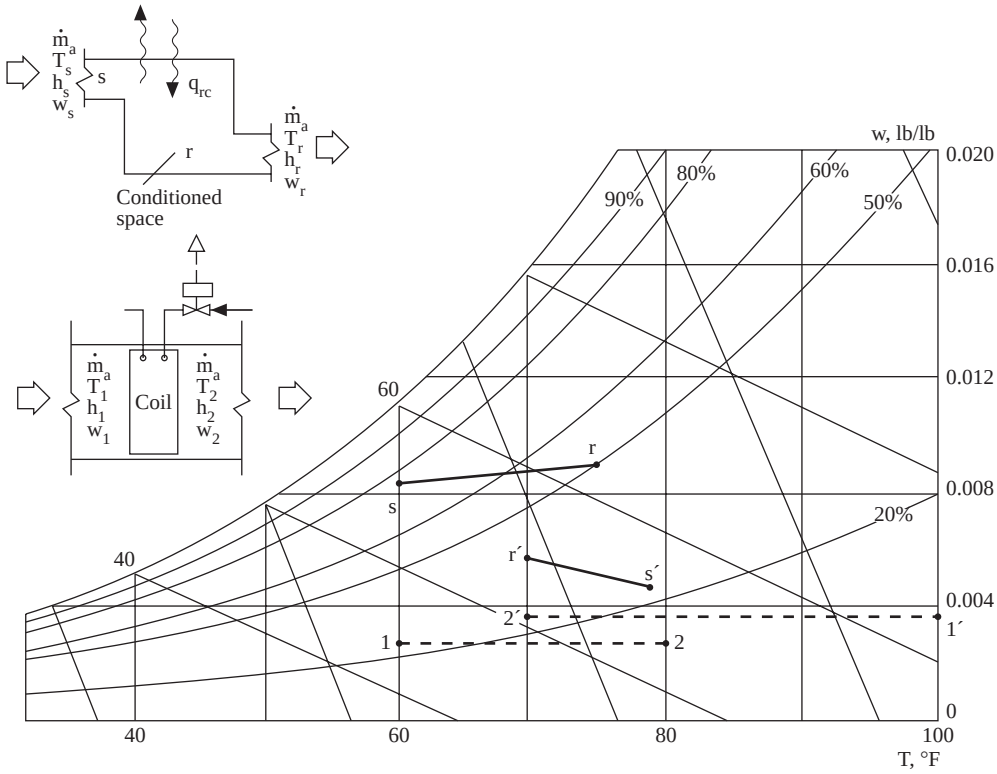

FIGURE 9.3.1 Supply conditioning, sensible heating, and sensible cooling processes.

$$q_{rc} = 60\dot{m}_a\left(h_r - h_s\right) = 60\mathring{V}_s\rho_s\left(h_r - h_s\right) \tag{9.3.6}$$

where h_r, h_s = enthalpy of space air and supply air, Btu/lb.

The space sensible cooling load q_{rs}, in Btu/hr, can be calculated from Equation (9.3.2) and the space latent load q_{rl}, in Btu/hr, from Equation (9.3.1). In Equation (9.3.4), T_2 should be replaced by T_r and T_1 by T_s. Also in Equation (9.3.1), w_2 should be replaced by w_r and w_1 by w_s. The space heating load q_{rh} is always a sensible load, in Btu/hr, and can be calculated as:

$$q_{rh} = 60\mathring{m}_a c_{pa}\left(T_s - T_r\right) = 60\mathring{V}_s\rho_s c_{pa}\left(T_s - T_r\right) \tag{9.3.7}$$

where T_s, T_r = temperature of supply and space air, °F.

A *sensible heating process* adds heat to the moist air in order to increase its temperature; its humidity ratio remains constant, as shown by line 12 in Figure 9.3.1. A sensible heating process occurs when moist air flows over a heating coil. Heat is transferred from the hot water inside the tubes to the moist air. The rate of heat transfer from the hot water to the colder moist air is often called the heating coil load q_{rh}, in Btu/hr, and is calculated from Equation (9.3.2).

A *sensible cooling process* removes heat from the moist air, resulting in a drop of its temperature; its humidity ratio remains constant, as shown by line 1′2′ in Figure 9.3.1. The sensible cooling process occurs when moist air flows through a cooling coil containing chilled water at a temperature equal to or greater than the dew point of the entering moist air. The sensible cooling load can also be calculated from Equation (9.3.2). T_2 is replaced by T_1 and T_1 by $T_{2'}$.

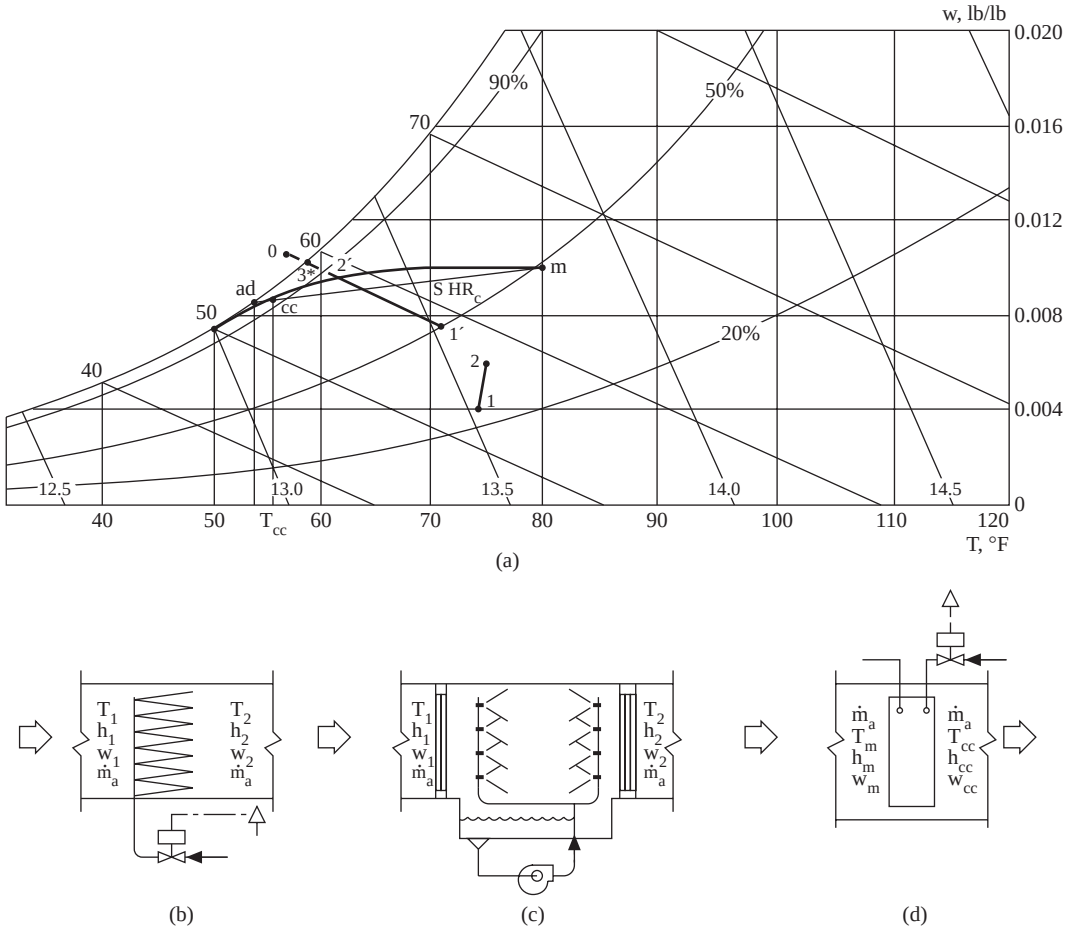

FIGURE 9.3.2 Humidifying and cooling and dehumidifying processes: (a) process on psychrometric chart, (b) steam humidifier, (c) air washer, and (d) water cooling or DX coil.

Humidifying and Cooling and Dehumidifying Processes

In a *humidifying process*, water vapor is added to moist air and increases the humidity ratio of the moist air entering the humidifier if the moist air is not saturated. Large-scale humidification of moist air is usually performed by steam injection, evaporation from a water spray, atomizing water, a wetted medium, or submerged heating elements. Some details of their construction and characteristics are covered in a later section. Dry steam in a steam injection humidifying process is often supplied from the main steam line to a grid-type humidifier and injected into the moist air directly through small holes at a pressure slightly above atmospheric, as shown by line 12 in Figure 9.3.2(a) and (b). The humidifying capacity $\mathring{m}_{hu}$, in lb/min, is given by:

$$\mathring{m}_{hu} = \mathring{V}_s \rho_s \left(w_{hl} - w_{he}\right) \tag{9.3.8}$$

where w_{hl}, w_{he} = humidity ratio of moist air leaving and entering the humidifier, lb/lb. The slight inclination at the top of line 12 is due to the high temperature of the steam. The increase in temperature of the moist air due to steam injection can be calculated as:

$$\left(T_2 - T_1\right) = w_{sm} c_{ps} T_s \Big/ \left(c_{pd} + w_{12} c_{ps}\right) \tag{9.3.9}$$

where T_2, T_1 = temperature of moist air at initial and final states, °F
w_{sm} = ratio of mass flow rate of injected steam to moist air, $\mathring{m}_s / \mathring{m}_a$
T_s = temperature of injected steam, °F
w_{12} = average humidity ratio of moist air, lb/lb

An *air washer* is a device that sprays water into moist air in order to humidify, to cool and dehumidify, and to clean the air, as shown in Figure 9.3.2(c). When moist air flows through an air washer, the moist air is humidified and approaches saturation. This actual adiabatic saturation process approximately follows the thermodynamic wet bulb line on the psychrometric chart as shown by line 1′2′. The humidity ratio of the moist air is increased while its temperature is reduced. The cooling effect of this adiabatic saturation process is called *evaporative cooling*.

Oversaturation occurs when the amount of water present in the moist air w_{os}, in lb/lb, exceeds the saturated humidity ratio at thermodynamic wet bulb temperature w_s^*, as shown in Figure 9.3.2(a). When moist air leaves the air washer, atomizing humidifier, or centrifugal humidifier after humidification, it often contains unevaporated water droplets at state point 2′, w_w, in lb/lb. Because of the fan power heat gain, duct heat gain, and other heat gains providing the latent heat of vaporization, some evaporation takes place due to the heat transfer to the water drops, and the humidity ratio increases further. Such evaporation of oversaturated drops is often a process with an increase of both humidity ratio and enthalpy of moist air. Oversaturation can be expressed as:

$$w_{os} = w_o - w_s^* = \left(w_{2'} + w_w\right) - w_s^* \tag{9.3.10}$$

where $w_{2'}$ = humidity ratio at state point 2′, lb/lb
w_o = sum of $w_{2'}$ and w_w, lb/lb

The magnitude of w_w depends mainly on the construction of the humidifier and water eliminator, if any. For an air washer, w_w may vary from 0.0002 to 0.001 lb/lb. For a pulverizing fan without an eliminator, w_w may be up to 0.00135 lb/lb.

Cooling and Dehumidifying Process

In a cooling and dehumidifying process, both the humidity ratio and temperature of moist air decrease. Some water vapor is condensed in the form of liquid water, called a *condensate*. This process is shown by curve m cc on the psychrometric chart in Figure 9.3.2(a). Here m represents the entering mixture of outdoor and recirculating air and cc the conditioned air leaving the cooling coil.

Three types of heat exchangers are used in a cooling and dehumidifying process: (1) water cooling coil as shown in Figure 9.3.2(d); (2) direct expansion DX coil, where refrigerant evaporates directly inside the coil's tubes; and (3) air washer, in which chilled water spraying contacts condition air directly.

The temperature of chilled water entering the cooling coil or air washer T_{we}, in °F, determines whether it is a sensible cooling or a cooling and dehumidifying process. If T_{we} is smaller than the dew point of the entering air T_{ae}'' in the air washer, or T_{we} makes the outer surface of the water cooling coil $T_{s.t} < T_{ae}''$, it is a cooling and dehumidifying process. If $T_{we} \geq T_{ae}''$, or $T_{s.t} \geq T_{ae}''$, sensible cooling occurs. The cooling coil's load or the cooling capacity of the air washer q_{cc}, in Btu/hr, is

$$q_{cc} = 60 \mathring{V}_s \rho_s \left(h_{ae} - h_{cc}\right) - 60 \mathring{m}_w h_w \tag{9.3.11a}$$

where h_{ae}, h_{cc} = enthalpy of moist air entering and leaving the coil or washer, Btu/lb
$\mathring{m}_w$ = mass flow rate of the condensate, lb/min
h_w = enthalpy of the condensate, Btu/lb

Since the thermal energy of the condensate is small compared with q_{cc}, in practical calculations the term $60\dot{m}_w h_w$ is often neglected, and

$$q_{cc} = 60\dot{V}_s \rho_s (h_{ae} - h_{cc}) \tag{9.3.11b}$$

The sensible heat ratio of the cooling and dehumidifying process SHR_c can be calculated from

$$SHR_c = q_{cs}/q_{cc} \tag{9.3.12}$$

where q_{cs} = sensible heat removed during the cooling and dehumidifying process, Btu/hr. SHR_c is shown by the slope of the straight line joining points m and cc.

The relative humidity of moist air leaving the water cooling coil or DX coil depends mainly on the outer surface area of the coil including pipe and fins. For coils with ten or more fins per inch, if the entering moist air is around 80°F dry bulb and 68°F wet bulb, the relative humidity of air leaving the coil (off-coil) may be estimated as:

Four-row coil	90 to 95%
Six-row and eight-row coils	96 to 98%

Two-Stream Mixing Process and Bypass Mixing Process

For a *two-stream adiabatic mixing process*, two moist air streams, 1 and 2, are mixed together adiabatically and a mixture *m* is formed in a mixing chamber as shown by line 1 m1 2 in Figure 9.3.3. Since the AHU or PU is well insulated, the heat transfer between the mixing chamber and ambient air is small and is usually neglected. Based on the principle of heat balance and conservation of mass:

$$\begin{aligned} \dot{m}_1 h_1 + \dot{m}_2 h_2 &= \dot{m}_m h_m \\ \dot{m}_1 w_1 + \dot{m}_2 w_2 &= \dot{m}_m w_m \\ \dot{m}_1 T_1 + \dot{m}_2 T_2 &= \dot{m}_m T_m \end{aligned} \tag{9.3.13}$$

In Equation (9.3.13), $\dot{m}$ represents the mass flow rate of air, lb/min; *h* the enthalpy, in Btu/lb; w the humidity ratio, in lb/lb; and *T* the temperature, in °F. Subscripts 1 and 2 indicate air streams 1 and 2 and m the mixture; also,

$$\begin{aligned} \dot{m}_1/\dot{m}_m &= (h_2 - h_m)/(h_2 - h_1) = (w_2 - w_m)/(w_2 - w_1) \\ &= (\text{line segment m1 2})/(\text{line segment 12}) \end{aligned} \tag{9.3.14}$$

Similarly,

$$\begin{aligned} \dot{m}_2/\dot{m}_m &= (h_m - h_1)/(h_2 - h_1) = (w_m - w_1)/(w_2 - w_1) \\ &= (\text{line segment 1 m1})/(\text{line segment 12}) \end{aligned} \tag{9.3.15}$$

Mixing point *m* must lie on the line that joins points 1 and 2 as shown in Figure 9.3.3.

If the differences between the density of air streams 1 and 2 and the density of the mixture are neglected,

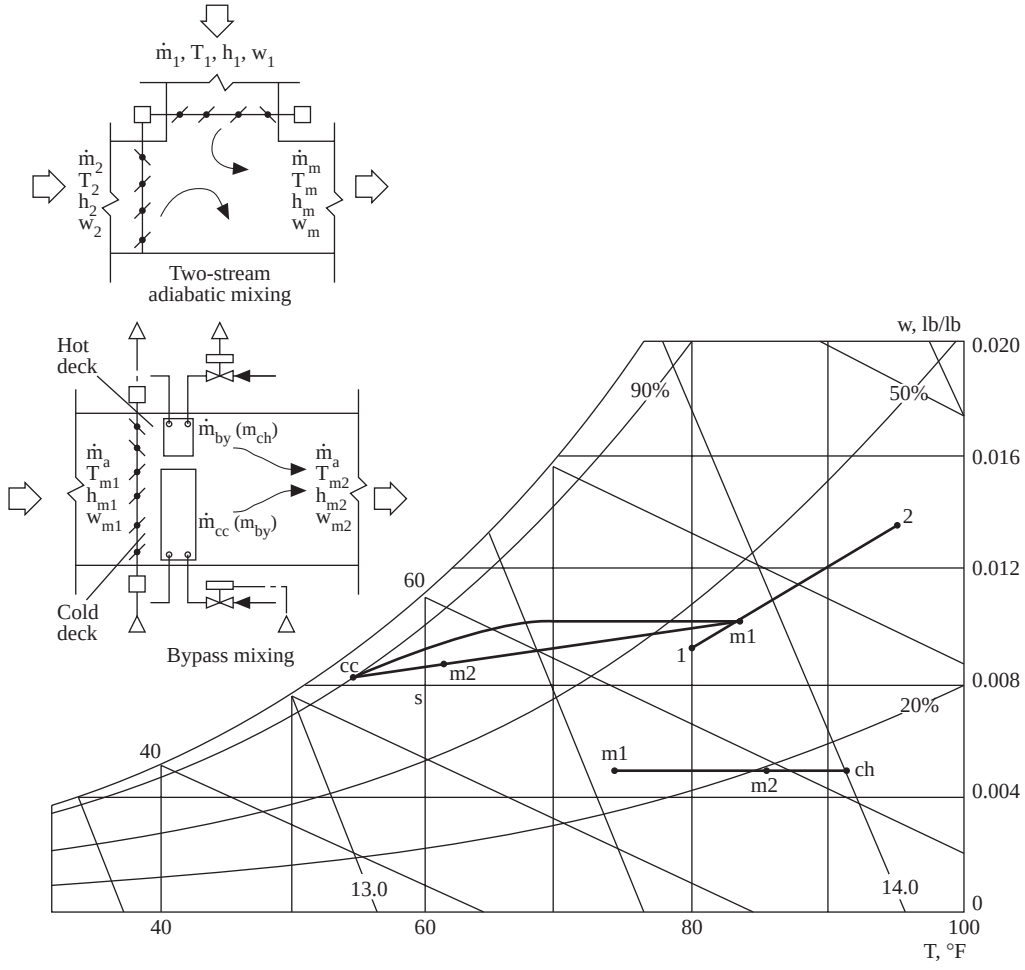

FIGURE 9.3.3 Mixing processes.

$$\mathring{V}_1 h_1 + \mathring{V}_2 h_2 = \mathring{V}_m h_m$$

$$\mathring{V}_1 w_1 + \mathring{V}_2 w_2 = \mathring{V}_m w_m \qquad (9.3.16)$$

$$\mathring{V}_1 T_1 + \mathring{V}_2 T_2 = \mathring{V}_m T_m$$

$$\mathring{V}_1 + \mathring{V}_2 = \mathring{V}_m \qquad (9.3.17)$$

In a *bypass mixing process*, a conditioned air stream is mixed with a bypass air stream that is not conditioned. The cold conditioned air is denoted by subscript cc, the heated air ch, and the bypass air by.

Equations (9.3.14) and (9.3.17) can still be used but subscript 1 should be replaced by cc or ch and subscript 2 by "by" (bypass).

Let $K_{cc} = \mathring{m}_{cc}/\mathring{m}_m$ and $K_{ch} = \mathring{m}_{ch}/\mathring{m}_m$; then the cooling coil's load q_{cc} and heating coil's load q_{ch}, both in Btu/hr, for a bypass mixing process are

$$q_{cc} = K_{cc} \dot{V}_s \rho_s (h_m - h_{cc})$$
$$q_{ch} = K_{ch} \dot{V}_s \rho_s (h_2 - h_1) \quad (9.3.18)$$

In Equation (9.3.18), subscript s denotes the supply air and m the mixture air stream.

Air-Conditioning Cycle and Operating Modes

An *air-conditioning cycle* comprises several air-conditioning processes that are connected in a sequential order. An air-conditioning cycle determines the operating performance of the air system in an air-conditioning system. The *working substance* to condition air may be chilled or hot water, refrigerant, desiccant, etc.

Each type of air system has its own air-conditioning cycle. Psychrometric analysis of an air-conditioning cycle is an important tool in determining its operating characteristics and the state of moist air at various system components, including the volume flow rate of supply air, the coil's load, and the humidifying and dehumidifying capacity.

According to the cycle performance, air-conditioning cycles can be grouped into two categories:

- *Open cycle*, in which the moist air at its end state does not resume its original state. An air-conditioning cycle with all outdoor air is an open cycle.
- *Closed cycle*, in which moist air resumes its original state at its end state. An air-conditioning cycle that conditions the mixture of recirculating and outdoor air, supplies it, recirculates part of the return air, and mixes it again with outdoor air is a closed cycle.

Based on the outdoor weather and indoor operating conditions, the operating modes of air-conditioning cycles can be classified as:

- *Summer mode*: when outdoor and indoor operating parameters are in summer conditions.
- *Winter mode*: when outdoor and indoor operating parameters are in winter conditions.
- *Air economizer mode*: when all outdoor air or an amount of outdoor air that exceeds the minimum amount of outdoor air required for the occupants is taken into the AHU or PU for cooling. The air economizer mode saves energy use for refrigeration.

Continuous modes operate 24 hr a day and 7 days a week. Examples are systems that serve hospital wards and refrigerated warehouses. An *intermittently operated mode* usually shuts down once or several times within a 24-hr operating cycle. Such systems serve offices, class rooms, retail stores, etc. The 24-hr day-and-night cycle of an intermittently operated system can again be divided into:

1. *Cool-down or warm-up period.* When the space is not occupied and the space air temperature is higher or lower than the predetermined value, the space air should be cooled down or warmed up before the space is occupied.
2. *Conditioning period*. The air-conditioning system is operated during the occupied period to maintain the required indoor environment.
3. *Nighttime shut-down period.* The air system or terminal is shut down or only partly operating to maintain a set-back temperature.

Summer, winter, air economizer, and continuously operating modes consist of *full-load* (design load) and part-load operations. *Part load* occurs when the system load is less than the design load. The capacity of the equipment is selected to meet summer and winter system design loads as well as system loads in all operating modes.

Basic Air-Conditioning Cycle — Summer Mode

A *basic air-conditioning system* is a packaged system of supply air at a constant volume flow rate, serving a single zone, equipped with only a single supply/return duct. A *single zone* is a conditioned space for which a single controller is used to maintain a unique indoor operating parameter, probably indoor temperature. A *basic air-conditioning cycle* is the operating cycle of a basic air-conditioning system. Figure 9.1.3 shows a basic air-conditioning system. Figure 9.3.4 shows the basic air-conditioning cycle of this system. In summer mode at design load, recirculating air from the conditioned space, a worship hall, enters the packaged unit through the return grill at point ru. It is mixed with the required minimum amount of outdoor air at point o for acceptable indoor air quality and energy saving. The mixture *m* is then cooled and dehumidified to point cc at the DX coil, and the conditioned air is supplied to the hall through the supply fan, supply duct, and ceiling diffuser. Supply air then absorbs the sensible and latent load from the space, becoming the space air r. Recirculating air enters the packaged unit again and forms a closed cycle. *Return air* is the air returned from the space. Part of the return air is exhausted to balance the outdoor air intake and infiltration. The remaining part is the *recirculating air* that enters the PU or AHU.

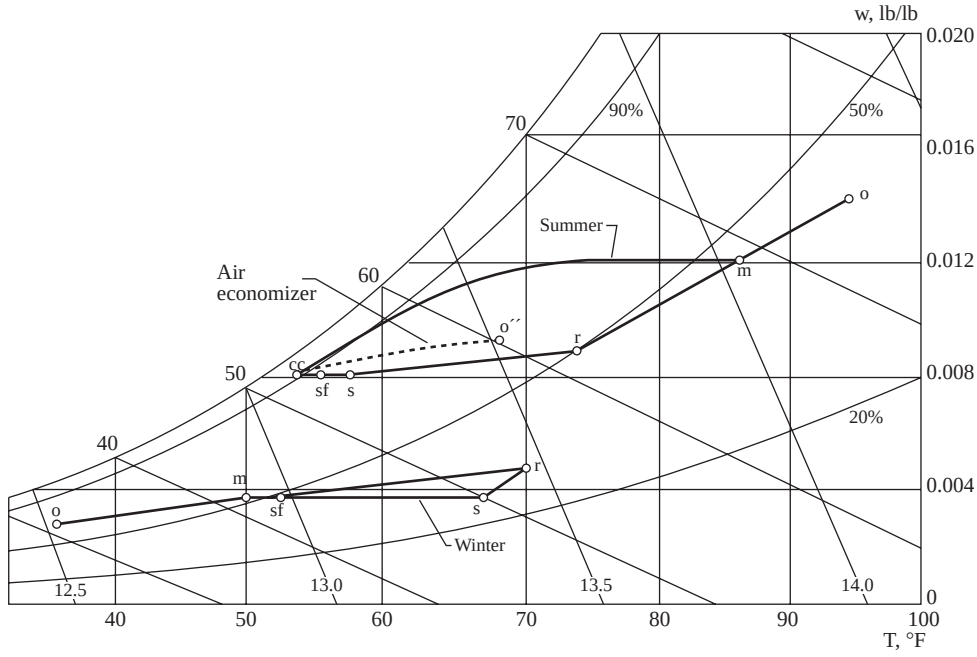

FIGURE 9.3.4 Basic air-conditioning cycle — summer, winter, and air economizer mode.

The summer mode operating cycle consists of the following processes:

1. Sensible heating process, represented by line r ru, due to the return system gain $q_{r.s}$, in Btu/hr, when recirculating air flows through the return duct, ceiling plenum, and return fan, if any. In this packaged system, the return system heat gain is small and neglected.
2. Adiabatic mixing process of recirculating air at point ru and outdoor air at point o in the mixing box, represented by line ru m o.
3. Cooling and dehumidifying process m cc at the DX coil whose coil load determines the cooling capacity of the system calculated from Equation (9.3.11).
4. Sensible heating process related to the supply system heat gain $q_{s.s}$, in Btu/hr, represented by line cc sf s. $q_{s.s}$ consists of the fan power heat gain q_{sf}, line cc sf, and duct heat gain q_{sd}, line sf s, that is:

$$q_{s.s} = q_{sf} + q_{sd} = \mathring{V}_s \rho_s c_{pa} \Delta T_{s.s} \tag{9.3.19}$$

It is more convenient to use the temperature rise of the supply system $\Delta T_{s.s}$ in psychrometric analysis.

5. Supply conditioning process line sr.

Design Supply Volume Flow Rate

Design supply volume flow rate and cooling and heating capacities are primary characteristics of an air-conditioning system. Design supply volume flow rate is used to determine the size of fans, grills, outlets, air-handling units, and packaged units. For most comfort systems and many processing air-conditioning systems, *design supply volume flow rate* $\mathring{V}_{s.d}$, in cfm, is calculated on the basis of the capacity to remove the space cooling load at summer design conditions to maintain a required space temperature T_r:

$$\mathring{V}_{s.d} = q_{rc.d} \Big/ \left[60\rho_s \left(h_r - h_s\right)\right] = q_{rs.d} \Big/ \left[60\rho_s c_{pa} \left(T_r - T_s\right)\right] \tag{9.3.20}$$

where $q_{rc.d}$, $q_{rs.d}$ = design space cooling load and design sensible cooling load, Btu/hr. In Equation (9.3.20), the greater the $q_{rs.d}$, the higher $\mathring{V}_s$ will be. Specific heat c_{pa} is usually considered constant. Air density ρ_s may vary with the various types of air systems used. A greater ρ_s means a smaller $\mathring{V}_{s.d}$ for a given supply mass flow rate. For a given $q_{rs.d}$, the supply temperature differential $\Delta T_s = (T_r - T_s)$ is an important parameter that affects $\mathring{V}_{s.d}$. Conventionally, a 15 to 20°F ΔT_s is used for comfort air-conditioning systems. Recently, a 28 to 34°F ΔT_s has been adopted for cold air distribution in ice-storage central systems. When ΔT_s has a nearly twofold increase, there is a considerable reduction in $\mathring{V}_s$ and fan energy use and saving in investment on ducts, terminals, and outlets.

The summer cooling load is often greater than the winter heating load, and this is why q_{rc} or $q_{rs.d}$ is used to determine $\mathring{V}_{s.d}$, except in locations where the outdoor climate is very cold.

Sometimes the supply volume flow rate may be determined from the following requirements:

- To dilute the concentration of air contaminants in the conditioned space C_i, in mg/m^3, the design supply volume flow rate is

$$\mathring{V}_{s.d} = 2118 \mathring{m}_{par} \Big/ \left(C_1 - C_s\right) \tag{9.3.21}$$

where C_s = concentration of air contaminants in supply air, mg/m^3
$\mathring{m}_{par}$ = rate of contaminant generation in the space, mg/sec

- To maintain a required space relative humidity φ_r and a humidity ratio w_r at a specific temperature, the design supply volume flow rate is

$$\mathring{V}_{s.d} = q_{rl.d} \Big/ \left[60\rho_s \left(w_r - w_s\right) h_{fg.58}\right] \tag{9.3.22}$$

where $q_{rl.d}$ = design space latent load, Btu/hr.

- To provide a required air velocity v_r, in fpm, within the working area of a clean room, the supply volume flow rate is given by

$$\mathring{V}_{s.d} = A_r v_r \tag{9.3.23a}$$

where A_r = cross-sectional area perpendicular to the air flow in the working area, ft^2.

- To exceed the outdoor air requirement for acceptable air quality for occupants, the supply volume flow rate must be equal to or greater than

$$\mathring{V}_s \geq n\mathring{V}_{oc} \tag{9.3.23b}$$

where n = number of occupants
$\mathring{V}_{oc}$ = outdoor air requirement per person, cfm/person

- To exceed the sum of the volume flow rate of exhaust air $\mathring{V}_{ex}$ and the exfiltrated or relief air $\mathring{V}_{ef}$, both in cfm,

$$\mathring{V}_s \geq \mathring{V}_{ex} + \mathring{V}_{ef} \tag{9.3.24}$$

The design supply volume flow rate should be the largest of any of the foregoing requirements.

Rated Supply Volume Flow Rate

For an air system at atmospheric pressure, since the required mass flow rate of the supply air is a function of air density and remains constant along the air flow,

$$\begin{aligned} \mathring{m}_a &= \mathring{V}_{cc}\rho_{cc} = \mathring{V}_s\rho_s = \mathring{V}_{sf}\rho_{sf} \\ \mathring{V}_{sf} &= \mathring{V}_s\rho_s/\rho_{sf} \end{aligned} \tag{9.3.25}$$

where $\mathring{V}_{sf}$ = volume flow rate at supply fan outlet, cfm
ρ_{sf} = air density at supply fan outlet, lb/ft^3

A supply fan is rated at *standard air conditions*, that is, dry air at a temperature of 70°F, an atmospheric pressure of 29.92 in. Hg (14.697 psia), and an air density of 0.075 lb/ft^3. However, a fan is a constant-volume machine at a given fan size and speed; that is, $\mathring{V}_{sf} = \mathring{V}_{sf.r}$. Here $\mathring{V}_{sf.r}$ represents the rated volume flow rate of a fan at standard air conditions. Therefore,

$$\mathring{V}_{sf.r} = \mathring{V}_{sf} = q_{rs.d}/\left[60\rho_{sf}c_{pa}\left(T_r - T_s\right)\right] \tag{9.3.26}$$

- For conditioned air leaving the cooling coil at T_{cc} = 55°F with a relative humidity of 92% and T_{sf} of 57°F, $\rho_{sf.r} = 1/v_{sf} = 1/13.20 = 0.0758$ lb/ft^3. From Equation (9.3.26):

$$\mathring{V}_{sf.r} = q_{rs.d}/\left[60\times 0.0758\times 0.243\left(T_r - T_s\right)\right] = q_{rs.d}/\left[1.1\left(T_r - T_s\right)\right] \tag{9.3.26a}$$

Equation (9.3.26a) is widely used in calculating the supply volume flow rate of comfort air-conditioning systems.

- For cold air distribution, T_{cc} = 40°F and φ_{cc} = 98%, if T_{sf} = 42°F, then v_{sf} = 12.80 ft^3/lb, and the rated supply volume flow rate:

$$\mathring{V}_{sf.r} = 12.80q_{rs.d}/\left[60\times 0.243\left(T_r - T_s\right)\right] = q_{rs.d}/\left[1.14\left(T_r - T_s\right)\right] \tag{9.3.26b}$$

- For a blow-through fan in which the fan is located upstream of the coil, if T_{sf} = 82°F and φ_{sf} = 43%, then v_{sf} = 13.87 ft^3/lb, and the rated supply volume flow rate:

$$\mathring{V}_{sf.r} = 13.87 q_{rs.d} / \left[60 \times 0.243 \left(T_r - T_s\right)\right] = q_{rs.d} / \left[1.05 \left(T_r - T_s\right)\right] \quad (9.3.26c)$$

Effect of the Altitude

The higher the altitude, the lower the atmospheric pressure and the air density. In order to provide the required mass flow rate of supply air, a greater $\mathring{V}_{sf.r}$ is needed. For an air temperature of 70°F:

$$\mathring{V}_{x.ft} = \mathring{V}_{sf.r} \left(p_{sea} / p_{x.ft}\right) = \mathring{V}_{sf.r} \left(\rho_{sea} / \rho_{x.ft}\right) \quad (9.3.27)$$

where $\mathring{V}_{x.ft}$ = supply volume flow rate at an altitude of *x* ft, cfm
p_{sea}, $p_{x.ft}$ = atmospheric pressure at sea level and an altitude of *x* ft, psia
ρ_{sea}, $\rho_{x.ft}$ = air density at sea level and an altitude of *x* ft, psia

Following are the pressure or air density ratios at various altitudes. At 2000 ft above sea level, the rated supply volume flow rate $\mathring{V}_{r.2000} = \mathring{V}_{sf.r}$ ($p_{sea}/p_{x.ft}$) = 1.076 $\mathring{V}_{sf.r}$ cfm instead of $\mathring{V}_{sf.r}$ cfm at sea level.

Altitude, ft	p_{at}, psia	ρ, lb/ft^3	($p_{sea}/p_{x,ft}$)
0	14.697	0.075	1.000
1000	14.19	0.0722	1.039
2000	13.58	0.0697	1.076
3000	13.20	0.0672	1.116
5000	12.23	0.0625	1.200

Off-Coil and Supply Air Temperature

For a given design indoor air temperature T_r, space sensible cooling load q_{rs}, and supply system heat gain $q_{s.s}$, a lower air off-coil temperature T_{cc} as well as supply temperature T_s means a greater supply temperature differential ΔT_s and a lower space relative humidity φ_r and vice versa. A greater ΔT_s decreases the supply volume flow rate $\mathring{V}_s$ and then the fan and terminal sizes, duct sizes, and fan energy use. The result is a lower investment and energy cost.

A lower T_{cc} and a greater ΔT_s require a lower chilled water temperature entering the coil T_{we}, a lower evaporating temperature T_{ev} in the DX coil or refrigerating plant, and therefore a greater power input to the refrigerating compressors. When an air-conditioning system serves a conditioned space of a single zone, optimum T_{cc}, T_s, and T_{we} can be selected. For a conditioned space of multizones, T_{cc}, T_s, and T_{we} should be selected to satisfy the lowest requirement. In practice, T_s and T_{we} are often determined according to previous experience with similar projects.

In general, the temperature rise due to the supply fan power system heat gain q_{sf} can be taken as 1 to 3°F depending on the fan total pressure. The temperature rise due to the supply duct system heat gain at design flow can be estimated as 1°F/100 ft insulated main duct length based on 1-in. thickness of duct insulation.

Outside Surface Condensation

The outside surface temperature of the ducts, terminals, and supply outlets T_{sur} in the ceiling plenum in contact with the return air should not be lower than the dew point of the space air T_r'', in °F. The temperature rise due to the fan power heat gain is about 2°F. According to Dorgan (1988), the temperature difference between the conditioned air inside the terminal and the outside surface of the terminal with insulation wrap is about 3°F. For a space air temperature of 75°F and a relative humidity of 50%, its dew point temperature is 55°F. If the outside surface temperature $T_s = (T_{cc} + 2 + 3) \le 55$°F, condensation may occur on the outside surface of the terminal. Three methods are often used to prevent condensation:

1. Increase the thickness of the insulation layer on the outside surface.
2. Adopt a supply outlet that induces more space air.

3. Equip with a terminal that mixes the supply air with the space air or air from the ceiling plenum.

During the cool-down period, due to the high dew point temperature of the plenum air when the air system is started, the supply air temperature must be controlled to prevent condensation.

Example 9.3.1

The worship hall of a church uses a package system with a basic air system. The summer space sensible cooling load is 75,000 Btu/hr with a latent load of 15,000 Btu/hr. Other design data for summer are as follows:

Outdoor summer design temperature: dry bulb 95°F and wet bulb 75°F
Summer indoor temperature: 75°F with a space relative humidity of 50%:
Temperature rise: fan power 2°F
supply duct 2°F
Relative humidity of air leaving cooling coil: 93%
Outdoor air requirement: 1800 cfm

Determine the

1. Temperature of supply air at summer design conditions
2. Rated volume flow rate of the supply fan
3. Cooling coil load
4. Possibility of condensation at the outside surface of the insulated branch duct to the supply outlet

Solution

1. From Equation 9.3.1 the sensible heat ratio of the space conditioning line is

$$\mathrm{SHR}_s = |q_{rs}| / (|q_{rs}| + |q_{rl}|) = 60{,}000/(60{,}000 + 15{,}000) = 0.8$$

   On the psychrometric chart, from given T_r = 75°F and φ_r = 50%, plot space point r. Draw a space conditioning line sr from point r with SHR_s = 0.8.
   Since $\Delta T_{s.s}$ = 2 + 2 = 4°F, move line segment cc s (4°F) up and down until point s lies on line sr and point cc lies on the φ_{cc} = 93% line. The state points s and cc are then determined as shown in Figure 9.3.4:

   T_s = 57.5°F, φ_s = 82%, and w_s = 0.0082 lb/lb
   T_{cc} = 53.5°F, φ_{cc} = 93%, h_{cc} = 21.8 Btu/lb, and w_{cc} = 0.0082 lb/lb

2. Since T_{sf} = 53.5 + 2 = 55.5°F and w_{sf} = 0.0082 lb/lb, $\rho_{sf} = 1/v_{sf}$ = 1/13.15 = 0.076 lb/ft^3. From Equation 9.4.2, the required rated supply volume flow rate is

$$\dot{V}_{sf.r} = q_{rs.d} / [60 \rho_{sf} c_{pa} (T_r - T_s)]$$

$$= 60{,}000 / [60 \times 0.076 \times 0.243 (75 - 57.5)] = 3094 \text{ cfm}$$

3. Plot outdoor air state point o on the psychrometric chart from given dry bulb 95°F and wet bulb 75°F. Connect line ro. Neglect the density differences between points r, m, and o; then

$$\mathrm{rm}/\mathrm{ro} = 1800/3094 = 0.58$$

   From the psychrometric chart, the length of line ro is 2.438 in. As shown in Figure 9.3.4, point m is then determined as:

$$T_m = 86.7°F, \qquad h_m = 35 \text{ Btu/lb}$$

From Equation (9.3.11), the cooling coil load is

$$q_{cc} = 60\dot{V}_s\rho_s\left(h_m - h_{cc}\right) = 60 \times 3094 \times 0.076(35 - 21.8) = 186{,}234 \text{ Btu/lb}$$

4. From the psychrometric chart, since the dew point of the space air T_r'' = 55°F and is equal to that of the plenum air, the outside surface temperature of the branch duct T_s = 53.5 + 2 + 3 = 58°F which is higher than T_r'' = 55°F. Condensation will not occur at the outside surface of the branch duct.

Basic Air-Conditioning Cycle — Winter Mode

When the basic air-conditioning systems are operated in winter mode, their air-conditioning cycles can be classified into the following four categories:

Cold Air Supply without Space Humidity Control. In winter, for a fully occupied worship hall, if the heat loss is less than the space sensible cooling load, a cold air supply is required to offset the space sensible cooling load and maintain a desirable indoor environment as shown by the lower cycle in Figure 9.3.4. Usually, a humidifier is not used.

The winter cycle of a cold air supply without humidity control consists of the following air-conditioning processes:

1. Adiabatic mixing process of outdoor air and recirculating air o m r.
2. Sensible heating process due to supply fan power heat gain m sf. Because of the smaller temperature difference between the air in the ceiling plenum and the supply air inside the supply duct, heat transfer through duct wall in winter can be neglected.
3. Supply conditioning line sr.

For a winter-mode basic air-conditioning cycle with a cold air supply without space humidity control, the space relative humidity depends on the space latent load, the humidity ratio of the outdoor air, and the amount of outdoor air intake. In order to determine the space humidity ratio w_r, in lb/lb, and the space relative humidity φ_r, in %, Equations (9.3.15) and (9.3.22) should be used to give the following relationships:

$$\begin{aligned} \left(w_r - w_m\right)/\left(w_r - w_o\right) &= \dot{V}_o/\dot{V}_s \\ \left(w_r - w_s\right) &= q_{rl}/\left(60\dot{V}_s\rho_s h_{fg.58}\right) \\ w_s &= w_m \end{aligned} \tag{9.3.28}$$

For a cold air supply, if there is a high space sensible cooling load, the amount of outdoor air must be sufficient, and the mixture must be cold enough to satisfy the following relationships:

$$\begin{aligned} \left(T_r - T_s\right) &= q_{rs}/\left(60\dot{V}_s\rho_s c_{pa}\right) \\ \left(T_r - T_s\right)/\left(T_r - T_o\right) &= \dot{V}_o/\dot{V}_s \end{aligned} \tag{9.3.29}$$

The heating coil load for heating of the outdoor air can be calculated using Equation (9.3.7).

Example 9.3.2

For the same packaged air-conditioning system using a basic air system to serve the worship hall in a church as in Example 9.3.1, the space heating load at winter design condition is 10,000 Btu/hr and the latent load is 12,000 Btu/hr. Other winter design data are as follows:

Winter outdoor design temperature	35°F
Winter outdoor design humidity ratio	0.00035 lb/lb
Winter indoor design temperature	70°F
Temperature rise due to supply fan heat gain	2°F
Outdoor air requirement	1800 cfm

Determine (1) the space relative humidity at winter design temperature and (2) the heating coil load.

Solution

1. Assume that the supply air density $\rho_{sf} = 1/v_{sf} = 1/13.0 = 0.0769$ lb/ft^3, and the mass flow rate of the supply air is the same as in summer mode. Then from Equation 9.3.28 the humidity ratio difference is

$$\left(w_r - w_s\right) = q_{rl} \Big/ \left(60\,\mathring{V}_{sf.r}\,\rho_{sf}\,h_{fg.58}\right) = 12{,}000/(60 \times 3094 \times 0.0769 \times 1060) = 0.00079 \text{ lb/lb}$$

   From Equation 9.3.29, the supply air temperature differential is

$$\left(T_r - T_s\right) = q_{rs.d} \Big/ \left(60\,\mathring{V}_{sf.r}\,\rho_{sf}\,c_{pa}\right) = 10{,}000/(60 \times 3094 \times 0.0769 \times 0.243) = 2.88°\text{F}$$

   Since $\mathring{V}_o / \mathring{V}_s$ = 1800/3094 = 0.58 and $w_s = w_m$,

$$\left(w_r - w_s\right)/\left(w_r - w_o\right) = 0.00079/\left(w_r - w_o\right) = \mathring{V}_o \Big/ \mathring{V}_s = 0.58$$

$$\left(w_r - w_o\right) = 0.00079/0.58 = 0.00136 \text{ lb/lb}$$

   And from given information,

$$w_r = 0.00136 + w_o = 0.00136 + 0.0035 = 0.00486 \text{ lb/lb}$$

   From the psychrometric chart, for T_r = 70°F and w_r = 0.00486 lb/lb, point r can be plotted, and φ_r is about 32% (see Figure 9.3.4).
2. Since mr/or = 0.58, point m can be determined, and from the psychrometric chart T_m = 50.0°F. As T_s = 70 – 2.88 = 67.12°F and $T_{sf} = T_m + 2 = 50.0 + 2 = 52.0$°F, from Equation 9.3.7 the heating coil's load is

$$q_{ch} = 60\,\mathring{V}_s\,\rho_s c_{pa}\left(T_s - T_{sf}\right) = 60 \times 3094 \times 0.0769 \times 0.243(67.12 - 52.0) = 52{,}451 \text{ Btu/hr}$$

Warm Air Supply without Space Humidity Control

When the sum of space heat losses is greater than the sum of the internal heat gains in winter, a warm air supply is needed. For many comfort systems such as those in offices and stores, in locations where winter is not very cold, humidification is usually not necessary. The basic air-conditioning cycle for a warm air supply without space humidity control is shown in Figure 9.3.5(a). This cycle is similar to the

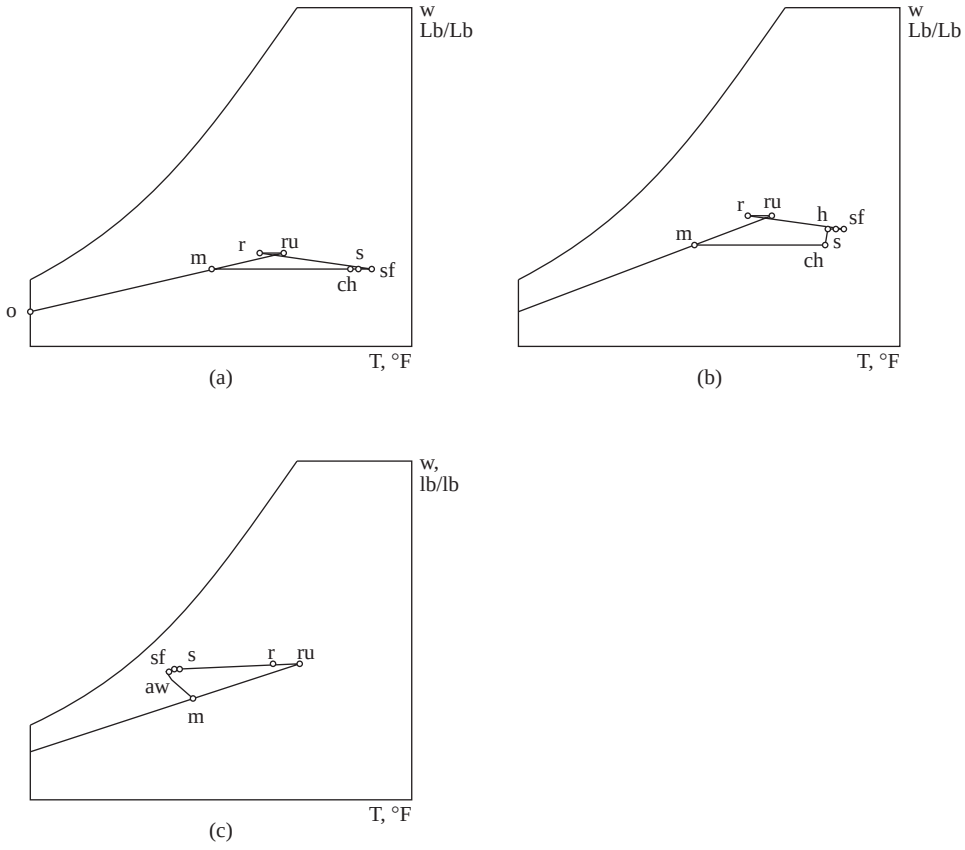

FIGURE 9.3.5 Basic air-conditioning cycle — winter modes: (a) warm air supply without space humidity control, (b) cold air supply without space humidity control, and (c) cold air supply with space humidity control. ch = air leaving heating coil, h = air leaving humidifer, and aw = air leaving air washer.

winter mode cycle of a cold air supply without space humidity control shown in Figure 9.3.4 except that the supply air temperature is higher than space temperature, that is, $T_s > T_r$. To prevent stratification, with the warm supply air staying at a higher level, $(T_s - T_r) > 20°F$ is not recommended.

Warm Air Supply with Space Humidity Control

This operating cycle (see Figure 9.3.5[b]) is often used for hospitals, nurseries, etc. or in locations where winter is very cold. The state point of supply air must be determined first by drawing a space conditioning line with known SHR_s and then from the calculated supply temperature differential ΔT_s. The difference in humidity ratio $(w_s - w_{ch})$ is the water vapor must be added at the humidifier. Humidifying capacity can be calculated from Equation 9.3.8.

Cold Air Supply with Space Humidity Control

This operating cycle (shown in Figure 9.3.5[c]) is widely used in industrial applications such as textile mills where a cold air supply is needed to remove machine load in winter and maintains the space relative humidity required for the manufacturing process. An outdoor air and recirculating air mixture is often used for the required cold air supply. An air washer is adopted for winter humidification.

Air Economizer Mode

In the *air economizer* mode, as shown by the middle dotted line cycle o″-cc-sf-s-r in Figure 9.3.4, all outdoor air or an outdoor air-recirculating air mixture is used to reduce the refrigeration capacity and improve the indoor air quality during spring, fall, or winter.

When all outdoor air is admitted, it is an open cycle. Outdoor air is cooled and often dehumidified to point cc. After absorbing fan and duct heat gains, it is supplied to the conditioned space. Space air is exhausted entirely through openings, relief dampers, or relief/exhaust fans to the outside. An all-outdoor air-operating mode before the space is occupied is often called an *air purge* operation, used to dilute space air contaminants.

Cool-Down and Warm-Up Modes

In summer, when an air system is shut down during an unoccupied period at night, the space temperature and relative humidity often tend to increase because of infiltration of hot and humid air and heat transfer through the building envelope. The air system is usually started before the space is occupied in cool-down mode to cool the space air until the space temperature falls within predetermined limits.

In winter, the air system is also started before the occupied period to warm up the space air to compensate for the nighttime space temperature setback to 55 to 60°F for energy saving or the drop of space temperature due to heat loss and infiltration.

If dilution of indoor air contaminants is not necessary, only recirculating space air is used during cool-down or warm-up periods in order to save energy.

9.4 Refrigerants and Refrigeration Cycles

Refrigeration and Refrigeration Systems

Refrigeration is the cooling effect of the process of extracting heat from a lower temperature heat source, a substance or cooling medium, and transferring it to a higher temperature heat sink, probably atmospheric air and surface water, to maintain the temperature of the heat source below that of the surroundings.

A *refrigeration system* is a combination of components, equipment, and piping, connected in a sequential order to produce the refrigeration effect. Refrigeration systems that provide cooling for air-conditioning are classified mainly into the following categories:

1. *Vapor compression systems.* In these systems, a compressor(s) compresses the refrigerant to a higher pressure and temperature from an evaporated vapor at low pressure and temperature. The compressed refrigerant is condensed into liquid form by releasing the latent heat of condensation to the condenser water. Liquid refrigerant is then throttled to a low-pressure, low-temperature vapor, producing the refrigeration effect during evaporation. Vapor compression is often called *mechanical refrigeration*, that is, refrigeration by mechanical compression.
2. *Absorption systems*. In an absorption system, the refrigeration effect is produced by means of thermal energy input. After liquid refrigerant produces refrigeration during evaporation at very low pressure, the vapor is absorbed by an aqueous absorbent. The solution is heated by a direct-fired gas furnace or waste heat, and the refrigerant is again vaporized and then condensed into liquid form. The liquid refrigerant is throttled to a very low pressure and is ready to produce the refrigeration effect again.
3. *Gas expansion systems.* In an air or other gas expansion system, air or gas is compressed to a high pressure by compressors. It is then cooled by surface water or atmospheric air and expanded to a low pressure. Because the temperature of air or gas decreases during expansion, a refrigeration effect is produced.

Refrigerants, Cooling Mediums, and Absorbents

A *refrigerant* is a primary working fluid used to produce refrigeration in a refrigeration system. All refrigerants extract heat at low temperature and low pressure during evaporation and reject heat at high temperature and pressure during condensation.

A *cooling medium* is a working fluid cooled by the refrigerant during evaporation to transport refrigeration from a central plant to remote cooling equipment and terminals. In a large, centralized air-conditioning system, it is more economical to pump the cooling medium to the remote locations where cooling is required. Chilled water and brine are cooling media. They are often called secondary refrigerants to distinguish them from the primary refrigerants.

A *liquid absorbent* is a working fluid used to absorb the vaporized refrigerant (water) after evaporation in an absorption refrigeration system. The solution that contains the absorbed vapor is then heated. The refrigerant vaporizes, and the solution is restored to its original concentration to absorb water vapor again.

A numbering system for refrigerants was developed for hydrocarbons and halocarbons. According to ANSI/ASHRAE Standard 34-1992, the first digit is the number of unsaturated carbon–carbon bonds in the compound. This digit is omitted if the number is zero. The second digit is the number of carbon atoms minus one. This is also omitted if the number is zero. The third digit denotes the number of hydrogen atoms plus one. The last digit indicates the number of fluorine atoms. For example, the chemical formula for refrigerant R-123 is $CHCl_2CF_3$. In this compound:

No unsaturated carbon–carbon bonds, first digit is 0
There are two carbon atoms, second digit is $2 - 1 = 1$
There is one hydrogen atom, third digit is $1 + 1 = 2$

There are three fluorine atoms, last digit is 3

To compare the relative ozone depletion of various refrigerants, an index called the *ozone depletion potential* (ODP) has been introduced. ODP is defined as the ratio of the rate of ozone depletion of 1 lb of any halocarbon to that of 1 lb of refrigerant R-11. For R-11, ODP = 1.

Similar to the ODP, halocarbon global warming potential (HGWP) is an index used to compare the global warming effect of a halocarbon refrigerant with the effect of refrigerant R-11.

Classification of Refrigerants

Nontoxic and nonflammable synthetic chemical compounds called *halogenated hydrocarbons*, or simply *halocarbons*, were used almost exclusively in vapor compression refrigeration systems for comfort air-conditioning until 1986. Because chlorofluorocarbons (CFCs) cause ozone depletion and global warming, they must be replaced. A classification of refrigerants based on ozone depletion follows (see Table 9.4.1):

Hydrofluorocarbons (HFCs)

HFCs contain only hydrogen, fluorine, and carbon atoms and cause no ozone depletion. HFCs group include R-134a, R-32, R-125, and R-245ca.

HFC's Azeotropic Blends or Simply HFC's Azeotropic

An azeotropic is a mixture of multiple components of volatilities (refrigerants) that evaporate and condense as a single substance and do not change in volumetric composition or saturation temperature when they evaporate or condense at constant pressure. HFC's azeotropics are blends of refrigerant with HFCs. ASHRAE assigned numbers between 500 and 599 for azeotropic. HFC's azeotropic R-507, a blend of R-125/R-143, is the commonly used refrigerant for low-temperature vapor compression refrigeration systems.

HFC's Near Azeotropic

A near azeotropic is a mixture of refrigerants whose characteristics are near those of an azeotropic. Because the change in volumetric composition or saturation temperature is rather small for a near azeotropic, such as, 1 to 2°F, it is thus named. ASHRAE assigned numbers between 400 and 499 for zeotropic. R-404A (R-125/R-134a/R-143a) and R-407B (R-32/R-125/R134a) are HFC's near azeotropic. R-32 is flammable; therefore, its composition is usually less than 30% in the mixture. HFC's near azeotropic are widely used for vapor compression refrigeration systems.

Zeotropic or nonazeotropic, including near azeotropic, shows a change in composition due to the difference between liquid and vapor phases, leaks, and the difference between charge and circulation. A shift in composition causes the change in evaporating and condensing temperature/pressure. The difference in dew point and bubble point during evaporation and condensation is called glide, expressed in °F. Near azeotropic has a smaller glide than zeotropic. The midpoint between the dew point and bubble point is often taken as the evaporating and condensing temperature for refrigerant blends.

Hydrochlorofluorocarbons (HCFCs) and Their Zeotropics

HCFCs contain hydrogen, chlorine, fluorine, and carbon atoms and are not fully halogenated. HCFCs have a much shorter lifetime in the atmosphere (in decades) than CFCs and cause far less ozone depletion (ODP 0.02 to 0.1). R-22, R-123, R-124, etc. are HCFCs. HCFCs are the most widely used refrigerants today.

HCFC's near azeotropic and *HCFC's zeotropic* are blends of HCFCs with HFCs. They are transitional or interim refrigerants and are scheduled for a restriction in production starting in 2004.

Inorganic Compounds

These compounds include refrigerants used before 1931, like ammonia R-717, water R-718, and air R-729. They are still in use because they do not deplete the ozone layer. Because ammonia is toxic and

flammable, it is used in industrial applications. Inorganic compounds are assigned numbers between 700 and 799 by ASHRAE.

Chlorofluorocarbons, Halons, and Their Azeotropic

CFCs contain only chlorine, fluorine, and carbon atoms. CFCs have an atmospheric lifetime of centuries and cause ozone depletion (ODP from 0.6 to 1). R-11, R-12, R-113, R-114, R-115… are all CFCs.

Halons or BFCs contain bromide, fluorine, and carbon atoms. R-13B1 and R-12B1 are BFCs. They cause very high ozone depletion (ODP for R-13B1 = 10). Until 1995, R-13B1 was used for very low temperature vapor compression refrigeration systems.

Phaseout of CFCs, BFCs, HCFCs, and Their Blends

On September 16, 1987, the European Economic Community and 24 nations, including the United States, signed a document called the Montreal Protocol. It is an agreement to restrict the production and consumption of CFCs and BFCs in the 1990s because of ozone depletion.

The Clean Air Act amendments, signed into law in the United States on November 15, 1990, concern two important issues: the phaseout of CFCs and the prohibition of deliberate venting of CFCs and HCFCs.

In February 1992, President Bush called for an accelerated ban of CFCs in the United States. In late November 1992, representatives of 93 nations meeting in Copenhagen agreed to phase out CFCs beginning January 1, 1996. Restriction on the use of HCFCs will start in 2004, with a complete phaseout by 2030.

In the earlier 1990s, R-11 was widely used for centrifugal chillers, R-12 for small and medium-size vapor compression systems, R-22 for all vapor compression systems, and CFC/HCFC blend R-502 for low-temperature vapor compression systems. Because of the phaseout of CFCs and BFCs before 1996 and HCFCs in the early years of the next century, alternative refrigerants have been developed to replace them:

- R-123 (an HCFC of ODP = 0.02) to replace R-11 is a short-term replacement that causes a slight reduction in capacity and efficiency. R-245ca (ODP = 0) may be the long-term alternative to R-11.
- R-134a (an HFC with ODP = 0) to replace R-12 in broad applications. R-134a is not miscible with mineral oil; therefore, a synthetic lubricant of polyolester is used.
- R-404A (R-125/R-134a/143a) and R-407C (R-32/R-125/R-134a) are both HFCs near azeotropic of ODP = 0. They are long-term alternatives to R-22. For R-407C, the composition of R-32 in the mixture is usually less than 30% so that the blend will not be flammable. R-407C has a drop of only 1 to 2% in capacity compared with R-22.
- R-507 (R-125/R-143a), an HFC's azeotropic with ODP = 0, is a long-term alternative to R-502. Synthetic polyolester lubricant oil will be used for R-507. There is no major performance difference between R-507 and R-502. R-402A (R-22/R-125/R-290), an HCFC's near azeotropic, is a short-term immediate replacement, and drop-in of R-502 requires minimum change of existing equipment except for reset of a higher condensing pressure.

Required Properties of Refrigerants

A refrigerant should not cause ozone depletion. A low global warming potential is required. Additional considerations for refrigerant selection are

1. *Safety*, including toxicity and flammability. ANSI/ASHRAE Standard 34-1992 classifies the *toxicity* of refrigerants as Class A and Class B. Class A refrigerants are of low toxicity. No toxicity was identified when their time-weighted average concentration was less than or equal to 400 ppm, to which workers can be exposed for an 8-hr workday and 40-hr work week without adverse effect. Class B refrigerants are of higher toxicity and produce evidence of toxicity.

ANSI/ASHRAE Standard 34-1982 classifies the *flammability* of refrigerants as Class 1, no flame propagation; Class 2, lower flammability; and Class 3, higher flammability.

The safety classification of refrigerants is based on the combination of toxicity and flammability: A1, A2, A3, B1, B2, and B3. R-134a and R-22 are in the A1 group, lower toxicity and nonflammable; R-123 in the B1 group, higher toxicity and nonflammable; and R-717 (ammonia) in the B2 group, higher toxicity and lower flammability.

2. *Effectiveness of refrigeration cycle*. High effectiveness is a desired property. The power consumed per ton of refrigeration produced, hp/ton or kW/ton, is an index for this assessment. Table 9.4.1 gives values for an ideal single-stage vapor compression cycle.
3. *Oil miscibility.* Refrigerant should be miscible with mineral lubricant oil because a mixture of refrigerant and oil helps to lubricate pistons and discharge valves, bearings, and other moving parts of a compressor. Oil should also be returned from the condenser and evaporator for continuous lubrication. R-22 is partially miscible. R-134a is hardly miscible with mineral oil; therefore, synthetic lubricant of polyolester will be used.
4. *Compressor displacement.* Compressor displacement per ton of refrigeration produced, in cfm/ton, directly affects the size of the positive displacement compressor and therefore its compactness. Ammonia R-717 requires the lowest compressor displacement (1.70 cfm/ton) and R-22 the second lowest (1.91 cfm/ton).
5. Desired properties:
   - Evaporating pressure p_{ev} should be higher than atmospheric. Then noncondensable gas will not leak into the system.
   - Lower condensing pressure for lighter construction of compressor, condenser, piping, etc.
   - A high thermal conductivity and therefore a high heat transfer coefficient in the evaporator and condenser.
   - Dielectric constant should be compatible with air when the refrigerant is in direct contact with motor windings in hermetic compressors.
   - An inert refrigerant that does not react chemically with material will avoid corrosion, erosion, or damage to system components. Halocarbons are compatible with all containment materials except magnesium alloys. Ammonia, in the presence of moisture, is corrosive to copper and brass.
   - Refrigerant leakage can be easily detected. Halide torch, electronic detector, and bubble detection are often used.

Ideal Single-Stage Vapor Compression Cycle

Refrigeration Process

A refrigeration process shows the change of the thermodynamic properties of the refrigerant and the energy and work transfer between the refrigerant and surroundings.

Energy and work transfer is expressed in British thermal units per hour, or Btu/hr. Another unit in wide use is ton of refrigeration, or ton. A ton = 12,000 Btu/hr of heat removed; i.e., 1 ton of ice melting in 24 hr = 12,000 Btu/hr.

Refrigeration Cycles

When a refrigerant undergoes a series of processes like evaporation, compression, condensation, throttling, and expansion, absorbing heat from a low-temperature source and rejecting it to a higher temperature sink, it is said to have undergone a refrigeration cycle. If its final state is equal to its initial state, it is a *closed cycle*; if the final state does not equal the initial state, it is an *open cycle*. Vapor compression refrigeration cycles can be classified as single stage, multistage, compound, and cascade cycles.

A *pressure-enthalpy diagram* or *p-h* diagram is often used to calculate the energy transfer and to analyze the performance of a refrigeration cycle, as shown in Figure 9.4.1. In a *p-h* diagram, pressure *p*, in psia or psig logarithmic scale, is the ordinate, and enthalpy *h*, in Btu/lb, is the abscissa. The saturated liquid and saturated vapor line encloses a two-phase region in which vapor and liquid coexist. The two-phase region separates the subcooling liquid and superheated vapor regions. The constant-temperature

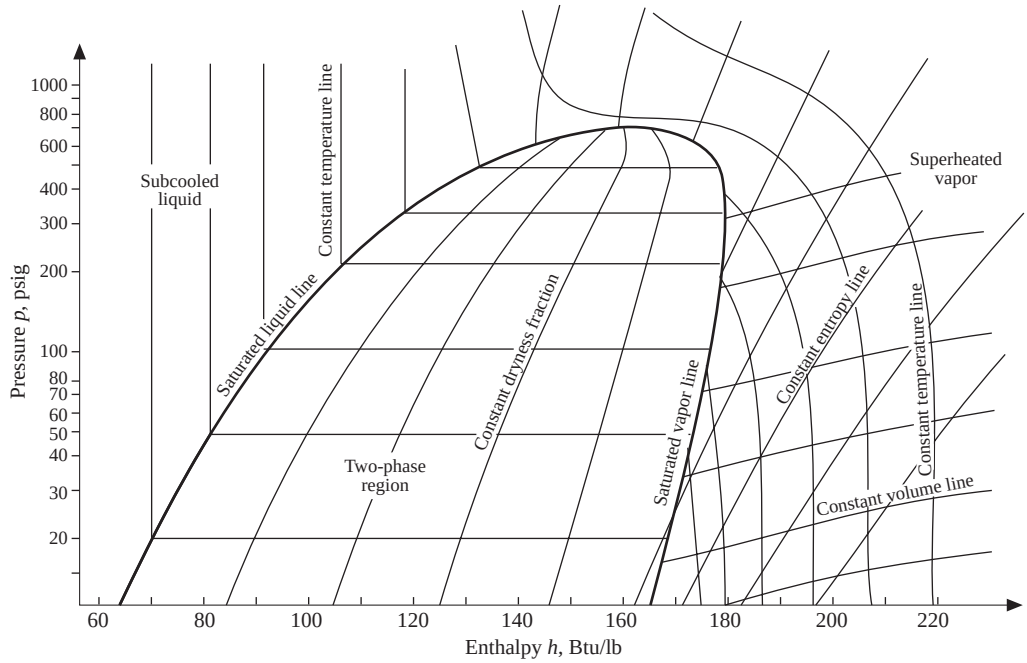

FIGURE 9.4.1 Skeleton of pressure-enthalpy diagram for R-22.

line is nearly vertical in the subcooling region, horizontal in the two-phase region, and curved down sharply in the superheated region.

In the two-phase region, a given saturated pressure determines the saturated temperature and vice versa. The constant-entropy line is curved upward to the right-hand side in the superheated region. Each kind of refrigerant has its own *p-h* diagram.

Refrigeration Processes in an Ideal Single-Stage Cycle

An *ideal cycle* has isentropic compression, and pressure losses in the pipeline, valves, and other components are neglected. All refrigeration cycles covered in this section are ideal. Single stage means a single stage of compression.

There are four refrigeration processes in an ideal single-stage vapor compression cycle, as shown in Figure 9.4.2(a) and (b):

1. Isothermal evaporation process 4–1 — The refrigerant evaporates completely in the evaporator and produces refrigeration effect q_{rf}, in Btu/lb:

$$q_{rf} = (h_1 - h_4) \tag{9.4.1}$$

   where h_1,h_4 = enthalpy of refrigerant at state points 1 and 4, respectively, Btu/lb.
2. Isentropic compression process 1–2 — Vapor refrigerant is extracted by the compressor and compressed isentropically from point 1 to 2. The work input to the compressor W_{in}, in Btu/lb, is

$$W_{in} = (h_2 - h_1) \tag{9.4.2}$$

   where h_2 = enthalpy of refrigerant at state point 2, Btu/lb.
   The greater the difference in temperature/pressure between the condensing pressure p_{con} and evaporating pressure p_{ev}, the higher will be the work input to the compressor.

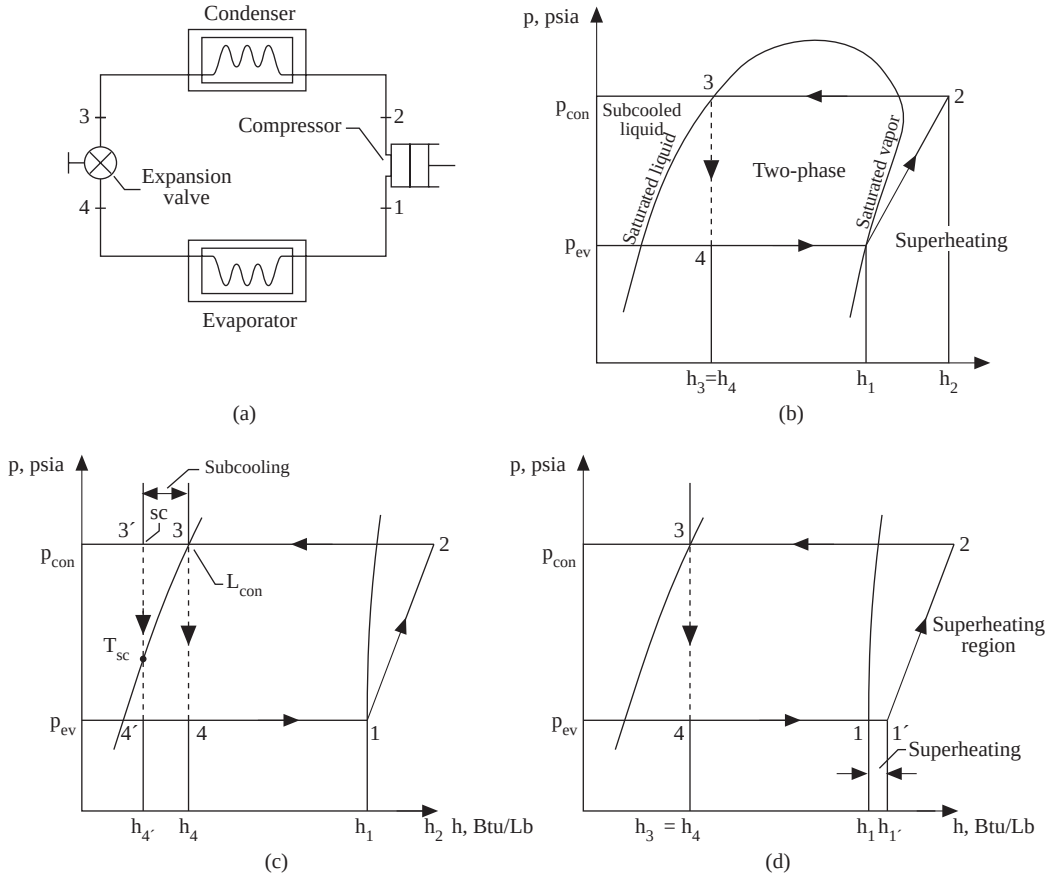

FIGURE 9.4.2 A single-stage ideal vapor compression refrigeration cycle: (a) schematic diagram, (b) *p-h* diagram, (c) subcooling, and (d) superheating.

3. Isothermal condensation process 2–3 — Hot gaseous refrigerant discharged from the compressor is condensed in the condenser into liquid, and the latent heat of condensation is rejected to the condenser water or ambient air. The heat rejection during condensation, q_{2-3}, in Btu/lb, is

$$-q_{2-3} = \left(h_2 - h_3\right) \tag{9.4.3}$$

where h_3 = enthalpy of refrigerant at state point 3, Btu/lb.

4. Throttling process 3–4 — Liquid refrigerant flows through a throttling device (e.g., an expansion valve, a capillary tube, or orifices) and its pressure is reduced to the evaporating pressure. A portion of the liquid flashes into vapor and enters the evaporator. This is the only irreversible process in the ideal cycle, usually represented by a dotted line. For a throttling process, assuming that the heat gain from the surroundings is negligible:

$$h_3 = h_4 \tag{9.4.4}$$

The mass flow rate of refrigerant $\mathring{m}_r$, in lb/min, is

$$\mathring{m}_r = q_{rc}/60q_{rf} \tag{9.4.5}$$

where q_{rc} = refrigeration capacity of the system, Btu/hr.
The ideal single-stage vapor compression refrigeration cycle on a *p-h* diagram is divided into two pressure regions: high pressure (p_{con}) and low pressure (p_{ev}).

Coefficient of Performance of Refrigeration Cycle

The *coefficient of performance* (COP) is a dimensionless index used to indicate the performance of a thermodynamic cycle or thermal system. The magnitude of COP can be greater than 1.

- If a *refrigerator* is used to produce a refrigeration effect, COP_{ref} is

$$COP_{ref} = q_{rf} / W_{in} \tag{9.4.6}$$

- If a *heat pump* is used to produce a useful heating effect, its performance denoted by COP_{hp} is

$$COP_{hp} = q_{2-3} / W_{in} \tag{9.4.7}$$

- For a heat recovery system when both refrigeration and heating effects are produced, the COP_{hr} is denoted by the ratio of the sum of the absolute values of q_{rf} and $q_{2\text{-}3}$ to the work input, or

$$COP_{hr} = \left(\left|q_{rf}\right| + \left|q_{2-3}\right|\right) / W_{in} \tag{9.4.8}$$

Subcooling and Superheating

Condensed liquid is often subcooled to a temperature lower than the saturated temperature corresponding to the condensing pressure p_{con}, in psia or psig, as shown in Figure 9.4.2(c). *Subcooling* increases the refrigeration effect to $q_{rf.sc}$ as shown in Figure 9.4.2(c):

$$q_{rf.sc} = \left(h_{4'} - h_1\right) > \left(h_4 - h_1\right) \tag{9.4.9}$$

The enthalpy of subcooled liquid refrigerant h_{sc} approximately equals the enthalpy of the saturated liquid refrigerant at subcooled temperature $h_{s.sc}$, both in Btu/lb:

$$h_{sc} = h_{3'} = h_{4'} = h_{1.con} - c_{pr}\left(T_{con} - T_{sc}\right) \approx h_{s.sc} \tag{9.4.10}$$

where $h_{3'}$, $h_{4'}$ = enthalpy of liquid refrigerant at state points 3′ and 4′ respectively, Btu/lb
$h_{l.con}$ = enthalpy of saturated liquid at condensing temperature, Btu/lb
c_{pr} = specific heat of liquid refrigerant at constant pressure, Btu/lb °F
T_{con} = condensing temperature or saturated temperature of liquid refrigerant at condensing pressure, °F
T_{sc} = temperature of subcooled liquid refrigerant, °F

The purpose of *superheating* is to prevent liquid refrigerant flooding back into the compressor and causing slugging damage as shown in Figure 9.4.2(d). The degree of superheating depends mainly on the types of refrigerant feed, construction of the suction line, and type of compressor. The state point of vapor refrigerant after superheating of an ideal system must be at the evaporating pressure with a specific degree of superheat and can be plotted on a *p-h* diagram for various refrigerants.

Refrigeration Cycle of Two-Stage Compound Systems with a Flash Cooler

A *multistage system* employs more than one compression stage. Multistage vapor compression systems are classified as compound systems and cascade systems. A *compound system* consists of two or more

compression stages connected in series. It may have one high-stage compressor (higher pressure) and one low-stage compressor (lower pressure), several compressors connected in series, or two or more impellers connected internally in series and driven by the same motor.

The *compression ratio* R_{com} is defined as the ratio of discharge pressure p_{dis} to the suction pressure at the compressor inlet p_{suc}:

$$R_{com} = p_{dis} / p_{suc} \tag{9.4.11}$$

Compared to a single-stage system, a multistage has a smaller compression ratio and higher compression efficiency for each stage of compression, greater refrigeration effect, lower discharge temperature at the high-stage compressor, and greater flexibility. At the same time, a multistage system has a higher initial cost and more complicated construction.

The pressure between the discharge pressure of the high-stage compressor and the suction pressure of the low-stage compressor of a multistage system is called *interstage pressure* p_i, in psia. Interstage pressure for a two-stage system is usually determined so that the compression ratios are nearly equal between two stages for a higher COP. Then the interstage pressure is

$$p_i = \sqrt{\left(p_{con} p_{ev}\right)} \tag{9.4.12}$$

where p_{con}, p_{ev} = condensing and evaporating pressures, psia.

For a multistage system of n stages, then, the compression ratio of each stage is

$$R_{com} = \left(p_{con} / p_{suc}\right)^{1/n} \tag{9.4.13}$$

Figure 9.4.3(a) shows a schematic diagram and Figure 9.4.3(b) the refrigeration cycle of a two-stage compound system with a flash cooler. A *flash cooler*, sometimes called an economizer, is used to subcool the liquid refrigerant to the saturated temperature corresponding to the interstage pressure by vaporizing a portion of the liquid refrigerant in the flash cooler.

Based on the principle of heat balance, the fraction of evaporated refrigerant, x, or quality of the mixture in the flash cooler is

$$x = \left(h_{5'} - h_8\right) / \left(h_7 - h_8\right) \tag{9.4.14}$$

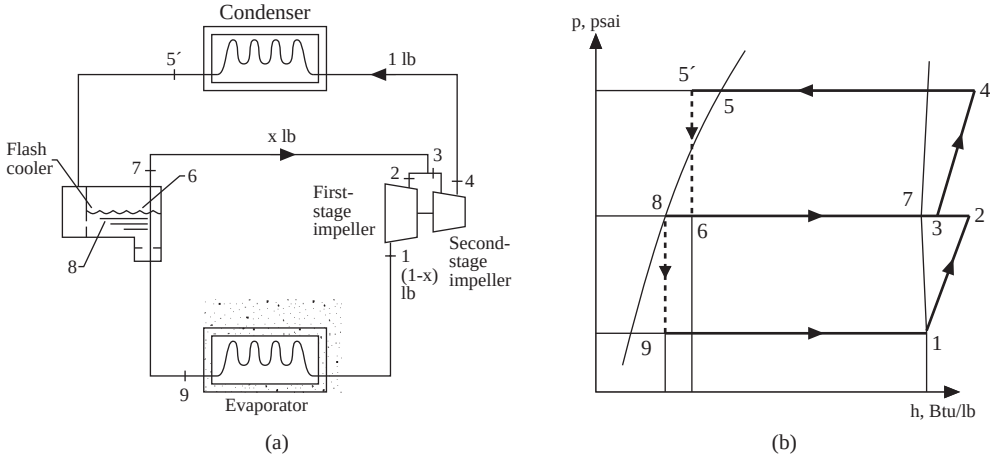

FIGURE 9.4.3 Two-stage compound system with a flash cooler: (a) schematic diagram and (b) refrigeration cycle.

where $h_{5'}$, h_7, h_8 = enthalpy of the refrigerant at state points 5′, 7, and 8, respectively, Btu/lb. The coefficient of performance of the refrigeration cycle of a two-stage compound system with a flash cooler, COP_{ref}, is given as

$$COP_{ref} = q_{rf}/W_{in} = (1-x)(h_1 - h_9)/[(1-x)(h_2 - h_1) + (h_4 - h_3)] \quad (9.4.15)$$

where h_1, h_2, h_3, h_4, h_9 = enthalpy of refrigerant at state points 1, 2, 3, 4, and 9, respectively, Btu/lb. The mass flow rate of refrigerant flowing through the condenser, $\mathring{m}_r$, in lb/min, can be calculated as

$$\mathring{m}_r = q_{rc}/60q_{rf} \quad (9.4.16)$$

Because a portion of liquid refrigerant is flashed into vapor in the flash cooler and goes directly to the second-stage impeller inlet, less refrigerant is compressed in the first-stage impeller. In addition, the liquid refrigerant in the flash cooler is cooled to the saturated temperature corresponding to the interstage temperature before entering the evaporator, which significantly increases the refrigeration effect of this compound system. Two-stage compound systems with flash coolers are widely used in large central air-conditioning systems.

Cascade System Characteristics

A *cascade system* consists of two independently operated single-stage refrigeration systems: a lower system that maintains a lower evaporating temperature and produces a refrigeration effect and a higher system that operates at a higher evaporating temperature as shown in Figure 9.4.4(a) and (b). These two separate systems are connected by a *cascade condenser* in which the heat released by the condenser in the lower system is extracted by the evaporator in the higher system.

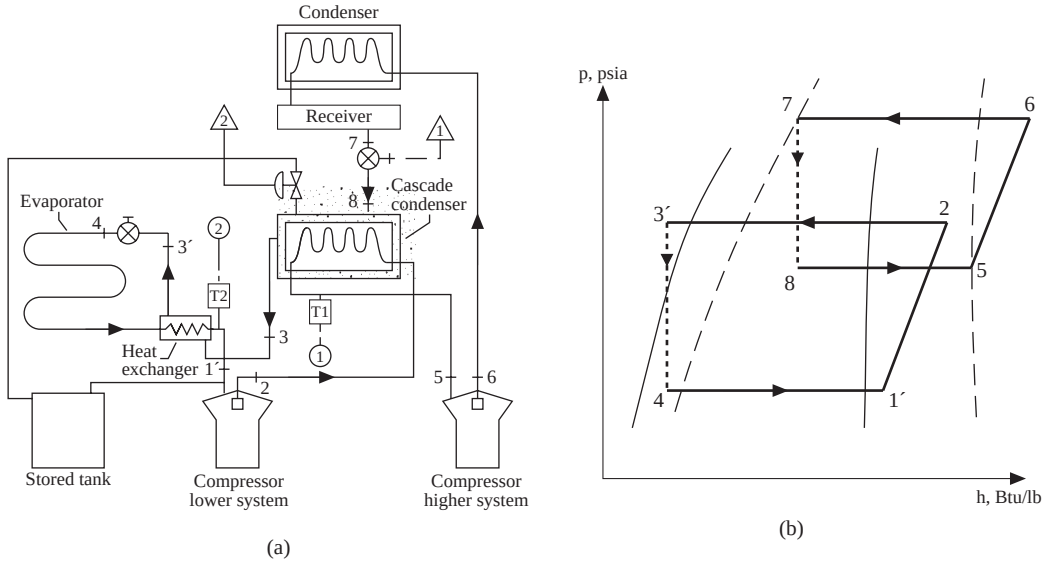

FIGURE 9.4.4 Cascade system: (a) schematic diagram and (b) refrigeration cycle.

A heat exchanger is often used between the liquid refrigerant from the condenser and the vapor refrigerant leaving the evaporator of the lower system. When the system is shut down in summer, a relief valve connected to a stored tank should be used to relieve the higher pressure of refrigerant at the higher storage temperature.

The main advantages of a cascade system compared with a compound system are that different refrigerants, oils, and equipment can be used for the lower and higher systems. Disadvantages are the overlap of the condensing temperature of the lower system and the evaporating temperature of the higher system because of the heat transfer in the cascade condenser and a more complicated system.

The refrigeration effect q_{rf} of the cascade system is

$$q_{rf} = \left(h_1 - h_4\right) \tag{9.4.17}$$

where h_1, h_4 = enthalpy of the refrigerant leaving and entering the evaporator of the lower system, Btu/lb. The total work input to the compressors in both higher and lower systems W_{in}, in Btu/lb, can be calculated as

$$W_{in} = \left(h_2 - h_{1'}\right) + \mathring{m}_h\left(h_6 - h_5\right) \Big/ \mathring{m}_1 \tag{9.4.18}$$

where h_2 = enthalpy of refrigerant discharged from the compressor of the lower system
$h_{1'}$ = enthalpy of the vapor refrigerant leaving the heat exchanger
h_6, h_5 = enthalpy of the refrigerant leaving and entering the high-stage compressor
$\mathring{m}_h, \mathring{m}_1$ = mass flow rate of the refrigerant of the higher and lower systems, respectively

The coefficient of performance of a cascade system COP_{ref} is

$$COP_{ref} = q_{rf} / W_{in} = \mathring{m}_1\left(h_1 - h_4\right) \Big/ \left[\mathring{m}_1\left(h_2 - h_{1'}\right) + \mathring{m}_h\left(h_6 - h_5\right)\right] \tag{9.4.19}$$

9.5 Outdoor Design Conditions and Indoor Design Criteria

Outdoor Design Conditions

In principle, the capacity of air-conditioning equipment should be selected to offset or compensate for the space load so that indoor design criteria can be maintained if the outdoor weather does not exceed the design values. Outdoor and indoor design conditions are used to calculate the design space loads. In energy use calculations, hour-by-hour outdoor climate data of a design day should be adopted instead of summer and winter design values.

ASHRAE Handbook 1993 Fundamentals (Chapter 24 and 27) and *Wang's Handbook of Air Conditioning and Refrigeration* (Chapter 7) both list tables of climate conditions for the U.S. and Canada based on the data from the National Climate Data Center (NCDC), U.S. Air Force, U.S. Navy, and Canadian Atmospheric Environment Service. In these tables:

- *Summer design dry bulb temperature* in a specific location $T_{o.s}$, in °F, is the rounded higher integral number of the statistically determined summer outdoor design dry bulb temperature $T_{o.ss}$ so that the average number of hours of occurrence of outdoor dry bulb temperature T_o higher than $T_{o.ss}$ during June, July, August, and September is less than 1, 2.5, or 5% of the total number of hours in these summer months (2928 hr). The data are an average of 15 years. An occurrence of less than 2.5% of 2928 hr of summer months, that is, $0.025 \times 2928 = 73$ hr, is most widely used.
- *Summer outdoor mean coincident wet bulb temperature* $T'_{o.s}$, in °F, is the mean of all the wet bulb temperatures at the specific summer outdoor design dry bulb temperature $T_{o.s}$ during the summer months.
- *Summer outdoor 2.5% design wet bulb temperature* is the design wet bulb temperature that has an average annual occurrence of $T'_o > T'_{o.s}$ less than 73 hr. This design value is often used for evaporative cooling design.
- *Mean daily range*, in °F, is the difference between the average daily maximum and the average daily minimum temperature during the warmest month.
- In *ASHRAE Handbook 1993 Fundamentals, solar heat gain factors* (SHGFs), in Btu/h.ft^2, are the average solar heat gain per hour during cloudless days through double-strength sheet (DSA) glass. The *maximum SHGFs* are the maximum values of SHGFs on the 21st of each month for a specific latitude.
- *Winter outdoor design dry bulb temperature* $T_{o.w}$, in °F, is the rounded lower integral value of the statically determined winter outdoor design temperature $T_{o.ws}$, so that the annual average number of hours of occurrence of outdoor temperature $T_o > T_{o.ws}$ is equal to or exceeds 99%, or 97.5% of the total number of hours in December, January, and February (2160 hr).

A *degree day* is the difference between a base temperature and the mean daily outdoor air temperature $T_{o.m}$ for any one day, in °F. The total numbers of heating degree days HDD65 and cooling degree days CDD65 referring to a base temperature of 65°F per annum are

$$\text{HDD65} = \sum_{n=1} \left(65 - T_{o.m}\right)$$
$$\text{CDD65} = \sum_{m=1} \left(T_{o.m} - 65\right) \qquad (9.5.1)$$

where n = number of days for which $T_{o.m} < 65$°F
m = number of days for which $T_{o.m} > 65$°F

Indoor Design Criteria and Thermal Comfort

Indoor design criteria, such as space temperature, humidity, and air cleanliness, specify the requirements for the indoor environment as well as the quality of an air-conditioning or HVAC&R project.

The human body requires energy for physical and mental activity. This energy comes from the oxidation of food. The rate of heat release from the oxidation process is called the *metabolic rate*, expressed in met (1 met = 18.46 Btu/h.ft^2). The metabolic rate depends mainly on the intensity of the physical activity of the human body. Heat is released from the human body by two means: *sensible heat exchange* and *evaporative heat loss*. Experience and experiments all show that there is thermal comfort only under these conditions:

- Heat transfer from the human body to the surrounding environment causes a steady state of thermal equilibrium; that is, there is no heat storage in the body core and skin surface.
- Evaporative loss or regulatory sweating is maintained at a low level.

The physiological and environmental factors that affect the thermal comfort of the occupants in an air-conditioned space are mainly:

1. Metabolic rate M determines the amount of heat that must be released from the human body.
2. *Indoor air temperature* T_r and *mean radiant temperature* T_{rad}, both in °F. The *operating temperature* T_o is the weighted sum of T_r and T_{rad}. T_{rad} is defined as the temperature of a uniform black enclosure in which the surrounded occupant would have the same radiative heat exchange as in an actual indoor environment. T_r affects both the sensible heat exchange and evaporative losses, and T_{rad} affects only sensible heat exchange. In many indoor environments, $T_{rad} \approx T_r$.
3. Relative humidity of the indoor air φ_r, in %, which is the primary factor that influences evaporative heat loss.
4. Air velocity of the indoor air v_r, in fpm, which affects the heat transfer coefficients and therefore the sensible heat exchange and evaporative loss.
5. *Clothing insulation* R_{cl}, in clo (1 clo = 0.88 h.ft^2.°F/Btu), affects the sensible heat loss. Clothing insulation for occupants is typically 0.6 clo in summer and 0.8 to 1.2 clo in winter.

Indoor Temperature, Relative Humidity, and Air Velocity

For comfort air-conditioning systems, according to ANSI/ASHRAE Standard 55-1981 and ASHRAE/IES Standard 90.1-1989, the following indoor design temperatures and air velocities apply for conditioned spaces where the occupant's activity level is 1.2 met, indoor space relative humidity is 50% (in summer only), and $T_r = T_{rad}$:

	Clothing insulation (clo)	**Indoor temperature (°F)**	**Air velocity (fpm)**
Winter	0.8–0.9	69–74	<30
Summer	0.5–0.6	75–78	<50

If a suit jacket is the clothing during summer for occupants, the summer indoor design temperature should be dropped to 74 to 75°F.

Regarding the indoor humidity:

1. Many comfort air-conditioning systems are not equipped with humidifiers. Winter indoor relative humidity should not be specified in such circumstances.
2. When comfort air-conditioning systems are installed with humidifiers, ASHRAE/IES Standard 90.1-1989 requires that the humidity control prevent "the use of fossil fuel or electricity to produce humidity in excess of 30% ... or to reduce relative humidity below 60%."

3. Indoor relative humidity should not exceed 75% to avoid increasing bacterial and viral populations.
4. For air-conditioning systems that use flow rate control in the water cooling coil, space indoor relative humidity may be substantially higher in part load than at full load.

Therefore, for comfort air-conditioning systems, the recommended indoor relative humidities, in %, are

	Tolerable range	**Preferred value**
Summer	30–65	40–50
Winter		
With humidifier		25–30
Without humidifier		Not specified

In surgical rooms or similar health care facilities, the indoor relative humidity is often maintained at 40 to 60% year round.

Indoor Air Quality and Outdoor Ventilation Air Requirements

According to the National Institute for Occcupational Safety and Health (NIOSH), 1989, the causes of indoor air quality complaints in buildings are inadequate outdoor ventilation air, 53%; indoor contaminants, 15%; outdoor contaminants, 10%; microbial contaminants, 5%; construction and furnishings, 4%; unknown and others, 13%. For space served by air-conditioning systems using low- and medium-efficiency air filters, according to the U.S. Environmental Protection Agency (EPA) and Consumer Product Safety Commission (CPSC) publication "A Guide to Indoor Air Quality" (1988) and the field investigations reported by Bayer and Black (1988), *indoor air contaminants* may include some of the following:

1. *Total particulate concentration.* This concentration comprises particles from building materials, combustion products, mineral fibers, and synthetic fibers. In February 1989, the EPA specified the allowable indoor concentration of particles of 10 μm and less in diameter (which penetrate deeply into lungs) as:

   50 $\mu g/m^3$ (0.000022 grain/ft^3), 1 year
   150 $\mu g/m^3$ (0.000066 grain/ft^3), 24 hr

   In these specifications, "1 year" means maximum allowable exposure per day over the course of a year.
2. *Formaldehyde and organic gases*. Formaldehyde is a colorless, pungent-smelling gas. It comes from pressed wood products, building materials, and combustion. Formaldehyde causes eye, nose, and throat irritation as well as coughing, fatigue, and allergic reactions. Formaldehyde may also cause cancer. Other organic gases come from building materials, carpeting, furnishings, cleaning materials, etc.
3. *Radon*. Radon, a colorless and odorless gas, is released by the decay of uranium from the soil and rock beneath buildings, well water, and building materials. Radon and its decay products travel through pores in soil and rock and infiltrate into buildings along the cracks and other openings in the basement slab and walls. Radon at high levels causes lung cancer. The EPA believes that levels in most homes can be reduced to 4 pCi/l (picocuries per liter) of air. The estimated national average is 1.5 pCi/l, and levels as high as 200 pCi/l have been found in houses.
4. *Biologicals*. These include bacteria, fungi, mold and mildew, viruses, and pollen. They may come from wet and moist walls, carpet furnishings, and poorly maintained dirty air-conditioning systems and may be transmitted by people. Some biological contaminants cause allergic reactions, and some transmit infectious diseases.

5. *Combustion products*. These include environmental tobacco smoke, nitrogen dioxide, and carbon monoxide. *Environmental tobacco* smoke from cigarettes is a discomfort factor to other persons who do not smoke, especially children. Nicotine and other tobacco smoke components cause lung cancer, heart disease, and many other diseases. *Nitrogen dioxide* and *carbon monoxide* are both combustion products from unvented kerosene and gas space heaters, woodstoves, and fireplaces. Nitrogen dioxide (NO_2) causes eye, nose, and throat irritation; may impair lung function; and increases respiratory infections. Carbon monoxide (CO) causes fatigue at low concentrations; impaired vision, headache, and confusion at higher concentrations; and is fatal at very high concentrations. Houses without gas heaters and gas stoves may have CO levels varying from 0.5 to 5 parts per million (ppm).
6. *Human bioeffluents*. These include the emissions from breath including carbon dioxide exhaled from the lungs, body odors from sweating, and gases emitted as flatus.

There are three basic means of reducing the concentration of indoor air contaminants and improving indoor air quality: (1) eliminate or reduce the source of air pollution, (2) enhance the efficiency of air filtration, and (3) increase the ventilation (outdoor) air intake. Dilution of the concentrations of indoor contaminants by outdoor ventilation air is often the simple and cheapest way to improve indoor air quality. The amount of outdoor air required for metabolic oxidation is rather small.

Abridged outdoor air requirements listed in ANSI/ASHRAE Standard 62-1989 are as follows:

Applications	cfm/person
Hotels, conference rooms, offices	20
Retail stores	0.2–0.3 cfm/ft^2
Classrooms, theaters, auditoriums	15
Hospital patient rooms	25

These requirements are based on the analysis of dilution of CO_2 as the representative human bioeffluent to an allowable indoor concentration of 1000 ppm. Field measurements of daily maximum CO_2 levels in office buildings reported by Persily (1993) show that most of them were within the range 400 to 820 ppm. The quality of outdoor air must meet the EPA's National Primary and Secondary Ambient Air Quality Standards, some of which is listed below:

	Long-term concentration			**Short-term concentration**		
Pollutants	**μg/m^3**	**ppm**	**Exposure**	**μg/m^3**	**ppm**	**Exposure**
Particulate	75		1 year	260		24 hr
SO_2	80	0.03	1 year	365	0.14	24 hr
CO				40,000	35	1 hr
				10,000	9	8 hr
NO_2	100	0.055	1 year			
Lead	1.5		3 months			

Here exposure means average period of exposure.

If unusual contaminants or unusually strong sources of contaminants are introduced into the space, or recirculated air is to replace part of the outdoor air supply for occupants, then acceptable indoor air quality is achieved by controlling known and specific contaminants. This is called an indoor air quality procedure. Refer to ANSI/ASHRAE Standard 62-1989 for details.

Clean Rooms

Electronic, pharmaceutical, and aerospace industries and operating rooms in hospitals all need strict control of air cleanliness during manufacturing and operations. According to ASHRAE Handbook 1991 HVAC Applications, clean rooms can be classified as follows based on the particle count per ft^3:

Class	Particle size	
	0.5 μm and larger	5 μm and larger
	Particle count per ft^3 not to exceed	
1	1	0
10	10	0
100	100	
1000	1000	
10,000	10,000	65
100,000	100,000	700

For clean rooms, space temperature is often maintained at 72 ± 2°F and space humidity at 45 ± 5%. Here, ±2°F and ±5% are allowable tolerances. Federal Standard 209B specifies that the ventilation (outdoor air) rate should be 5 to 20% of the supply air.

Space Pressure Differential

Most air-conditioning systems are designed to maintain a slightly higher pressure than the surroundings, a positive pressure, to prevent or reduce infiltration and untreated air entering the space directly. For laboratories, restrooms, or workshops where toxic, hazardous, or objectional gases or contaminants are produced, a slightly lower pressure than the surroundings, a negative pressure, should be maintained to prevent or reduce the diffusion of these contaminants' exfiltrate to the surrounding area.

For comfort air-conditioning systems, the recommended pressure differential between the indoor and outdoor air is 0.02 to 0.05 in in. WG. WG indicates the pressure at the bottom of a top-opened water column of specific inches of height; 1 in. WG = 0.03612 psig.

For clean rooms, Federal Standard No. 209B, Clean Rooms and Work Stations Requirements (1973), specifies that the minimum positive pressure between the clean room and any adjacent area with lower cleanliness requirements should be 0.05 in. WG with all entryways closed. When the entryways are open, an outward flow of air is to be maintained to prevent migration of contaminants into the clean room. In comfort systems, the space pressure differential is usually not specified in the design documents.

Sound Levels

Noise is any unwanted sound. In air-conditioning systems, noise should be attenuated or masked with another less objectionable sound.

Sound power is the capability to radiate power from a sound source exited by an energy input. The intensity of sound power is the output from a sound source expressed in watts (W). Due to the wide variation of sound output at a range of 10^{20} to 1, it is more convenient to use a logarithmic expression to define a *sound power level* L_w, in dB:

$$L_w = 10\log\left(w/10^{-12}\ \text{W}\right)\ \text{re 1 pW} \tag{9.5.2}$$

where w = sound source power output, W.

The human ear and microphones are sound pressure sensitive. Similarly to the sound power level, the *sound pressure level* L_p, in dB, is defined as:

$$L_p = 20\log\left(p/2\times10^{-5}\ \text{Pa}\right)\ \text{re 20 μPa} \tag{9.5.3}$$

where p = sound pressure, Pa.

The sound power level of any sound source is a fixed output. It cannot be measured directly; it can only be calculated from the measured sound pressure level. The sound pressure level at any one point is affected by the distance from the source and the characteristics of the surroundings.

Human ears can hear frequencies from 20 Hz to 20 kHz. For convenience in analysis, sound frequencies are often subdivided into eight octave bands. An *octave* is a frequency band in which the frequency of the upper limit of the octave is double the frequency of the lower limit. An octave band is represented by its center frequency, such as 63, 125, 250, 500, 1000, 2000, 4000, and 8000 Hz. On 1000 Hz the octave band has a higher limit of 1400 Hz and a lower limit of 710 Hz. Human ears do not respond in the same way to low frequencies as to high frequencies.

The object of noise control in an air conditioned space is to provide background sound low enough that it does not interfere with the acoustical requirements of the occupants. The distribution of background sound should be balanced over a broad range of frequencies, that is, without whistle, hum, rumble, and beats.

The most widely used criteria for sound control are the noise criteria NC curves. The shape of NC curves is similar to the equal-loudness contour representing the response of the human ear. NC curves also intend to indicate the permissible sound pressure level of broad-band noise at various octave bands rated by a single NC curve. NC curves are practical and widely used.

Other criteria used are room criteria RC curves and A-weighted sound level, dBA. RC curves are similar to NC curves except that the shape of the RC curves is a close approximation to a balanced, bland-sounding spectrum. The A-weighted sound level is a single value and simulates the response of the human ear to sound at low sound pressure levels.

The following are abridged indoor design criteria, NC or RC range, listed in *ASHRAE Handbook 1987 Systems and Applications*:

Type of area	Recommended NC or RC range (dB)
Hotel guest rooms	30–35
Office	
Private	30–35
Conference	25–30
Open	30–35
Computer equipment	40–45
Hospital, private	25–30
Churches	25–30
Movie theaters	30–35

For industrial factories, if the machine noise in a period of 8 hr exceeds 90 dBA, Occupational Safety and Health Administration Standard Part 1910.95 requires the occupants to use personal protection equipment. If the period is shorter, the dBA level can be slightly higher. Refer to this standard for details.

9.6 Load Calculations

Space Loads

Space, Room, and Zone

Space indicates a volume or a site without partitions, or a partitioned room or a group of rooms. A *room* is an enclosed or partitioned space that is considered as a single load. An air-conditioned room does not always have an individual zone control system. A *zone* is a space of a single room or group of rooms having similar loads and operating characteristics. An air-conditioned zone is always installed with an individual control system. A typical floor in a building may be treated as a single zone space, or a *multizone space* of perimeter, interior, east, west, south, north, ... zones.

Space and equipment loads can be classified as:

1. *Space heat gain* q_e, in Btu/hr, is the rate of heat transfer entering a conditioned space from an external heat source or heat releases to the conditioned space from an internal source. The rate of sensible heat entering the space is called *sensible heat gain* q_{es}, whereas the rate of latent heat entering the space is called *latent heat gain* q_{el}. In most load calculations, the time interval is often 1 hr, and therefore q_e, q_{es}, and q_{el} are all expressed in Btu/hr.
2. *Space cooling load* or simply *cooling load* q_{rc}, also in Btu/hr, is the rate at which heat must be removed from a conditioned space to maintain a constant space temperature and an acceptable relative humidity. The sensible heat removed is called *sensible cooling load* q_{rs}, and the latent heat removed is called *latent cooling load* q_{rl}, both in Btu/hr.
3. *Space heat extraction rate* q_{ex}, in Btu/hr, is the rate at which heat is removed from the conditioned space. When the space air temperature is constant, $q_{ex} = q_{rc}$.
4. *Space heating load* q_{rh}, in Btu/hr, is the rate at which heat must be added to the conditioned space to maintain a constant temperature.
5. *Coil load* q_c, in Btu/hr, is the rate of heat transfer at the coil. The cooling *coil load* q_{cc} is the rate of heat removal from the conditioned air by the chilled water or refrigerant inside the coil. The *heating coil load* q_{ch} is the rate of heat energy addition to the conditioned air by the hot water, steam, or electric elements inside the coil.
6. *Refrigeration load* q_{rl}, in Btu/hr, is the rate at which heat is extracted by the evaporated refrigerant at the evaporator. For packaged systems using a DX coil, $q_{rl} = q_{cc}$. For central systems:

$$q_{rl} = q_{cc} + q_{pi} + q_{pu} + q_{s.t} \tag{9.6.1}$$

where q_{pi} = chilled water piping heat gain, Btu/hr
q_{pu} = pump power heat gain, Btu/hr
$q_{s.t}$ = storage tank heat gain, if any, Btu/hr

Heat gains q_{pi} and q_{pu} are usually about 5 to 10% of the cooling coil load q_{cc}.

Convective Heat and Radiative Heat

Heat enters a space and transfer to the space air from either an external source or an internal source is mainly in the form of *convective heat* and *radiative heat* transfer.

Consider radiative heat transfer, such as solar radiation striking the outer surface of a concrete slab as shown in Figure 9.6.1(a) and (b). Most of the radiative heat is absorbed by the slab. Only a small fraction is reflected. After the heat is absorbed, the outer surface temperature of the slab rises. If the slab and space air are in thermal equilibrium before the absorption of radiative heat, heat is convected from the outer surface of the slab to the space air as well as radiated to other surfaces. At the same time, heat is conducted from the outer surface to the inner part of the slab and stored there when the temperature of the inner part of the slab is lower than that of its outer surface. Heat convected from the outer surface of the concrete slab to the space air within a time interval forms the sensible cooling load.

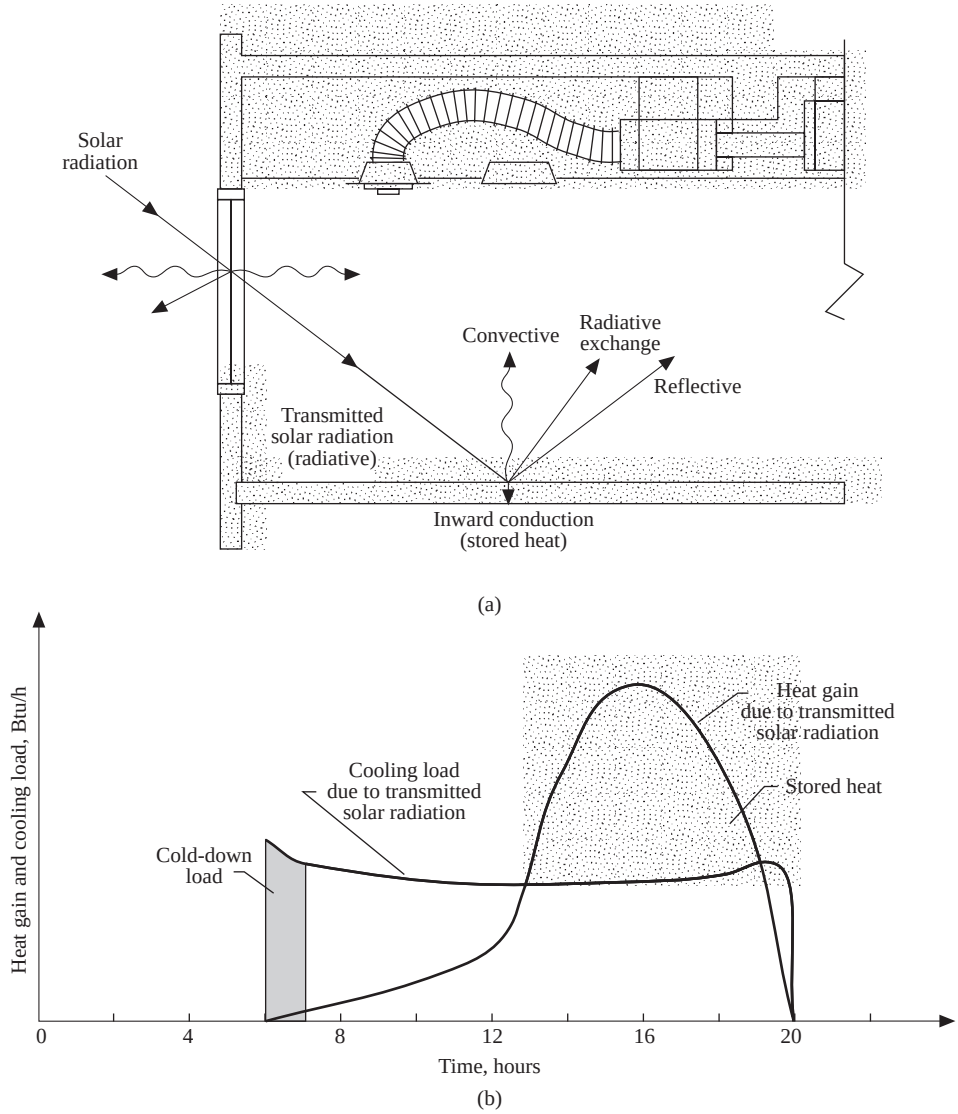

FIGURE 9.6.1 Solar heat gain from west window and its corresponding space cooling load for a night shutdown air system: (a) convective and radiative heat transfer and (b) heat gain and cooling load curves.

The sensible heat gain entering the conditioned space does not equal the sensible cooling load during the same time interval because of the stored heat in the building envelope. Only the convective heat becomes cooling load instantaneously. The sum of the convective heats from the outer surfaces, including the outer surfaces of the internal heat gains in a conditioned space, becomes cooling load. This phenomenon results in a smaller cooling load than heat gain, as shown in Figure 9.6.1(a) and (b). According to *ASHRAE Handbook 1993 Fundamentals*, the percentages of convective and radiative components of the sensible heat gains are as follows:

Sensible heat gains	Convective (%)	Radiative (%)
Solar radiation with internal shading	42	58
Fluorescent lights	50	50
Occupants	67	33
External wall, inner surface	40	60

Load Profile, Peak Load, and Block Load

A *load profile* shows the variation of space, zone, floor, or building load in a certain time period, such as a 24-hr day-and-night cycle. In a load profile, load is always plotted against time. The load profile depends on the outdoor climate as well as the space operating characteristics.

Peak load is the maximum cooling load in a load profile. *Block load* is the sum of the zone loads and floor loads at a specific time. The sum of the zone peak loads in a typical floor does not equal the block load of that floor because the zone peak loads may all not appear at the same time.

Moisture Transfer in Building Envelope

Moisture transfer takes place along two paths:

1. Moisture migrates in the building envelope in both liquid and vapor form. It is mainly liquid if the relative humidity of the ambient air exceeds 50%. Liquid flow is induced by capillary flow and moisture content gradient. Vapor diffusion is induced by vapor pressure gradients. *Moisture content* is defined as the ratio of the mass of moisture contained in a solid to the mass of bone-dry solid. During the migration, the moisture content and the vapor pressure are in equilibrium at a specific temperature and location.
2. Air leakage and its associated water vapor infiltrate or exfiltrate through the cracks, holes, and gaps between joints because of poor construction of the building envelope. The driving potential of this air leakage and associated water vapor is the pressure differential across the building envelope. If the insulating material is of open-cell structure, air leakage and associated water vapor may penetrate the perforated insulating board through cracks and gaps. Condensation, even freezing, will occur inside the perforated insulation board if the temperature of the board is lower than the dew point of the leaked air or the freezing point of the water.

In most comfort air-conditioning systems, usually only the space temperature is controlled within limits. A slight variation of the space relative humidity during the operation of the air system is often acceptable. Therefore, the store effect of moisture is ignored except in conditioned spaces where both temperature and relative humidity need to be controlled or in a hot and humid area where the air system is operated at night shutdown mode. In most cases, latent heat gain is considered equal to latent cooling load instantaneously. For details refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993), Chapters 6 and 7.

Cooling Load Calculation Methodology

Basic considerations include the following:

- It is assumed that equations of heat transfer for cooling load calculation within a time interval are linear. It is also assumed that the superposition principle holds. When a number of changes occur simultaneously in the conditioned space, they will proceed as if independent of each other. The total change is the sum of the responses caused by the individual changes.
- Space load calculations are often performed by computer-aided design (CAD), with market-available software like DOE-2.1D, TRACE-600, and Carrier E20-II Loads.
- Peak load calculations evaluate the maximum load to size and select the equipment. The energy analysis program compares the total energy use in a certain period with various alternatives in order to determine the optimum one.
- The methodology of various cooling load calculations is mainly due to their differences in the conversion of space radiative heat gains into space cooling loads. Convective heat, latent heat, and sensible heat gains from infiltration are all equal to cooling loads instantaneously.
- Space cooling load is used to calculate the supply volume flow rate and to determine the size of the air system, ducts, terminals, and diffusers. The coil load is used to determine the size of the

cooling coil and the refrigeration system. Space cooling load is a component of the cooling coil load.

The Rigorous Approach

The rigorous approach to the calculation of the space cooling load consists of (1) finding the inside surface temperatures of the building structures that enclose the conditioned space due to heat balance at time t and (2) calculating the sum of the convective heats transferred from these surfaces as well as from the occupants, lights, appliances, and equipment in the conditioned space at time t.

The inside surface temperature of each surface $T_{i,t}$, in °F, can be found from the following simultaneous heat balance equations:

$$q_{i,t} = \left[h_{ci}\left(T_{r,t} - T_{i,t}\right) + \sum_{j=1}^{m} g_{ij}\left(T_{j,t} - T_{i,t}\right) \right] A_i + S_{i,t} + L_{i,t} + P_{i,t} + E_{i,t} \qquad (9.6.2)$$

where h_{ci} = convective heat transfer coefficient, Btu/hr.ft^2.°F
g_{ij} = radiative heat transfer factor between inside surface i and inside surface j, Btu/hr.ft^2.°F
$T_{r,t}$ = space air temperature at time t, °F
$T_{i,t}$, $T_{j,t}$ = average temperature of inside surfaces i and j at time t, °F
A_i = area of inside surface i, ft^2
$S_{i,t}$, $L_{i,t}$, $P_{i,t}$, $E_{i,t}$ = solar radiation transmitted through windows and radiative heat from lights, occupants, and equipment absorbed by inside surface i at time t, Btu/hr

In Equation (9.6.2), $q_{i,t}$, in Btu/hr, is the conductive heat that comes to surface i at time t because of the temperature excitation on the outer opposite surface of i. This conductive heat can be found by solving the partial differential equations or by numerical solutions. The number of inside surfaces i is usually equal to 6, and surface i is different from j so that radiative exchange can proceed. $q_{i,t}$ could also be expressed in Btu/min or even Btu/sec.

The space sensible cooling load q_{rs}, in Btu/hr, is the sum of the convective heat from the inside surfaces, including the convective heat from the inner window glass due to the absorbed solar radiation and the infiltration:

$$q_{rs} = \left[\sum_{i=1}^{6} h_{ci}\left(T_{i,t} - T_{r,t}\right) \right] A_i + 60\dot{V}_{if}\rho_o c_{pa}\left(T_{o,t} - T_{r,t}\right) + S_{c,t} + L_{c,t} + P_{c,t} + E_{c,t} \qquad (9.6.3)$$

where $\dot{V}_{if}$ = volume flow rate of infiltrated air, cfm
ρ_o = air density of outdoor air, lb/ft^3
c_{pa} = specific heat of moist air, Btu/lb.°F
$T_{o,t}$ = temperature of outdoor air at time t, °F
$S_{c,t}$, $L_{c,t}$, $P_{c,t}$, $E_{c,t}$ = heat convected from the windows, lights, occupants, and equipment, Btu/hr

Equations (9.6.2) and (9.6.3), and partial differential equations to determine conductive heat $q_{i,t}$ must be solved simultaneously. Using a rigorous approach to find the space cooling load requires numerous computer calculations. It is laborious and time consuming. The rigorous approach is impractical and is suitable for research work only.

Transfer Function Method (TFM)

The *transfer function* of a system relates its output in Laplace transform Y to its input in Laplace transform G by a ratio K, that is,

$$K = Y/G = \left(v_o + v_1 z^{-1} + v_2 z^{-2} + \ldots\right) \Big/ \left(1 + w_1 z^{-1} + w_2 z^{-2} + \ldots\right)$$
$$z = e^{s\Delta} \tag{9.6.4}$$

where Δ = time interval.

In Equation (9.6.4), K, Y, and G are all expressed in z-transforms of the time series function. Coefficients v_n and w_n are called *transfer function coefficients*, or weighting factors. *Weighting factors* are used to weight the importance of the effect of current and previous heat gains as well as the previous space sensible cooling load on the current space sensible cooling load $q_{rs,t}$. Then, the output $q_{rs,t}$ can be related to the input, the space sensible heat gain $q_{es,t}$, through $q_{rs,t} = Kq_{es,t}$.

Mitalas and Stevenson (1967) and others developed a method for determining the transfer function coefficients of a zone of given geometry and details of the calculated space heat gains and the previously known space sensible cooling load through rigorous computation or through tests and experiments. In DOE 2.1A (1981) software for custom weighting factors (tailor made according to a specific parametric zone) is also provided. Sowell (1988) and Spitler et al. (1993) expanded the application of TFM to zones with various parameters: zone geometry, different types of walls, roof, floor, ceilings, building material, and mass locations. Mass of construction is divided into light construction, 30 lb/ft^2 of floor area; medium construction, 70 lb/ft^2; and heavy construction, 130 lb/ft^2. Data are summarized into groups and listed in tabular form for user's convenience.

Cooling Load Temperature Difference/Solar Cooling Load Factor/Cooling Load Factor (CLTD/SCL/CLF) Method

The *CLTD/SCL/CLF method* is a one-step simplification of the transfer function method. The space cooling load is calculated directly by multiplying the heat gain q_e with CLTD, SCL, or CLF instead of first finding the space heat gains and then converting into space cooling loads through the room transfer function. In the CLTD/SCL/CLF method, the calculation of heat gains is the same as in the transfer function method.

The CLTD/SCL/CLF method was introduced by Rudoy and Duran (1975). McQuiston and Spitler (1992) recommended a new SCL factor. In 1993 they also developed the CLTD and CLF data for different zone geometries and constructions.

Finite Difference Method

Since the development of powerful personal computers, the finite difference or numerical solution method can be used to solve transient simultaneous heat and moisture transfer in space cooling load calculations. Wong and Wang (1990) emphasized the influence of moisture stored in the building structure on the cool-down load during the night shut-down operating mode in locations where the summer outdoor climate is hot and humid. The finite difference method is simple and clear in concept as well as more direct in computation than the transfer function method. Refer to Wang's *Handbook of Air Conditioning and Refrigeration* for details.

Total Equivalent Temperature Differential/Time Averaging (TETD/TA) Method

In this method, the heat gains transmitted through external walls and roofs are calculated from the Fourier series solution of one-dimensional transient heat conduction. The conversion of space heat gains to space cooling loads takes place by (1) averaging the radiative heat gains to the current and successive hours according to the mass of the building structure and experience and (2) adding the instantaneous convective fraction and the allocated radiative fraction in that time period. The TETD/TA method is simpler and more subjective than the TFM.

Conduction Heat Gains

Following are the principles and procedures for the calculation of space heat gains and their conversion to space cooling loads by the TFM. TFM is the method adopted by software DOE-2.1D and is also one

of the computing programs adopted in TRACE 600. Refer to *ASHRAE Handbook 1993 Fundamentals*, Chapters 26 and 27, for detail data and tables.

Surface Heat Transfer Coefficients

ASHRAE Handbook 1993 Fundamentals adopts a constant *outdoor heat transfer coefficient* h_o = 3.0 Btu/hr.ft^2.°F and a constant *inside heat transfer coefficient* h_i = 1.46 Btu/hr.ft^2.°F during cooling load calculations. However, many software programs use the following empirical formula (TRACE 600 *Engineering Manual*):

$$h_{o.t} = 2.00 + 0.27v_{\text{wind}.t} \tag{9.6.5}$$

where $h_{o.t}$ = h_o at time t, Btu/hr.ft^2.°F
$v_{\text{wind}.t}$ = wind velocity at time t, ft/sec

Coefficient h_i may be around 2.1 Btu/hr.ft^2.°F when the space air system is operating, and h_i drops to only about 1.4 Btu/hr.ft^2.°F when the air system is shut down. The *R value*, expressed in hr.ft^2.°F/Btu, is defined as the reciprocal of the overall heat transfer coefficient *U* value, in Btu/hr.ft^2.°F. The *R* value is different from the thermal resistance R^*, since $R^* = 1/UA$, which is expressed in hr.°F/Btu.

Sol-air temperature T_{sol} is a fictitious outdoor air temperature that gives the rate of heat entering the outer surface of walls and roofs due to the combined effect of incident solar radiation, radiative heat exchange with the sky vault and surroundings, and convective heat exchange with the outdoor air. T_{sol}, in °F, is calculated as

$$T_{sol} = T_o + \alpha I_t / h_o - \varepsilon \Delta R / h_o \tag{9.6.6}$$

where T_o = outdoor air temperature, °F
α = absorptance of incident solar radiation on outer surface
ϵ = hemispherical emittance of outer surface, assumed equal to 1
I_t = total intensity of solar radiation including diffuse radiation, Btu/hr.ft^2

Tabulated sol-air temperatures that have been calculated and listed in *ASHRAE Handbook 1993 Fundamentals* are based on the following: if $\epsilon = 1$ and $h_o = 3$ Btu/hr.ft^2.°F, $\Delta R/h_o$ is –7°F for horizontal surfaces and 0°F for vertical surfaces, assuming that the long-wave radiation from the surroundings compensates for the loss to the sky vault.

External Wall and Roof

The sensible heat gain through a wall or roof at time t, $q_{e,t}$, in Btu/hr, can be calculated by using the sol-air temperature at time t-$n\delta$, $T_{sol,t-n\delta}$, in °F, as the outdoor air temperature and a constant indoor space air temperature T_r, in °F, as

$$q_{e,t} = A\left[\sum_{n=0} b_n T_{sol,t-n\delta} - \sum_{n=1} d_n \left(q_{e,t-n\delta}/A\right)\right] - T_r \sum_{n=0} c_n \tag{9.6.7}$$

where A = surface area of wall or roof, ft^2
$q_{e,t-n\delta}$ = heat gain through wall or roof at time t-$n\delta$, Btu/hr
n = number of terms in summation

In Equation (9.6.7), b_n, c_n, and d_n are *conduction transfer function* coefficients.

Ceiling, Floor, and Partition Wall

If the variation of the temperature of the adjacent space T_{aj}, in °F, is small compared with the differential ($T_{aj} - T_r$), or even when T_{aj} is constant, the heat gain to the conditioned space through ceiling, floor, and partition wall $q_{aj,t}$, in Btu/hr, is

$$q_{aj,t} = UA\left(T_{aj} - T_r\right) \tag{9.6.8}$$

where U = overall heat transfer coefficient of the ceiling, floor, and partition (Btu/hr.ft².°F).

Heat Gain through Window Glass

Shading Devices. There are two types of shading devices: indoor shading devices and outdoor shading devices. *Indoor shading devices* increase the reflectance of incident radiation. *Venetian blinds* and draperies are the most widely used indoor shading devices. Most horizontal venetian blinds are made of plastic, aluminum, or rigid woven cloth slats spaced 1 to 2 in. apart. Vertical venetian blinds with wider slats are also used. *Draperies* are made of fabrics of cotton, rayon, or synthetic fibers. They are usually loosely hung, wider than the window, often pleated, and can be drawn open and closed as needed. Draperies also increase thermal resistance in winter.

External shading devices include overhangs, side fins, louvers, and pattern grilles. They reduce the sunlit area of the window glass effectively and therefore decrease the solar heat gain. External shading devices are less flexible and are difficult to maintain.

Shading Coefficient (SC). The shading coefficient is an index indicating the glazing characteristics and the associated indoor shading device to admit solar heat gain. SC of a specific window glass and shading device assembly at a summer design solar intensity and outdoor and indoor temperatures can be calculated as

$$\text{SC} = \frac{\text{solar heat gain of specific type of window glass assembly}}{\text{solar heat gain of reference (DSA) glass}} \tag{9.6.9}$$

Double-strength sheet glass (DSA) has been adopted as the reference glass with a transmittance of $\tau = 0.86$, reflectance $\rho = 0.08$, and absorptance $\alpha = 0.06$.

Solar Heat Gain Factors (SHGFs). SHGFs, in Btu/hr.ft², are the average solar heat gains during cloudless days through DSA glass. SHGF_{max} is the maximum value of SHGF on the 21st day of each month for a specific latitude as listed in *ASHRAE Handbook 1993 Fundamentals*. At high elevations and on very clear days, the actual SHGF may be 15% higher.

Heat Gain through Window Glass. There are two kinds of heat gain through window glass: heat gain due to the solar radiation transmitted and absorbed by the window glass, $q_{es,t}$, and conduction heat gain due to the outdoor and indoor temperature difference, $q_{ec,t}$, both in Btu/hr:

$$q_{es,t} = \left(A_s \times \text{SHGF} \times \text{SC}\right) + \left(A_{sh} \times \text{SHGF}_{sh} \times \text{SC}\right) \tag{9.6.10}$$

where A_s, A_{sh} = sunlit and shaded areas of the glass (ft²).

In Equation (9.6.10), SHGF_{sh} represents the SHGF of the shaded area of the glass having only diffuse radiation. Generally, the SHGF of solar radiation incident on glass facing north without direct radiation can be considered as SHGF_{sh}. Because the mass of window glass is small, its heat storage effect is often neglected; then the conduction heat gain at time t is

$$q_{ec,t} = U_g\left(A_s + A_{sh}\right)\left(T_{o,t} - T_r\right) \tag{9.6.11}$$

where U_g = overall heat transfer coefficient of window glass, Btu/hr.ft^2.°F
$T_{o,t}$ = outdoor air temperature at time t, °F

The inward heat transfer due to the solar radiation absorbed by the glass and the conduction heat transfer due to the outdoor and indoor temperature difference is actually combined. It is simple and more convenient if they are calculated separately.

Internal Heat Gains

Internal heat gains are heat released from the internal sources.

People

The sensible heat gain and latent heat gain per person, $q_{es,t}$ and $q_{el,t}$, both in Btu/hr, are given as

$$q_{es,t} = N_t q_{os}$$
$$q_{el,t} = N_t q_{ol} \tag{9.6.12}$$

where N_t = number of occupants in the conditioned space at time t.

Heat gains q_{os} and q_{ol} depend on the occupant's metabolic level, whether the occupant is an adult or a child, male or female, and the space temperature. For a male adult seated and doing very light work, such as system design by computer in an office of space temperature 75°F, q_{os} and q_{ol} are both about 240 Btu/hr.

Lights

Heat gain in the conditioned space because of the electric lights, $q_{e.li}$, in Btu/hr, is calculated as

$$q_{e.li} = \sum_{n=1}\left[3.413 W_{li} N_{li} F_{ul} F_{al}\left(1 - F_{lp}\right)\right] = 3.413 W_{lA} A_{fl} \tag{9.6.13}$$

where W_{li} = watt input to each lamp, W
W_{lA} = lighting power density, W/ft^2
A_{fl} = floor area of conditioned space, ft^2
N_{li}, n = number of lamps (each type) and number of types of electric lamp
F_{al}, F_{ul} = use factor of electric lights and allowance factor for ballast loss, usually taken as 1.2
F_{lp} = heat gain carried away by the return air to plenum or by exhaust device; it varies from 0.2 to 0.5

Machines and Appliances

The sensible and latent heat gains in the conditioned space from machines and appliances, $q_{e.ap}$ and $q_{l.ap}$, both in Btu/hr, can be calculated as

$$q_{e.ap} = 3.413 W_{ap} F_{ua} F_{load} F_{ra} = q_{is} F_{ua} F_{ra}$$
$$q_{l.ap} = q_{il} F_{ua} \tag{9.6.14}$$

where W_{ap} = rated power input to the motor of the machines and appliances, W
F_{ua} = use factor of machine and appliance
F_{load} = ratio of actual load to the rated power
F_{ra} = radiation reduction factor because of the front shield of the appliance
q_{is}, q_{il} = sensible and latent heat input to the appliance, Btu/hr

Infiltration

Infiltration is the uncontrolled inward flow of unconditioned outdoor air through cracks and openings on the building envelope because of the pressure difference across the envelope. The pressure difference is probably caused by wind pressure, stack effect due to outdoor–indoor temperature difference, and the operation of an air system(s).

Today new commercial buildings have their external windows well sealed. If a positive pressure is maintained in the conditioned space when the air system is operating, infiltration is normally considered as zero.

When the air system is shut down, or for hotels, motels, and high-rise residential buildings, ASHRAE/IES Standard 90.1-1989 specifies an infiltration of 0.038cfm/ft^2 of gross area of the external wall, 0.15 air change per hour (ach) for the perimeter zone.

When exterior windows are not well sealed, the outdoor wind velocity is high at winter design conditions, or there is a door exposed to the outdoors directly, an infiltration rate of 0.15 to 0.4 ach for perimeter zone should be considered.

When the volume flow rate of infiltration is determined, the sensible heat gain due to infiltration $q_{s.if}$ and latent heat gain due to infiltration $q_{l.if}$, in Btu/hr, are

$$q_{s.if} = 60\,\mathring{V}_{if}\,\rho_o c_{pa}\left(T_o - T_r\right)$$
$$q_{l.if} = 60\times 1060\,\mathring{V}_{if}\,\rho_o\left(w_o - w_r\right) \tag{9.6.15}$$

where $\mathring{V}_{if}$ = volume flow rate of infiltration, cfm
ρ_o = air density of outdoor air, lb/ft^3
c_{pa} = specific heat of moist air, 0.243 Btu/lb.°F
w_o,w_r = humidity ratio of outdoor and space air, lb/lb
$h_{fg.58}$ = latent heat of vaporization, 1060 Btu/lb

Infiltration enters the space directly and mixes with space air. It becomes space cooling load instantaneously. Ventilation air is often taken at the AHU or PU and becomes sensible and latent coil load components.

Conversion of Heat Gains into Cooling Load by TFM

The space sensible cooling load $q_{rs,t}$, in Btu/hr, is calculated as

$$q_{rs,t} = q_{s-e,t} + q_{s-c,t} \tag{9.6.16}$$

where $q_{s\text{-}e,t}$ = space sensible cooling load converted from heat gains having radiative and convective components, Btu/hr
$q_{s\text{-}c,t}$ = space sensible cooling load from convective heat gains, Btu/hr

Based on Equation (9.6.4), space sensible cooling load $q_{s\text{-}e,t}$ can be calculated as

$$q_{s-e,t} = \sum_{i=1}\left(v_o q_{e,t} + v_1 q_{e,t-\delta} + v_2 q_{e,t-2\delta} + \ldots\right) - \left(w_1 q_{r,t-\delta} + w_2 q_{r,t-2\delta} + \ldots\right) \tag{9.6.17}$$

where $q_{e,t}$, $q_{e,t\text{-}\delta}$, $q_{e,t\text{-}2\delta}$ = space sensible heat gains having both radiative and convective heats at time t, t-δ, and t-2δ, Btu/hr
$q_{r,t\text{-}\delta}$, $q_{r,t\text{-}2\delta}$ = space sensible cooling load at time t-δ, and t-2δ, Btu/hr

In Equation (9.6.17), v_n and w_n are called *room transfer function coefficients* (RTFs). RTF is affected by parameters like zone geometry; wall, roof, and window construction; internal shades; zone location; types of building envelope; and air supply density. Refer to RTF tables in *ASHRAE Handbook 1993 Fundamentals*, Chapter 26, for details.

Space sensible cooling load from convective heat gains can be calculated as

$$q_{s-c,t} = \sum_{k=1} q_{ec,t} \tag{9.6.18}$$

where $q_{ec,t}$ = each of k space sensible heat gains that have convective heat gains only (Btu/hr). Space latent cooling load at time t, $q_{rl,t}$, in Btu/hr, can be calculated as

$$q_{rl,t} = \sum_{m=1} q_{el,t} \tag{9.6.19}$$

where $q_{el,t}$ = each of m space latent heat gains (Btu/hr).

Space Air Temperature and Heat Extraction Rate

At equilibrium, the space sensible heat extraction rate at time t, $q_{xs,t}$, is approximately equal to the space sensible cooling load, $q_{rs,t}$, when zero offset proportional plus integral or proportional-integral-derivative control mode is used. During the cool-down period, the sensible heat extraction rate of the cooling coil or DX coil at time t, $q_{xs,t}$, or the sensible cooling coil load, in Btu/hr, is greater than the space sensible cooling load at time t and the space temperature T_r, in °F then drops gradually. According to *ASHRAE Handbook 1993 Fundamentals*, the relationship between the space temperature T_r and the sensible heat extraction rate $q_{xs,t}$ can be expressed as

$$\sum_{i=0}^{1} p_i \left(q_{xs,t} - q_{rs,t-i\delta}\right) = \sum_{i=0}^{2} g_i \left(T_r - T_{r,t-i\delta}\right) \tag{9.6.20}$$

where $q_{rs,t\text{-}i\delta}$ = space sensible cooling load calculated on the basis of constant space air temperature T_r, Btu/hr
$T_{r,t\text{-}i\delta}$ = space temperature at time t-iδ

In Equation (9.6.20), p_i, g_i are called *space air transfer function coefficients*. Space air temperature T_r can be considered an average reference temperature within a time interval.

Cooling Coil Load

Cooling coil load q_{cc}, in Btu/hr, can be calculated from Equation (9.3.11). The sensible and latent cooling coil loads can then be calculated as

$$\begin{aligned} q_{cs} &= 60 \mathring{V}_s \rho_s c_{pa} \left(T_m - T_{cc}\right) \\ q_{cl} &= 60 \mathring{V}_s \rho_s \left(w_m - w_{cc}\right) \end{aligned} \tag{9.6.21}$$

where q_{cs}, q_{cl} = sensible and latent cooling coil load, Btu/hr
T_m, T_{cc} = air temperature of the mixture and leaving the cooling coil, °F
w_m, w_{cc} = humidity ratio of the air mixture and air leaving the cooling coil, lb/lb

Heating Load

The *space heating load* or simply *heating load* is always the possible maximum heat energy that must be added to the conditioned space at winter design conditions to maintain the indoor design temperature. It is used to size and select the heating equipment. In heating load calculations, solar heat gain, internal heat gains, and the heat storage effect of the building envelope are usually neglected for reliability and simplicity.

Normally, space heating load q_{rh}, in Btu/hr, can be calculated as

$$\begin{aligned} q_{rl} &= q_{trans} + q_{if.s} + q_{ma} + q_{hu} \\ &= \left[\left(\sum_{n=1} AU\right) + 60\,\mathring{V}_{if}\,\rho_o c_{pa}\,\mathring{m}_m\,c_m\right]\left(T_r - T_o\right) + \mathring{m}_w\,h_{fg.58} \end{aligned} \tag{9.6.22}$$

where A = area of the external walls, roofs, glasses, and floors, ft²
U = overall heat transfer coefficient of the walls, roofs, glasses, and floors, Btu/hr.ft².°F
c_m, $\mathring{m}_m$ = specific heat and mass flow rate of the cold product entering the space per hour, Btu/lb.°F and lb/hr
$\mathring{m}_w$ = mass flow rate of water evaporated for humidification, lb/hr
$h_{fg.58}$ = latent heat of vaporization at 58°F, 1060 Btu/lb

In Equation 9.88, q_{trans} indicates the *transmission loss* through walls, roofs, glasses, and floors, $q_{if.s}$ the *sensible infiltration heat loss*, q_{ma} the heat required to heat the cold product that enters the conditioned space, and q_{hu} the heat required to raise the space air temperature when water droplets from a space humidifier are evaporated in the conditioned space. For details, refer to *ASHRAE Handbook 1993 Fundamentals*.

9.7 Air Handling Units and Packaged Units

Terminals and Air Handling Units

A *terminal unit*, or *terminal*, is a device or equipment installed directly in or above the conditioned space to cool, heat, filter, and mix outdoor air with recirculating air. Fan-coil units, VAV boxes, fan-powered VAV boxes, etc. are all terminals.

An *air handling unit* (AHU) handles and conditions the air, controls it to a required state, and provides motive force to transport it. An AHU is the primary equipment of the air system in a central air-conditioning system. The basic components of an AHU include a supply fan with a fan motor, a water cooling coil, filters, a mixing box except in a makeup AHU unit, dampers, controls, and an outer casing. A return or relief fan, heating coil(s), and humidifier are optional depending on requirements. The supply volume flow rate of AHUs varies from 2000 to about 60,000 cfm.

AHUs are classified into the followings groups according to their structure and location.

Horizontal or Vertical Units

Horizontal AHUs have their fan, coils, and filters installed at the same level as shown in Figure 9.7.1(a). They need more space and are usually for large units. In *vertical units*, as shown in Figure 9.7.1(b), the supply fan is installed at a level higher than coils and filters. They are often comparatively smaller than horizontal units.

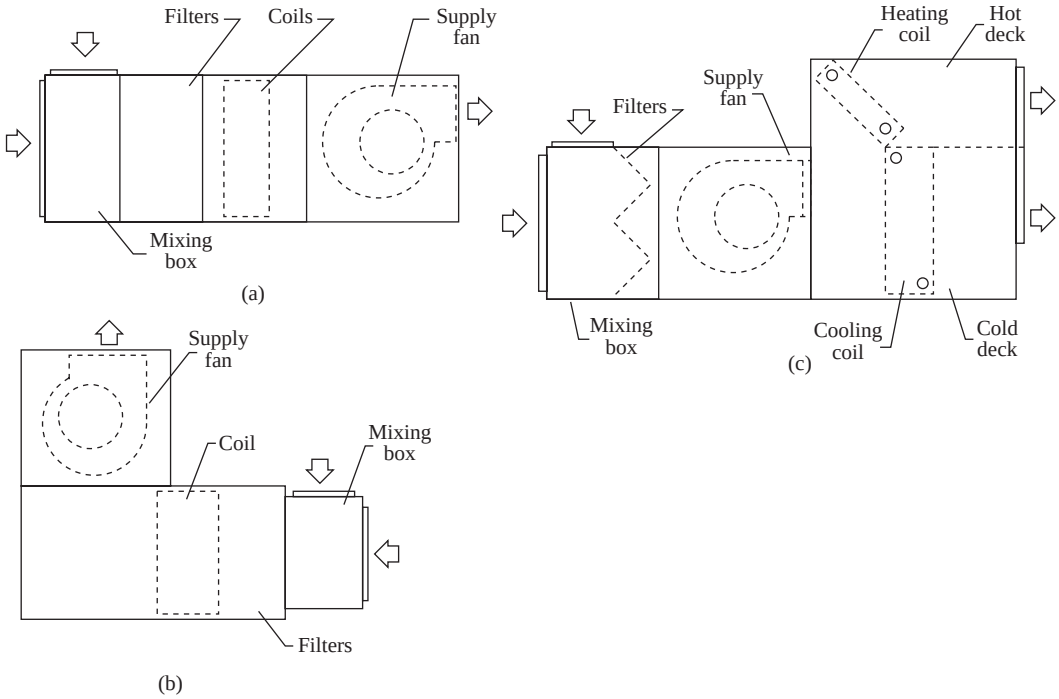

FIGURE 9.7.1 Type of air handling units: (a) horizontal draw-through unit, (b) vertical draw-through unit, and (c) multizone blow-through unit.

Draw-Through or Blow-Through Units

In a *draw-through unit*, as shown in Figure 9.7.1(a), the supply fan is located downstream of the coils. Air is evenly distributed over the coil section, and the fan discharge can easily be connected to a supply duct of nearly the same air velocity. In a *blow-through unit*, as shown in Figure 9.7.1(c), the supply fan

is located upstream of the coils. It usually has hot and cold decks with discharge dampers connected to warm and cold ducts, respectively.

Factory-Fabricated and Field Built-Up Units

Factory-fabricated units are standard in construction and layout, low in cost, of higher quality, and fast in installation. *Field built-up units* or *custom-built units* are more flexible in construction, layout, and dimensions than factory-built standardized units.

Rooftop and Indoor Units

A *rooftop AHU*, sometimes called a penthouse unit, is installed on the roof and will be completely weatherproof. An *indoor AHU* is usually located in a fan room or ceiling and hung like small AHU units.

Make-Up Air and Recirculating Units

A *make-up AHU*, also called a primary-air unit, is used to condition outdoor air entirely. It is a once-through unit. There is no return air and mixing box. *Recirculating units* can have 100% outdoor air intake or mixing of outdoor air and recirculating air.

Packaged Units

A *packaged unit* (PU) is a self-contained air conditioner. It conditions the air and provides it with motive force and is equipped with its own heating and cooling sources. The packaged unit is the primary equipment in a packaged air-conditioning system and is always equipped with a DX coil for cooling, unlike an AHU. R-22, R-134a, and others are used as refrigerants in packaged units. The portion that handles air in a packaged unit is called an *air handler* to distinguish it from an AHU. Like an AHU, an indoor air handler has an indoor fan, a DX coil (indoor coil), filters, dampers, and controls. Packaged units can be classified according to their place of installation: rooftop, indoor, and split packaged units.

Rooftop Packaged Units

A *rooftop packaged unit* is mounted on the roof of the conditioned space as shown in Figure 9.7.2. From the types of heating/cooling sources provided, rooftop units can be subdivided into:

- Gas/electric rooftop packaged unit, in which heating is provided by gas furnace and cooling by electric power-driven compressors.
- Electric/electric rooftop packaged unit, in which electric heating and electric power-driven compressors provide heating and cooling.
- Rooftop packaged heat pump, in which both heating and cooling are provided by the same refrigeration system using a four-way reversing valve (heat pump) in which the refrigeration flow changes when cooling mode is changed to heating mode and vice versa. Auxiliary electric heating is provided if necessary.

Rooftop packaged units are single packaged units. Their cooling capacity may vary from 3 to 220 tons with a corresponding volume flow rate of 1200 to 80,000 cfm. Rooftop packaged units are the most widely used packaged units.

Indoor Packaged Units

An *indoor packaged unit* is also a single packaged and factory-fabricated unit. It is usually installed in a fan room or a machinery room. A small or medium-sized indoor packaged unit could be floor mounted directly inside the conditioned space with or without ductwork. The cooling capacity of an indoor packaged unit may vary from 3 to 100 tons and volume flow rate from 1200 to 40,000 cfm.

Indoor packaged units are also subdivided into:

- Indoor packaged cooling units

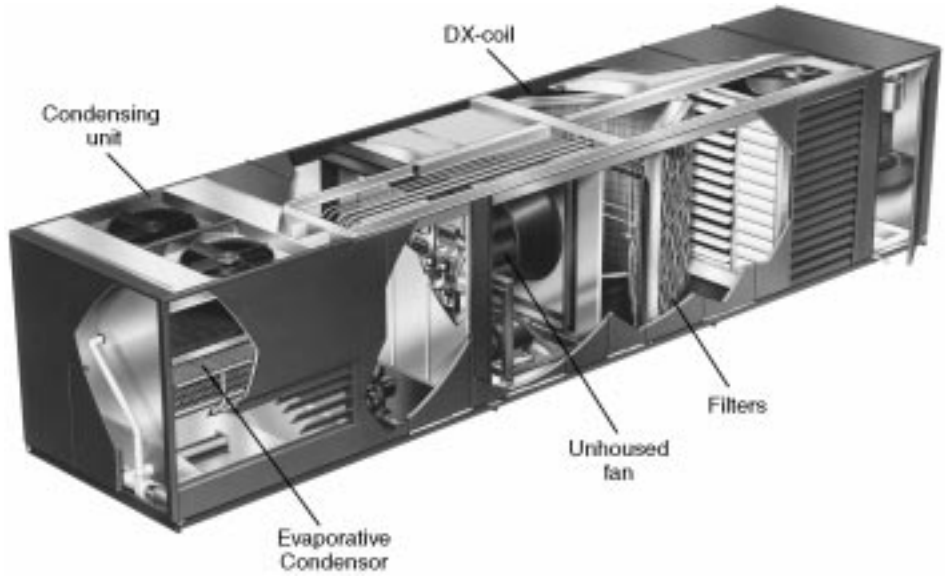

FIGURE 9.7.2 A cut view of a rooftop package unit. (Source: Mammoth, Inc. Reprinted by permission.)

- Indoor packaged cooling/heating units, in which heating may be provided from a hot water heating coil, a steam heating coil, and electric heating
- Indoor packaged heat pumps

Indoor packaged units have either an air-cooled condenser on the rooftop or a shell-and-tube or double-tube water-cooled condenser inside the unit.

Split Packaged Units

A *split packaged unit* consists of two separate pieces of equipment: an indoor air handler and an outdoor condensing unit. The indoor air handler is often installed in the fan room. Small air handlers can be ceiling hung. The condensing unit is usually located outdoors, on a rooftop or podium or on the ground.

A split packaged unit has its compressors and condenser in its outdoor condensing unit, whereas an indoor packaged unit usually has its compressors indoors. The cooling capacity of split packaged units varies from 3 to 75 tons and the volume flow rate from 1200 to 30,000 cfm.

Rating Conditions and Minimum Performance

Air Conditioning and Refrigeration Institute (ARI) Standards and ASHRAE/IES Standard 90.1-1989 specified the following rating indices:

- Energy efficiency ratio (EER) is the ratio of equipment cooling capacity, in Btu/hr, to the electric input, in W, under rating conditions.
- SEER is the seasonal EER, or EER during the normal annual usage period.
- IPLV is the integrated part-load value. It is the summarized single index of part-load efficiency of PUs based on weighted operations at several load conditions.
- HSPF is the heating seasonal performance factor. It is the total heating output of a heat pump during its annual usage period for heating, in Btu, divided by the total electric energy input to the heat pump during the same period, in watt-hours.

According to ARI standards, the minimum performance for air-cooled, electrically operated single packaged units is

	q_{rc} (Btu/hr)	T_o (°F)	EER	T_o (°F)	IPLV
Air-cooled	<65,000	95	9.5		
	65,000 ≤ q_{rc} < 135,000	95	8.9	80	8.3
	135,000 ≤ q_{rc} < 760,000		8.5		7.5

For water- and evaporatively cooled packaged units including heat pumps, refer to ASHRAE/IES Standard 90.1-1989 and also ARI Standards.

Coils

Coils, Fins, and Water Circuits

Coils are indirect contact heat exchangers. Heat transfer or heat and mass transfer takes place between conditioned air flowing over the coil and water, refrigerant, steam, or brine inside the coil for cooling, heating, dehumidifying, or cooling/dehumidifying. Chilled water, brine, and refrigerants that are used to cool and dehumidify the air are called *coolants*. Coils consist of tubes and external fins arranged in rows along the air flow to increase the contact surface area. Tubes are usually made of copper; in steam coils they are sometimes made of steel or even stainless steel. Copper tubes are staggered in 2, 3, 4, 6, 8, or up to 10 rows.

Fins are extended surfaces often called *secondary surfaces* to distinguish them from the *primary surfaces*, which are the outer surfaces of the tubes. Fins are often made from aluminum, with a thickness F_t = 0.005 to 0.008 in., typically 0.006 in. Copper, steel, or sometimes stainless steel fins are also used. Fins are often in the form of continuous plate fins, corrugated plate fins to increase heat transfer, crimped spiral or smooth spiral fins that may be extruded from the aluminum tubes, and spine pipes, which are shaved from the parent aluminum tubes. Corrugated plate fins are most widely used.

Fin spacing S_f is the distance between two fins. *Fin density* is often expressed in fins per inch and usually varies from 8 to 18 fins/in.

In a water cooling coil, *water circuits* or *tube feeds* determine the number of water flow passages. The greater the finned width, the higher the number of water circuits and water flow passages.

Direct Expansion (DX) Coil

In a *direct expansion coil*, the refrigerant, R-22, R-134a, or others, is evaporated and expanded directly inside the tubes to cool and dehumidify the air as shown in Figure 9.7.3(a). Refrigerant is fed to a distributor and is then evenly distributed to various copper tube circuits typically 0.375 in. in diameter. Fin density is usually 12 to 18 fins/in. and a four-row DX coil is often used. On the inner surface of the copper tubes, microfins, typically at 60 fins/in. and a height of 0.008 in., are widely used to enhance the boiling heat transfer.

Air and refrigerant flow is often arranged in a combination of counterflow and cross flow and the discharge header is often located on the air-entering side. Refrigerant distribution and loading in various circuits are critical to the coil's performance. Vaporized vapor refrigerant is superheated 10 to 20°F in order to prevent any liquid refrigerant from flooding back to the reciprocating compressors and damaging them. Finally, the vapor refrigerant is discharged to the suction line through the header.

For comfort air-conditioning systems, the evaporating temperature of refrigerant T_{ev} inside the tubes of a DX coil is usually between 37 and 50°F. At such a temperature, the surface temperature of the coil is often lower than the dew point of the entering air. Condensation occurs at the coil's outside surface, and the coil becomes a wet coil. A condensate *drain pan* is necessary for each vertically banked DX coil, and a trap should be installed to overcome the negative pressure difference between the air in the coil section and the ambient air.

Face velocity of the DX coil v_a, in fpm, is closely related to the blow-off of the water droplets of the condensate, the heat transfer coefficients, the air-side pressure drop, and the size of the air system. For corrugated fins, the upper limit is 600 fpm, with an air-side pressure drop of 0.20 to 0.30 in. WG/row.

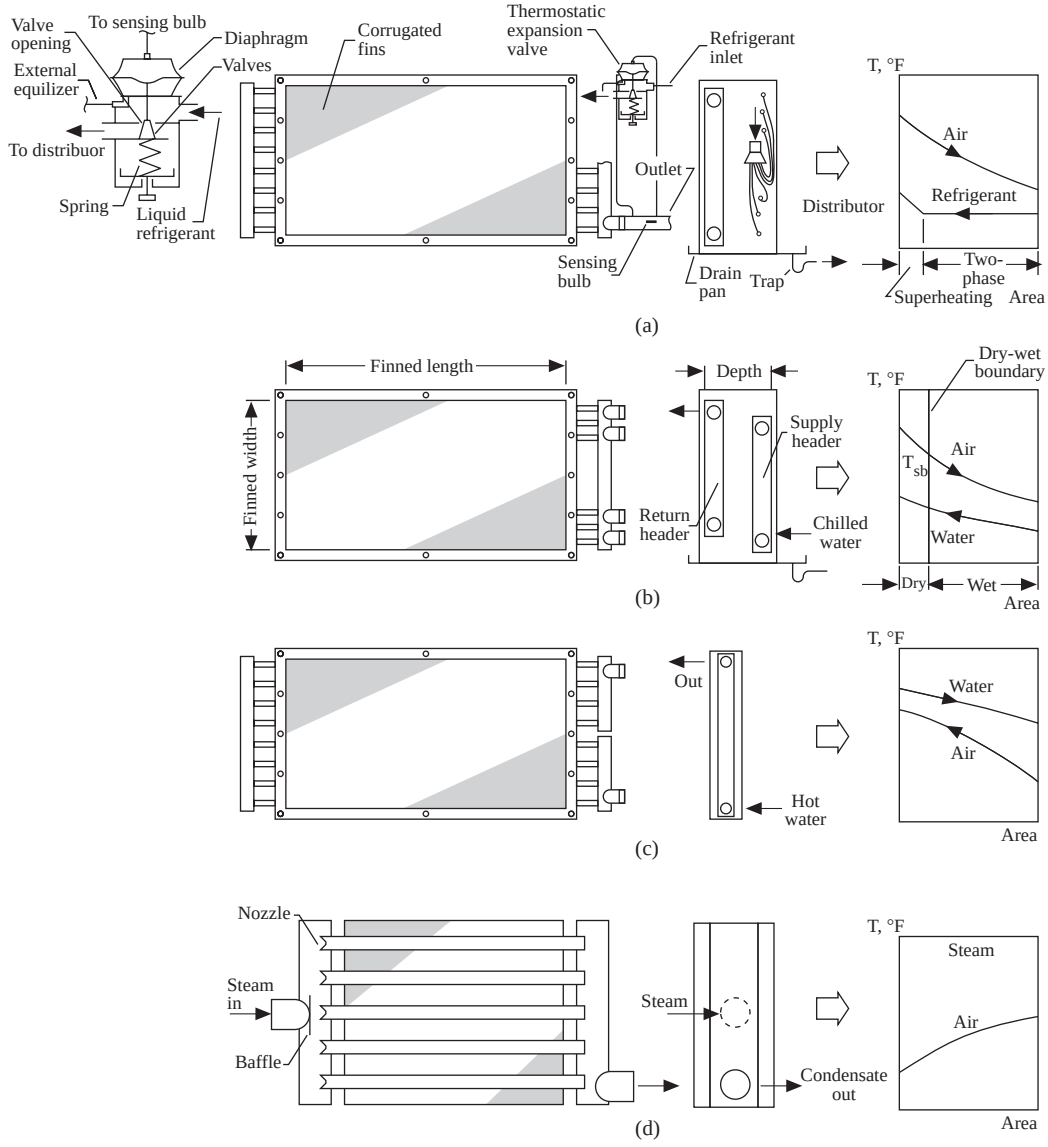

FIGURE 9.7.3 Types of coils: (a) direct expansion coil, (b) water cooling coil, (c) water heating coil, and (d) steam heating coil.

A large DX coil is often divided into two refrigerant sections, each with its own expansion valve, distributor, and discharge header.

For a packaged unit of a specific model, size, face velocity and condition of entering air and outdoor air, the DX coil's cooling capacities in nominal tons, number of rows, and fin density are all fixed values.

Water Cooling Coils — Dry–Wet Coils

In a water cooling coil, chilled water at a temperature of 40 to 50°F, brine, or glycol-water at a temperature of 34 to 40°F during cold air distribution enters the coil. The temperature of chilled water, brine, or glycol-water is usually raised 12 to 24°F before it leaves the water cooling coil.

The water tubes are usually copper tubes of 1/2 to 5/8 in. diameter with a tube wall thickness of 0.01 to 0.02 in. They are spaced at a center-to-center distance of 0.75 to 1.25 in. longitudinally and 1 to 1.5

in. transversely. These tubes may be staggered in 2, 3, 4, 6, 8, or 10 rows. Chilled water coils are often operated at a pressure of 175 to 300 psig.

As in a DX coil, the air flow and water flow are in a combination of counterflow and cross flow. The outer surface of a chilled water cooling coil at the air entering side T_{se} is often greater than the dew point of the entering air T''_{ae}, or $T_{se} > T''_{ae}$. The outer surface temperature of coil at the air leaving side T_{sl} may be smaller than T''_{ae}, or $T_{sl} < T''_{ae}$. Then the water cooling coil becomes a dry–wet coil with part of the dry surface on the air entering side and part of the wet surface on the air leaving side. A *dry–wet boundary* divides the dry and wet surfaces. At the boundary, the tube outer surface temperature $T_{sb} = T''_{ae}$ as shown in Figure 9.7.3(b). A condensate drain pan is necessary for a dry–wet coil.

A water cooling coil is selected from the manufacturer's selection program or from its catalog at (1) a dry and wet bulb of entering air, such as 80°F dry bulb and 67°F wet bulb; (2) an entering water temperature, such as 44 or 45°F; (3) a water temperature rise between 10 and 24°F; and (4) a coil face velocity between 400 and 600 fpm. The number of rows and fins per inch is varied to meet the required sensible and cooling coil load, in Btu/hr.

Water Cooling Coil–Dry Coil

When the temperature of chilled water entering the water cooling coil $T_{we} \geq T''_{ae}$, condensation will not occur on the outer surface of the coil. This coil becomes a sensible cooling–dry coil, and the humidity ratio of the conditioned air w_a remains constant during the sensible cooling process.

The construction of a sensible cooling–dry coil, such as material, tube diameter, number of rows, fin density, and fin thickness, is similar to that of a dry–wet coil except that a dry coil always has a poorer surface heat transfer coefficient than a wet coil, and therefore a greater coil surface area is needed; the maximum face velocity of a dry coil can be raised to $v_a \leq 800$ fpm; and the coil's outer surface is less polluted. The effectiveness of a dry coil $\in_{dry}$ is usually 0.55 to 0.7.

Water Heating Coil

The construction of a water heating coil is similar to that of a water cooling coil except that in water heating coils hot water is supplied instead of chilled water and there are usually fewer rows, only 2, 3, and 4 rows, than in water cooling coils. Hot water pressure in water heating coils is often rated at 175 to 300 psig at a temperature up to 250°F. Figure 9.7.3(c) shows a water heating coil.

Steam Heating Coil

In a steam heating coil, latent heat of condensation is released when steam is condensed into liquid to heat the air flowing over the coil, as shown in Figure 9.7.3(d). Steam enters at one end of the coil, and the condensate comes out from the opposite end. For more even distribution, a baffle plate is often installed after the steam inlet. Steam heating coils are usually made of copper, steel, or sometimes stainless steel.

For a steam coil, the coil core inside the casing should expand or contract freely. The coil core is also pitched toward the outlet to facilitate condensate drainage. Steam heating coils are generally rated at 100 to 200 psig at 400°F.

Coil Accessories and Servicing

Coil accessories include air vents, drain valves, isolation valves, pressure relief valves, flow metering valves, balancing valves, thermometers, pressure gauge taps, condensate drain taps, and even distribution baffles. They are employed depending on the size of the system and operating and serving requirements.

Coil cleanliness is important for proper operation. If a medium-efficiency air filter is installed upstream of the coil, dirt accumulation is often not a problem. If a low-efficiency filter is employed, dirt accumulation may block the air passage and significantly increase the pressure drop across the coil. Coils should normally be inspected and cleaned every 3 months in urban areas when low-efficiency filters are used. Drain pans should be cleaned every month to prevent buildup of bacteria and microorganisms.

Coil Freeze-Up Protection

Improper mixing of outdoor air and recirculating air in the mixing box of an AHU or PU may cause coil freeze-up when the outdoor air temperature is below 32°F. Outdoor air should be guided by a baffle plate and flow in an opposite direction to the recirculating air stream so that they can be thoroughly mixed without stratification.

Run the chilled water pump for the idle coil with a water velocity of 2.5 ft/sec, so that the cooling coil will not freeze when the air temperature drops to 32°F. A better method is to drain the water completely. For a hot water coil, it is better to reset the hot water temperature at part-load operation instead of running the system intermittently. A steam heating coil with inner distributor tubes and outer finned heating tubes provides better protection against freeze-up.

Air Filters

Air Cleaning and Filtration

Air cleaning is the process of removing airborne particles from the air. Air cleaning can be classified into air filtration and industrial air cleaning. Industrial air cleaning involves the removal of dust and gaseous contaminants from manufacturing processes as well as from the space air, exhaust air, and flue gas for air pollution control. In this section, only air filtration is covered.

Air filtration involves the removal of airborne particles presented in the conditioned air. Most of the airborne particles removed by air filtration are smaller than 1 μm, and the concentration of these particles in the airstream seldom exceeds 2 mg/m^3. The purpose of air filtration is to benefit the health and comfort of the occupants as well as meet the cleanliness requirements of the working area in industrial buildings.

An *air filter* is a kind of air cleaner that is installed in AHUs, PUs, and other equipment to filter the conditioned air by inertial impaction or interception and to diffuse and settle fine dust particles on the fibrous medium. The filter medium is the fabricated material that performs air filtration.

Operating performance of air filters is indicated by their:

- *Efficiency* or effectiveness of dust removal
- *Dust holding capacity* m_{dust}, which is the amount of dust held in the air filter, in grains/ft^2
- *Initial pressure drop* when the filter is clean Δp_{fi} and *final pressure drop* Δp_{ff} when the filter's m_{dust} is maximum, both in in. WG
- *Service life*, which is the operating period between Δp_{fi} and Δp_{ff}

Air filters in AHUs and PUs can be classified into low-, medium-, and high-efficiency filters and carbon activated filters.

Test Methods

The performance of air filters is usually tested in a test unit that consists of a fan, a test duct, the tested filter, two samplers, a vacuum pump, and other instruments. Three test methods with their own test dusts and procedures are used for the testing of low-, medium-, and high-efficiency air filters.

The *weight arrestance test* is used for low-efficiency air filters to assess their ability to remove coarse dusts. Standard synthetic dusts that are considerably coarser than atmospheric dust are fed to the test unit. By measuring the weight of dust fed and the weight gain due to the dust collected on the membrane of the sampler after the tested filter, the arrestance can be calculated.

The *atmospheric dust spot efficiency test* is used for medium-efficiency air filters to assess their ability to remove atmospheric dusts. *Atmospheric dusts* are dusts contained in the outdoor air, the outdoor atmosphere. Approximately 99% of atmospheric dusts are dust particles <0.3 μm that make up 10% of the total weight; 0.1% of atmospheric dusts is particles >1 μm that make up 70% of the total weight.

Untreated atmospheric dusts are fed to the test unit. Air samples taken before and after the tested filter are drawn through from identical fiber filter-paper targets. By measuring the light transmission of these discolored white filter papers, the efficiency of the filter can be calculated. Similar atmospheric

dust spot test procedures have been specified by American Filter Institute (AFI), ASHRAE Standard 52.1, and former National Bureau of Standards (NBS).

The *DOP penetration and efficiency test* or simply *DOP test* is used to assess high-efficiency filters removing dusts particles of 0.18 μm. According to U.S. Military Standard MIL-STD-282 (1956), a smoke cloud of uniform dioctyl phthalate (DOP) droplets 0.18 μm in diameter, generated from the condensation of the DOP vapor, is fed to the test unit. By measuring the concentration of these particles in the air stream upstream and downstream of the tested filter using an electronic particle counter or laser spectrometer, the penetration and efficiency of the air filter can be calculated.

Low-Efficiency Air Filters

ASHRAE weight arrestance for low-efficiency filters is between 60 and 95%, and ASHRAE dust spot efficiency for low-efficiency filters is less than 20%. These filters are usually in panels as shown in Figure 9.7.4(a). Their framework is typically 20 × 20 in. or 24 × 24 in. Their thickness varies from 1 to 4 in.

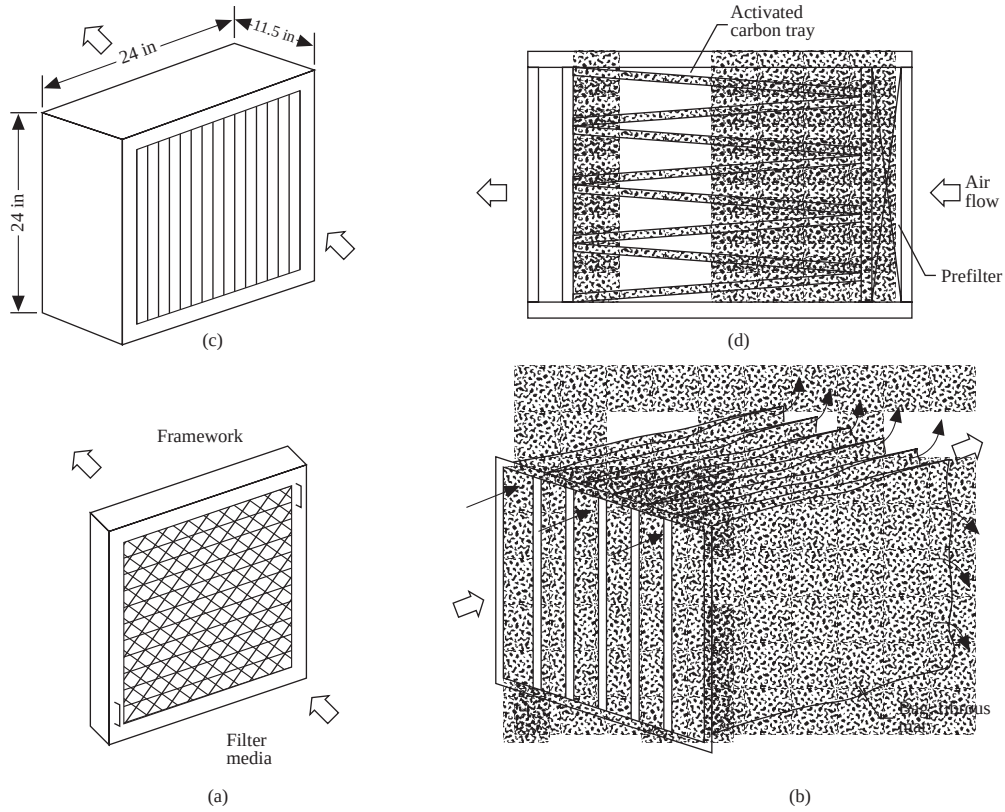

FIGURE 9.7.4 Various types of air filters: (a) low efficiency, (b) medium efficiency, (c) HEPA and ULPA filters, and (d) activated carbon filter.

For low-efficiency filters, the filter media are often made of materials such as

- Corrugated wire mesh and screen strips coated with oil, which act as adhesives to enhance dust removal. Detergents may be used to wash off dusts so that the filter media can be cleaned and reused — they are therefore called *viscous and reusable*.
- Synthetic fibers (nylon, terylene) and polyurethane foam can be washed, cleaned, and reused if required — *dry and reusable*.

- Glass fiber mats with fiber diameter greater than 10 μm. The filter medium is discarded when its final pressure drop is reached — *dry and disposable*. The face velocity of the panel filter is usually between 300 and 600 fpm. The initial pressure drop varies from 0.05 to 0.25 in. WG and the final pressure drop from 0.2 to 0.5 in. WG.

Medium-Efficiency Air Filters

These air filters have an ASHRAE dust spot efficiency usually between 20 and 95%. Filter media of medium-efficiency filters are usually made of glass fiber mat with a fiber diameter of 10 to 1 μm using nylon fibers to join them together. They are usually dry and disposable. In addition:

- As the dust spot efficiency increases, the diameter of glass fibers is reduced, and they are placed closer together.
- Extended surfaces, such as pleated mats or bags, are used to increase the surface area of the medium as shown in Figure 9.7.4(b). Air velocity through the medium is 6 to 90 fpm. Face velocity of the air filter is about 500 fpm to match the face velocity of the coil in AHUs and PUs.
- Initial pressure drop varies from 0.20 to 0.60 in. WG and final pressure drop from 0.50 to 1.20 in. WG.

High-Efficiency Particulate Air (HEPA) Filters and Ultra-Low-Penetration Air (ULPA) Filters

HEPA filters have a DOP test efficiency of 99.97% for dust particles ≥0.3 μm in diameter. *ULPA filters* have a DOP test efficiency of 99.999% for dust particles ≥0.12 μm in diameter.

A typical HEPA filter, shown in Figure 9.7.4(d), has dimensions of 24 × 24 × 11.5 in. Its filter media are made of glass fibers of submicrometer diameter in the form of pleated paper mats. The medium is dry and disposable. The surface area of the HEPA filter may be 50 times its face area, and its rated face velocity varies from 190 to 390 fpm, normally at a pressure drop of 0.50 to 1.35 in. WG for clean filters. The final pressure drop is 0.8 to 2 in. WG. Sealing of the filter pack within its frame and sealing between the frame and the gaskets are critical factors that affect the penetration and efficiency of the HEPA filter.

An ULPA filter is similar to a HEPA filter in construction and filter media. Both its sealing and filter media are more efficient than those of a HEPA filter.

To extend the service life of HEPA filters and ULPA filters, both should be protected by a medium-efficiency filter, or a low-efficiency and a medium-efficiency filter in the sequence low–medium just before the HEPA or ULPA filters. HEPA and ULPA filters are widely used in clean rooms and clean spaces.

Activated Carbon Filters

These filters are widely used to remove objectional odors and irritating gaseous airborne particulates, typically 0.003 to 0.006 μm in size, from the air stream by adsorption. *Adsorption* is physical condensation of gas or vapor on the surface of an activated substance like activated carbon. Activated substances are extremely porous. One pound of activated carbon contains 5,000,000 ft^2 of internal surface.

Activated carbon in the form of granules or pellets is made of coal, coconut shells, or petroleum residues and is placed in trays to form activated carbon beds as shown in Figure 9.7.4(d). A typical carbon tray is 23 × 23 × 5/8 in. thick. Low-efficiency prefilters are used for protection. When air flows through the carbon beds at a face velocity of 375 to 500 fpm, the corresponding pressure drop is 0.2 to 0.3 in. WG.

Humidifiers

A *humidifier* adds moisture to the air. Air is humidified by: (1) heating the liquid to evaporate it; (2) atomizing the liquid water into minute droplets by mechanical means, compressed air, or ultrasonic vibration to create a larger area for evaporation; (3) forcing air to flow through a wetted element in

which water evaporates; and (4) injecting steam into air directly before it is supplied to the conditioned space.

For comfort air-conditioning systems, a steam humidifier with a separator as shown in Figure 9.7.5(a) is widely used. Steam is supplied to a jacketed distribution manifold. It enters a separating chamber with its condensate. Steam then flows through a control valve, throttles to a pressure slightly above atmospheric, and enters a dry chamber. Due to the high temperature in the surrounding separating chamber, the steam is superheated. Dry steam is then discharged into the ambient air stream through the orifices on the inner steam discharge tubes.

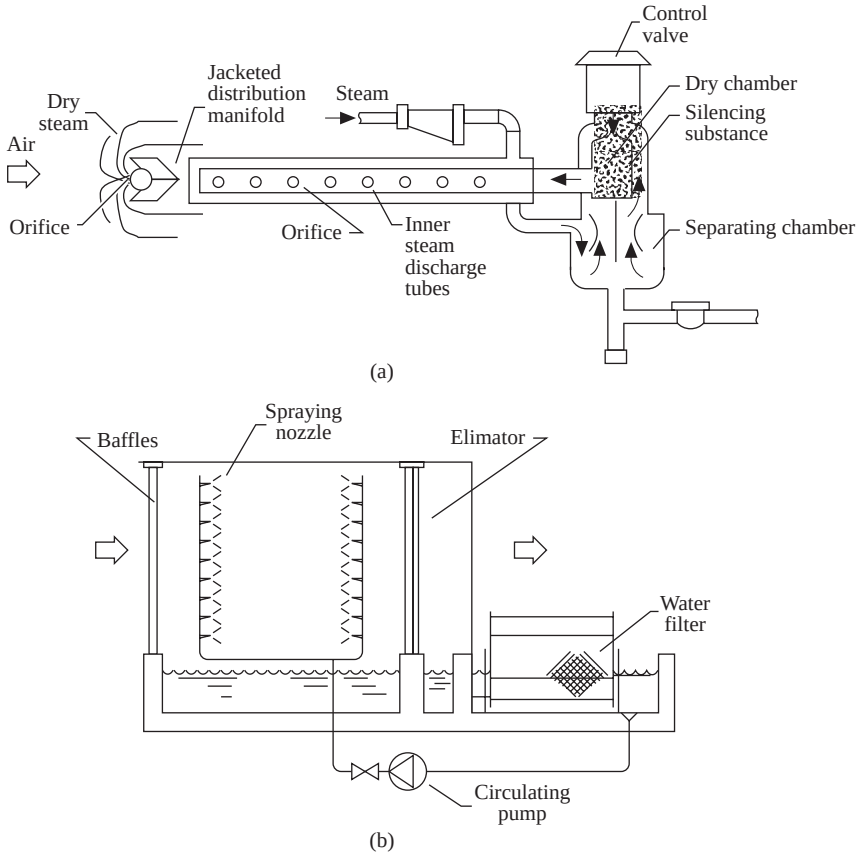

FIGURE 9.7.5 Steam grid humidifier (a) and air washer (b).

For an air system of cold air supply with humidity control during winter mode operation, an air washer is economical for large-capacity humidification in many industrial applications.

An air washer is a humidifier, a cooler, a dehumidifier, and an air cleaner. An air washer usually has an outer casing, two banks of spraying nozzles, one bank of guide baffles at the entrance, one bank of eliminators at the exit, a water tank, a circulating pump, a water filter, and other accessories as shown in Figure 9.7.5(b). Outer casing, baffles, and eliminators are often made of plastics or sometimes stainless steel. Spraying nozzles are usually made of brass or nylon, with an orifice diameter of 1/16 to 3/16 in., a smaller orifice for humidification, and a larger orifice for cooling and dehumidification. An eccentric inlet connected to the discharge chamber of the spraying nozzle gives centrifugal force to the water stream and atomizes the spraying water. Water is supplied to the spraying nozzle at a pressure of 15 to 30 psig. The distance between two spraying banks is 3 to 4.5 ft, and the total length of the air water from 4 to 7 ft. The air velocity inside an air washer is usually 500 to 800 fpm.

Selection of AHUs and PUs

- The size of an AHU is usually selected so that the face velocity of its coil is 600 fpm or less in order to prevent entrained condensate droplets. The cooling and heating capacities of an AHU can be varied by using coils of different numbers of rows and fin densities. The size of a PU is determined by its cooling capacity. Normally, the volume flow rate per ton of cooling capacity in PUs is 350 to 400 cfm. In most packaged units whose supply fans have belt drives, the fan speed can be selected so that the volume flow rate is varied and external pressure is met.
- ASHRAE/IES Standard 90.1-1989 specifies that the selected equipment capacity may exceed the design load only when it is the smallest size needed to meet the load. Selected equipment in a size larger always means a waste of energy and investment.
- To improve the indoor air quality, save energy, and prevent smudging and discoloring building interiors, a medium-efficiency filter of dust spot efficiency ≥50% and an air economizer are preferable for large AHUs and PUs.

9.8 Refrigeration Components and Evaporative Coolers

Refrigeration Compressors

A refrigeration compressor is the heart of a vapor compression system. It raises the pressure of refrigerant so that it can be condensed into liquid, throttled, and evaporated into vapor to produce the refrigeration effect. It also provides the motive force to circulate the refrigerant through condenser, expansion valve, and evaporator.

According to the compression process, refrigeration compressors can be divided into *positive displacement* and *nonpositive displacement* compressors. A positive displacement compressor increases the pressure of the refrigerant by reducing the internal volume of the compression chamber. Reciprocating, scroll, rotary, and screw compressors are all positive displacement compressors. The centrifugal compressor is the only type of nonpositive displacement refrigeration compressor widely used in refrigeration systems today.

Based on the sealing of the refrigerant, refrigeration compressors can be classified as

- *Hermetic compressors*, in which the motor and the compressor are sealed or welded in the same housing to minimize leakage of refrigerant and to cool the motor windings by using suction vapor
- *Semihermetic compressors*, in which motor and compressor are enclosed in the same housing but are accessible from the cylinder head for repair and maintenance
- *Open compressors*, in which compressor and motor are enclosed in two separate housings

Refrigeration compressors are often driven by motor directly or by gear train.

Performance Indices

Volumetric efficiency η_v of a refrigeration compressor is defined as

$$\eta_v = \mathring{V}_{a.v} \Big/ \mathring{V}_p \tag{9.8.1}$$

where $\mathring{V}_{a.v}$ = actual induced volume of the suction vapor at suction pressure, cfm
$\mathring{V}_p$ = calculated displacement of the compressor, cfm

Isentropic efficiency η_{isen}, *compression efficiency* η_{cp}, compressor efficiency η_{com}, and *mechanical efficiency* η_{mec} are defined as

$$\begin{aligned} \eta_{isen} &= (h_2 - h_1) \Big/ (h_2' - h_1) = \eta_{cp}\eta_{mec} = \eta_{com} \\ \eta_{cp} &= W_{sen} / W_v \\ \eta_{mec} &= W_v / W_{com} \end{aligned} \tag{9.8.2}$$

where h_1, h_2, h_2' = enthalpy of the suction vapor, ideal discharged hot gas, and actual discharged hot gas, respectively, Btu/lb
W_{isen}, W_v, W_{com} = isentropic work = $(h_2 - h_1)$, work delivered to the vapor refrigerant, and work delivered to the compressor shaft, Btu/lb

The actual power input to the compressor P_{com}, in hp, can be calculated as

$$\begin{aligned} P_{com} &= \mathring{m}_r (h_2 - h_1) \Big/ (42.41\eta_{isen}\eta_{mo}) \\ \mathring{m}_r &= \mathring{V}_p \eta_v \rho_{suc} \\ \eta_{mo} &= P_{com} / P_{mo} \end{aligned} \tag{9.8.3}$$

where $\dot{m}_r$ = mass flow rate of refrigerant, lb/min
ρ_{suc} = density of suction vapor, lb/ft^3
P_{mo} = power input to the compressor motor, hp

Power consumption, kW/ton refrigeration, is an energy index used in the HVAC&R industry in addition to EER and COP.

Currently used refrigeration compressors are reciprocating, scroll, screw, rotary, and centrifugal compressors.

Reciprocating Compressors

In a reciprocating compressor, as shown in Figure 9.8.1(a), a crankshaft connected to the motor shaft drives 2, 3, 4, or 6 single-acting pistons moving reciprocally in the cylinders via a connecting rod.

The refrigeration capacity of a reciprocating compressor is a fraction of a ton to about 200 tons. Refrigerants R-22 and R-134a are widely used in comfort and processing systems and sometimes R-717 in industrial applications. The maximum compression ratio R_{com} for a single-stage reciprocating compressor is about 7. Volumetric efficiency η_v drops from 0.92 to 0.65 when R_{com} is raised from 1 to 6. Capacity control of reciprocating compressor including: on-off and cylinder unloader in which discharge gas is in short cut and return to the suction chamber.

Although reciprocating compressors are still widely used today in small and medium-sized refrigeration systems, they have little room for significant improvement and will be gradually replaced by scroll and screw compressors.

Scroll Compressors

A scroll compressor consists of two identical spiral scrolls assembled opposite to each other, as shown in Figure 9.8.1(b). One of the scrolls is fixed, and the other moves in an orbit around the motor shaft whose amplitude equals the radius of the orbit. The two scrolls are in contact at several points and therefore form a series of pockets.

Vapor refrigerant enters the space between two scrolls through lateral openings. The lateral openings are then sealed and the formation of the two trapped vapor pockets indicates the end of the suction process. The vapor is compressed and the discharge process begins when the trapped gaseous pockets open to the discharge port. Compressed hot gas is then discharged through this opening to the discharge line. In a scroll compressor, the scrolls touch each other with sufficient force to form a seal but not enough to cause wear.

The upper limit of the refrigeration capacity of currently manufactured scroll compressors is 60 tons. A scroll compressor has $\eta_v > 95\%$ at $R_{com} = 4$ and $\eta_{isen} = 80\%$. A scroll compressor also has only about half as many parts as a reciprocating compressor at the same refrigeration capacity. Few components result in higher reliability and efficiency. Power input to the scroll compressor is about 5 to 10% less than to the reciprocating compressor. A scroll compressor also operates more smoothly and is quieter.

Rotary Compressors

Small rotary compressors for room air conditioners and refrigerators have a capacity up to 4 tons. There are two types of rotary compressors: rolling piston and rotating vane. A typical rolling piston rotary compressor is shown in Figure 9.8.1(c). A rolling piston mounted on an eccentric shaft is kept in contact with a fixed vane that slides in a slot. Vapor refrigerant enters the compression chamber and is compressed by the eccentric motion of the roller. When the rolling piston contacts the top housing, hot gas is squeezed out from the discharge valve.

Screw Compressors

These are also called *helical rotary compressors*. Screw compressors can be classified into single-screw compressors, in which there is a single helical rotor and two star wheels, and twin-screw compressors. Twin-screw compressors are widely used.

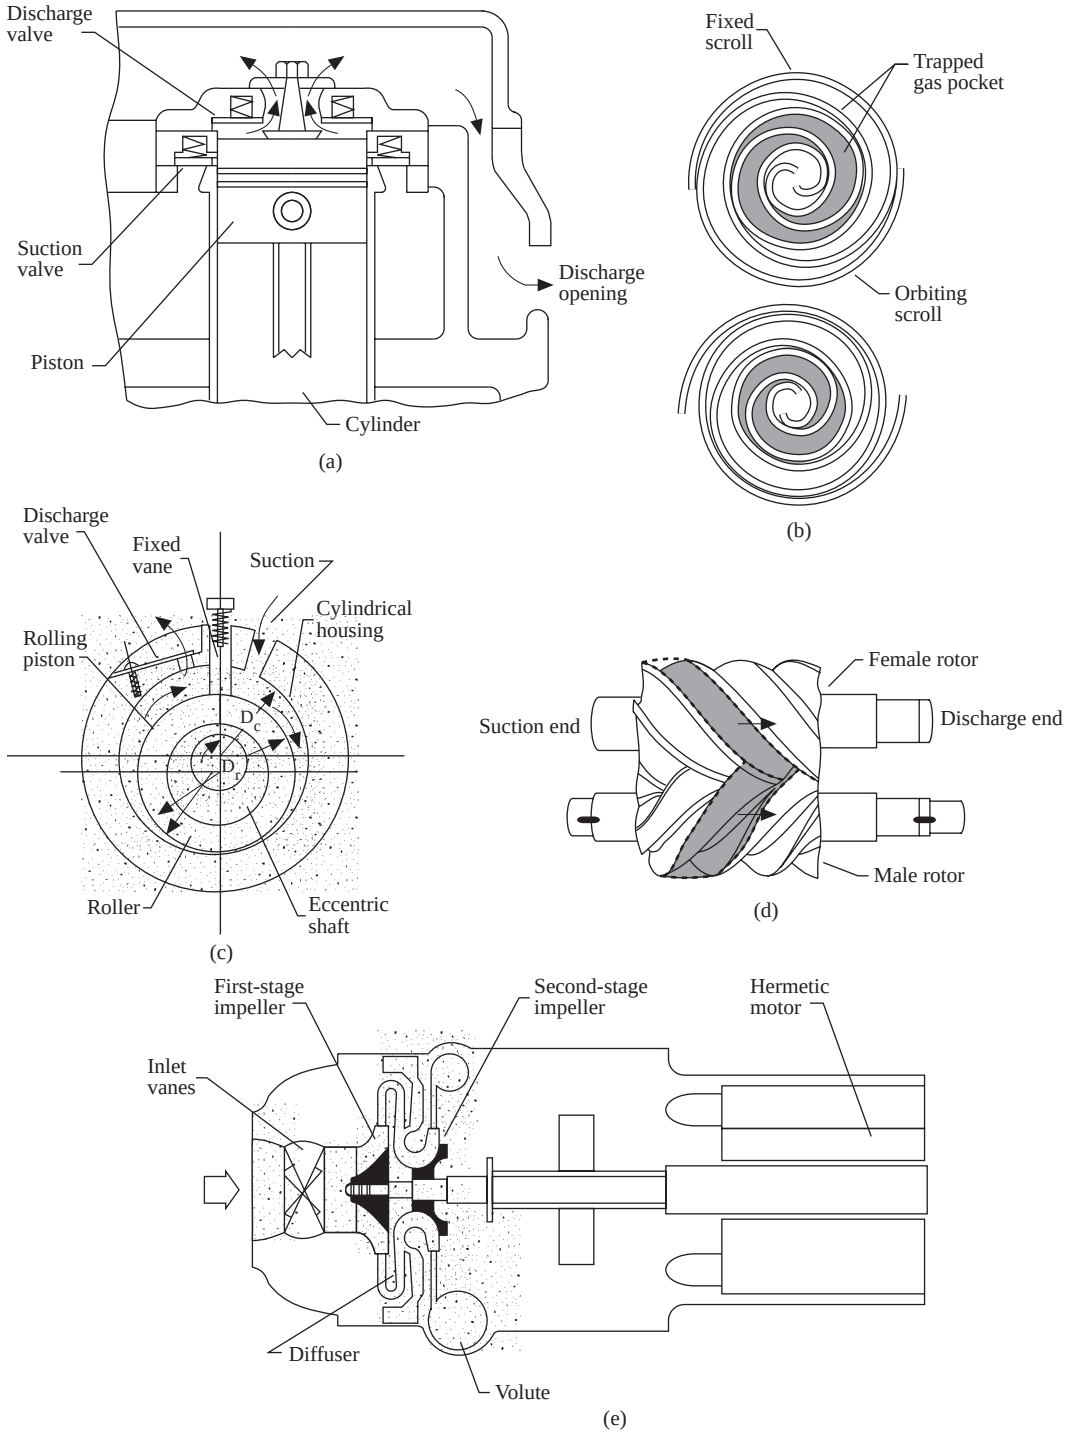

FIGURE 9.8.1 Various types of refrigeration compressors: (a) reciprocating, (b) scroll, (c) rotary, (d) twin-screw, and (e) centrifugal.

A typical twin-screw compressor, as shown in Figure 9.8.1(d) consists of a four-lobe male rotor and a six-lobe female rotor, a housing with suction and discharge ports, and a sliding valve to adjust the

capacity during part load. Normally, the male rotor is the driver. Twin-screw compressors are often direct driven and of hermetic type.

Vapor refrigerant is extracted into the interlobe space when the lobes are separated at the suction port. During the successive rotations of the rotor, the volume of the trapped vapor is compressed. When the interlobe space is in contact with the discharge port, the compressed hot gas discharges through the outlet. Oil injection effectively cools the rotors and results in a lower discharge temperature. Oil also provides a sealing effect and lubrication. A small clearance of 0.0005 in. as well as the oil sealing minimizes leakage of the refrigerant.

The refrigeration capacity of twin-screw compressors is 50 to 1500 tons. The compression ratio of a twin-screw compressor can be up to 20:1. R-22 and R-134a are the most widely used refrigerants in comfort systems. In a typical twin-screw compressor, η_v decreases from 0.92 to 0.87 and η_{isen} drops from 0.82 to 0.67 when R_{com} increases from 2 to 10. Continuous and stepless capacity control is provided by moving a sliding valve toward the discharge port, which opens a shortcut recirculating passage to the suction port.

Twin-screw compressors are more efficient than reciprocating compressors. The low noise and vibration of the twin-screw compressor together with its positive displacement compression results in more applications today.

Centrifugal Compressors

A *centrifugal compressor* is a turbomachine and is similar to a centrifugal fan. A hermetic centrifugal compressor has an outer casing with one, two, or even three impellers internally connected in series and is driven by a motor directly or by a gear train. At the entrance to the first-stage impeller are inlet guide vanes positioned at a specific opening to adjust refrigerant flow and therefore the capacity of the centrifugal compressor.

Figure 9.8.1(e) shows a two-stage hermetic centrifugal compressor. The total pressure rise in a centrifugal compressor, often called head lift, in psi, is due to the conversion of the velocity pressure into static pressure. Although the compression ratio R_{com} of a single-stage centrifugal compressor using R-123 and R-22 seldom exceeds 4, two or three impellers connected in series satisfy most of the requirements in comfort systems.

Because of the high head lift to raise the evaporating pressure to condensing pressure, the discharge velocity at the exit of the second-stage impeller approaches the acoustic velocity of saturated vapor v_{ac} of R-123, 420 ft/sec at atmospheric pressure and a temperature of 80°F. Centrifugal compressors need high peripheral velocity and rotating speeds (up to 50,000 rpm) to produce such a discharge velocity. It is not economical to manufacture small centrifugal compressors. The available refrigeration capacity for centrifugal compressors ranges from 100 to 10,000 tons. Centrifugal compressors have higher volume flow per unit refrigeration capacity output than positive displacement compressors. Centrifugal compressors are efficient and reliable. Their volumetric efficiency almost equals 1. At design conditions, their η_{isen} may reach 0.83, and it drops to 0.6 during part-load operation. They are the most widely used refrigeration compressors in large air-conditioning systems.

Refrigeration Condensers

A *refrigeration condenser* or simply a *condenser* is a heat exchanger in which hot gaseous refrigerant is condensed into liquid and the latent heat of condensation is rejected to the atmospheric air, surface water, or well water. In a condenser, hot gas is first desuperheated, then condensed into liquid, and finally subcooled.

The capacity of a condenser is rated by its *total heat rejection* Q_{rej}, in Btu/hr, which is defined as the total heat removed from the condenser during desuperheating, condensation, and subcooling. For a refrigeration system using a hermetic compressor, Q_{rej} can be calculated as

$$Q_{rej} = U_{con} A_{con} \Delta T_m = 60 \dot{m}_r \left(h_2 - h_3'\right) = q_{rl} + \left(2545 P_{com}\right) / \eta_{mo} \tag{9.8.4}$$

where U_{con} = overall heat transfer coefficient across the tube wall in the condenser, Btu/hr.ft^2.°F
A_{con} = condensing area in the condenser, ft^2
ΔT_m = logarithmic temperature difference, °F
$\dot{m}_r$ = mass flow rate of refrigerant, lb/min
h_2, h_3' = enthalpy of suction vapor refrigerant and hot gas, Btu/lb
q_{rl} = refrigeration load at the evaporator, Btu/hr

A factor that relates Q_{rej} and q_{rl} is the *heat rejection factor* F_{rej}, which is defined as the ratio of total heat rejection to the refrigeration load, or

$$F_{rej} = Q_{rej} / q_{rl} = 1 + \left(2545 P_{com}\right) / \left(q_{rl} \eta_{mo}\right) \tag{9.8.5}$$

Fouling factor R_f, in hr.ft^2.°F/Btu, is defined as the additional resistance caused by a dirty film of scale, rust, or other deposits on the surface of the tube. ARI Standard 550-88 specifies the following for evaporators and condensers:

Field fouling allowance	0.00025 hr.ft^2.°F/Btu
New evaporators and condensers	0

According to the cooling process used during condensation, refrigeration condensers can be classified as air-cooled, water-cooled, and evaporative-cooled condensers.

Air-Cooled Condensers

In an *air-cooled condenser*, air is used to absorb the latent heat of condensation released during desuperheating, condensation, and subcooling.

An air-cooled condenser consists of a condenser coil, a subcooling coil, condenser fans, dampers, and controls as shown in Figure 9.8.2(a). There are refrigeration circuits in the condensing coil. Condensing coils are usually made of copper tubes and aluminum fins. The diameter of the tubes is 1/4 to 3/4 in., typically 3/8 in., and the fin density is 8 to 20 fins/in. On the inner surface of the copper tubes, microfins, typically 60 fins/in. with a height of 0.008 in., are used. A condensing coil usually has only two to three rows due to the low pressure drop of the propeller-type condenser fans. A subcooling coil is located at a lower level and is connected to the condensing coil.

Hot gas from the compressor enters the condensing coil from the top. When the condensate increases, part of the condensing area can be used as a subcooling area. A receiver is necessary only when the liquid refrigerant cannot all be stored in the condensing and subcooling coils during the shut-down period in winter.

Cooling air is drawn through the coils by a condenser fan(s) for even distribution. Condenser fans are often propeller fans for their low pressure and large volume flow rate. A damper(s) may be installed to adjust the volume flow of cooling air.

In air-cooled condensers, the volume flow of cooling air per unit of total heat rejection $\dot{V}_{ca} / Q_{u.rej}$ is 600 to 1200 cfm/ton of refrigeration capacity at the evaporator, and the optimum value is about 900 cfm/ton. The corresponding cooling air temperature difference — cooling air leaving temperature minus outdoor temperature ($T_{ca.l} - T_o$) — is around 13°F.

The condenser temperature difference (CTD) for an air-cooled condenser is defined as the difference between the saturated condensing temperature corresponding to the pressure at the inlet and the air intake temperature, or ($T_{con.i} - T_o$). Air-cooled condensers are rated at a specific CTD, depending on the evaporating temperature of the refrigeration system T_{ev} in which the air-cooled condenser is installed. For a refrigeration system having a lower T_{ev}, it is more economical to equip a larger condenser with a smaller CTD. For a comfort air-conditioning system having a T_{ev} of 45°F, CTD = 20 to 30°F.

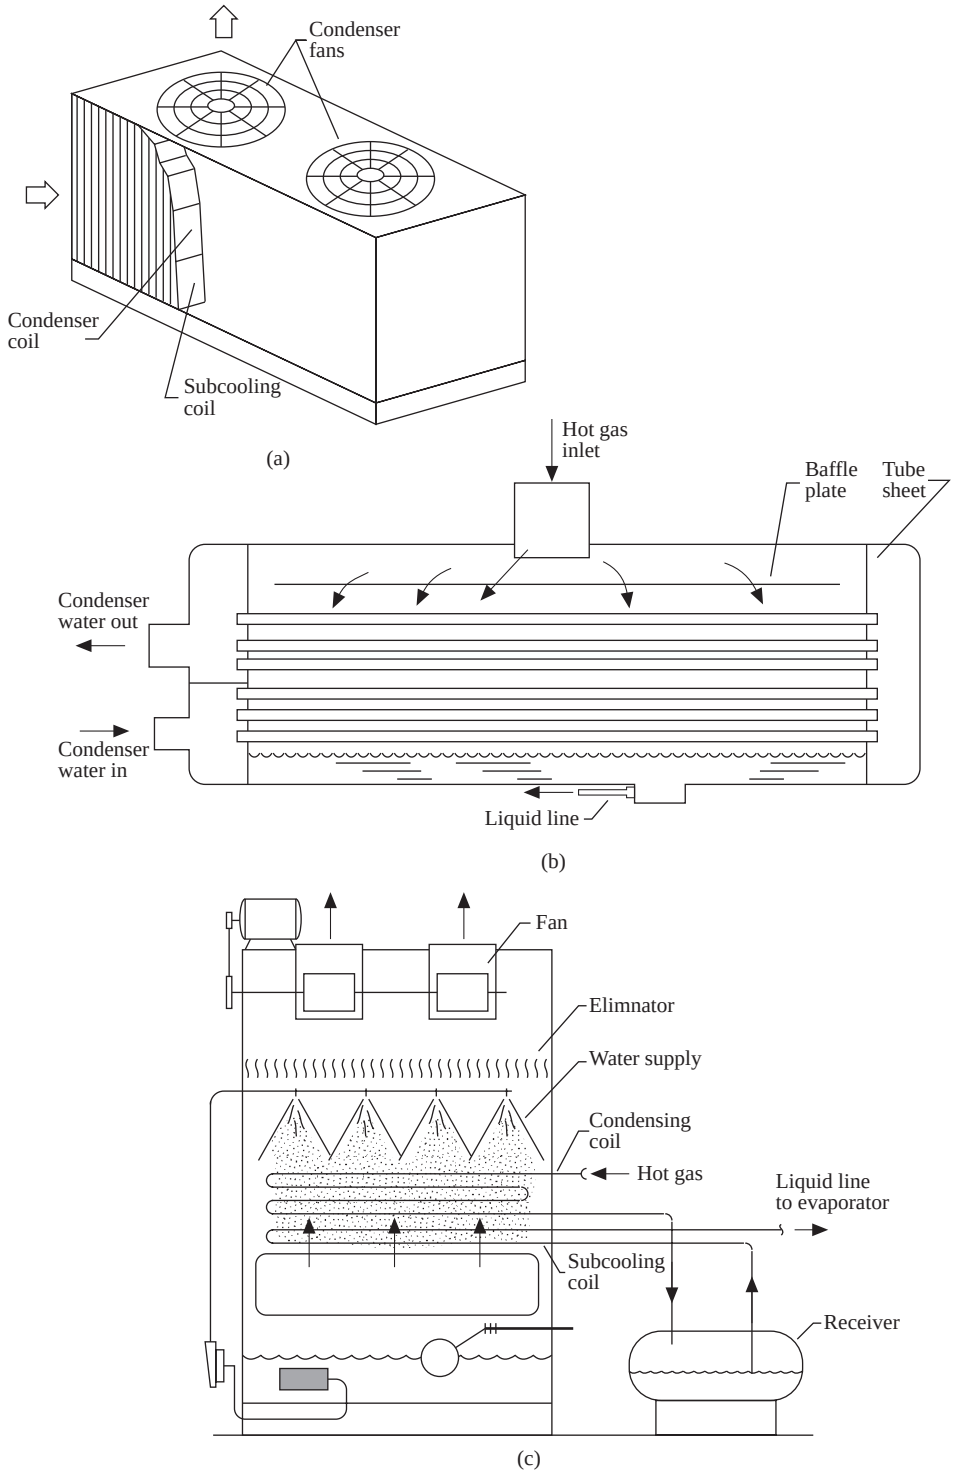

FIGURE 9.8.2 Various types of refrigeration condensers: (a) air-cooled, (b) shell-and-tube water-cooled, and (c) evaporative cooled.

A higher condensing temperature T_{con}, a higher condensing pressure p_{con}, and a higher compressor power input may be due to an undersized air-cooled condenser, lack of cooling air or low $\mathring{V}_{ca}/Q_{u.rej}$ value, a high entering cooling air temperature at the roof, a dirty condensing coil, warm air circulation because of insufficient clearance between the condenser and the wall, or a combination of these. The clearance should not be less than the width of the condensing coil.

If p_{con} drops below a certain value because of a lower outdoor temperature, the expansion valve in a reciprocating vapor compression system may not operate properly. At a low ambient temperature T_o, the following controls are often used:

- Duty cycling, turning the condenser fans on and off until all of them are shut down, to reduce cooling air volume flow
- Modulating the air dampers to reduce the volume flow
- Reducing the fan speed

Some manufacturers' catalogs start low ambient control at T_o = 65°F and some specify a minimum operating temperature at T_o = 0°F.

Water-Cooled Condensers

In a *water-cooled condenser*, latent heat of condensation released from the refrigerant during condensation is extracted by water. This cooling water, often called condenser water, is taken directly from river, lake, sea, underground well water or a cooling tower.

Two types of water-cooled condensers are widely used for air-conditioning and refrigeration: double-tube condensers and horizontal shell-and-tube condensers.

A *double-tube condenser* consists of two tubes, one inside the other. Condenser water is pumped through the inner tube and refrigerant flows within the space between the inner and outer tubes in a counterflow arrangement. Because of its limited condensing area, the double-tube condenser is used only in small refrigeration systems.

A horizontal *shell-and-tube water-cooled condenser* using halocarbon refrigerant usually has an outer shell in which copper tubes typically 5/8 to 3/4 in. in diameter are fixed in position by tube sheets as shown in Figure 9.8.2(b). Integral external fins of 19 to 35 fins/in. and a height of 0.006 in. and spiral internal grooves are used for copper tubes to increase both the external and the inner surface area and their heat transfer coefficients.

Hot gas from the compressor enters the top inlet and is distributed along the baffle to fill the shell. Hot gas is then desuperheated, condensed, subcooled into liquid, and discharged into the liquid line at the bottom outlet. Usually one sixth of the volume is filled with subcooled liquid refrigerant. Subcooling depends on the entering temperature of condenser water T_{ce}, in °F, and usually varies between 2 and 8°F.

Condenser water enters the condenser from the bottom for effective subcooling. After extracting heat from the gaseous refrigerant, condenser water is discharged at a higher level. Two-pass or three-pass water flow arrangements are usually used in shell-and-tube water-cooled condensers. The two-pass arrangement means that water flows from one end to the opposite end and returns to the original end. Two-pass is the standard setup. In a shell-and-tube water-cooled condenser, the condensing temperature T_{con} depends mainly on the entering temperature of condenser water T_{ce}, the condenser area, the fouling factor, and the configuration of the copper tube.

Evaporative Condenser

An *evaporative condenser* uses the evaporation of water spray on the outer surface of the condensing tubes to remove the latent heat of condensation of refrigerant during condensation.

An evaporative condenser consists of a condensing coil, a subcooling coil, a water spray, an induced draft or sometimes forced draft fan, a circulating water pump, a water eliminator, a water basin, an outer casing, and controls as shown in Figure 9.8.2(c). The condensing coil is usually made of bare copper, steel, or sometimes stainless steel tubing.

Water is sprayed over the outside surface of the tubing. The evaporation of a fraction of condenser water from the saturated air film removes the sensible and latent heat rejected by the refrigerant. The wetted outer surface heat transfer coefficient h_{wet} is about four or five times greater than the dry surface heat transfer coefficient h_o, in Btu/hr.ft^2.°F. The rest of the spray falls and is collected by the basin. Air enters from the inlet just above the basin. It flows through the condensing coil at a face velocity of 400 to 700 fpm, the water spray bank, and the eliminator. After air absorbs the evaporated water vapor, it is extracted by the fan and discharged at the top outlet. The water circulation rate is about 1.6 to 2 gpm/ton, which is far less than that of the cooling tower.

An evaporative condenser is actually a combination of a water-cooled condenser and a cooling tower. It is usually located on the rooftop and should be as near the compressor as possible. Clean tube surface and good maintenance are critical factors for evaporative condensers. An evaporative condenser also needs low ambient control similar as in an air-cooled condenser.

Comparison of Air-Cooled, Water-Cooled, and Evaporative Condensers

An air-cooled condenser has the highest condensing temperature T_{con} and therefore the highest compressor power input. For an outdoor dry bulb temperature of 90°F and a wet bulb temperature of 78°F, a typical air-cooled condenser has T_{con} = 110°F. An evaporative condenser has the lowest T_{con} and is most energy efficient. At the same outdoor dry and wet bulb temperatures, its T_{con} may be equal to 95°F, even lower than that of a water-cooled condenser incorporating with a cooling tower, whose T_{con} may be equal to 100°F. An evaporative condenser also consumes less water and pump power. The drawback of evaporative condensers is that the rejected heat from the interior zone is difficult to recover and use as winter heating for perimeter zones and more maintenance is required.

Evaporators and Refrigerant Flow Control Devices

An *evaporator* is a heat exchanger in which the liquid refrigerant is vaporized and extracts heat from the surrounding air, chilled water, brine, or other substance to produce a refrigeration effect.

Evaporators used in air-conditioning can be classified according to the combination of the medium to be cooled and the type of refrigerant feed, as the following.

Direct expansion DX coils are air coolers, and the refrigerant is fed according to its degree of superheat after vaporization. DX coils were covered earlier.

Direct expansion ice makers or *liquid overfeed ice makers* are such that liquid refrigerant is forced through the copper tubes or the hollow inner part of a plate heat exchanger and vaporized. The refrigeration effect freezes the water in the glycol-water that flows over the outside surface of the tubes or the plate heat exchanger. In direct expansion ice makers, liquid refrigerant completely vaporizes inside the copper tubes, and the superheated vapor is extracted by the compressor. In liquid overfeed ice makers, liquid refrigerant floods and wets the inner surface of the copper tubes or the hollow plate heat exchanger. Only part of the liquid refrigerant is vaporized. The rest is returned to a receiver and pumped to the copper tubes or plate heat exchanger again at a circulation rate two to several times greater than the evaporation rate.

Flooded shell-and-tube liquid coolers, or simply *flooded liquid coolers*, are such that refrigerant floods and wets all the boiling surfaces and results in high heat transfer coefficients. A flooded shell-and-tube liquid cooler is similar in construction to a shell-and-tube water-cooled condenser, except that its liquid refrigeration inlet is at the bottom and the vapor outlet is at the top. Water velocity inside the copper tubes is usually between 4 and 12 ft/sec and the water-side pressure normally drops below 10 psi. Flooded liquid coolers can provide larger evaporating surface area and need minimal space. They are widely used in large central air-conditioning systems.

Currently used refrigerant flow control devices include thermostatic expansion valves, float valves, multiple orifices, and capillary tubes.

A *thermostatic expansion valve* throttles the refrigerant pressure from condensing to evaporating pressure and at the same time regulates the rate of refrigerant feed according to the degree of superheat

of the vapor at the evaporator's exit. A thermostatic expansion valve is usually installed just prior to the refrigerant distributor in DX coils and direct-expansion ice makers.

A thermostatic expansion valve consists of a valve body, a valve pin, a spring, a diaphragm, and a sensing bulb near the outlet of the DX coil, as shown in Figure 9.7.3(a). The sensing bulb is connected to the upper part of the diaphragm by a connecting tube.

When the liquid refrigerant passes through the opening of the thermostatic expansion valve, its pressure is reduced to the evaporating pressure. Liquid and a small fraction of vaporized refrigerant then flow through the distributor and enter various refrigerant circuits. If the refrigeration load of the DX coil increases, more liquid refrigerant evaporizes. This increases the degree of superheat of the leaving vapor at the outlet and the temperature of the sensing bulb. A higher bulb temperature exerts a higher saturated pressure on the top of the diaphragm. The valve pin then moves downward and widens the opening. More liquid refrigerant is allowed to enter the DX coil to match the increase of refrigeration load. If the refrigeration load drops, the degree of superheat at the outlet and the temperature of the sensing bulb both drop, and the valve opening is narrower. The refrigeration feed decreases accordingly. The degree of superheat is usually 10 to 20°F. Its value can also be adjusted manually by varying the spring tension.

A *float valve* is a valve in which a float is used to regulate the valve opening to maintain a specific liquid refrigerant level. A lower liquid level causes a lower valve pin and therefore a wider opening and vice versa.

In a centrifugal refrigeration system, two or more orifice plates, *multiple orifices*, are sometimes installed in the liquid line between the condenser and the flash cooler and between the flash cooler and the flooded liquid cooler to throttle their pressure as well as to regulate the refrigerant feed.

A *capillary tube*, sometimes called a *restrictor tube*, is a fixed length of small-diameter tubing installed between the condenser and the evaporator to throttle the refrigerant pressure from p_{con} to p_{ev} and to meter the refrigerant flow to the evaporator. Capillary tubes are usually made of copper. The inside diameter D_{cap} is 0.05 to 0.06 in. and the length L_{cap} from an inch to several feet. There is a trend to use short capillary tubes of L_{cap}/D_{cap} between 3 and 20. Capillary tubes are especially suitable for a heat pump system in which the refrigerant flow may be reversed.

Evaporative Coolers

An evaporative cooling system is an air-conditioning system in which air is cooled evaporatively. It consists of evaporative coolers, fan(s), filters, dampers, controls, and others. A mixing box is optional. An evaporative cooler could be a stand-alone cooler or installed in an air system as a component. There are three types of evaporative coolers: (1) direct evaporative coolers, (2) indirect evaporative coolers, and (3) indirect–direct evaporative coolers.

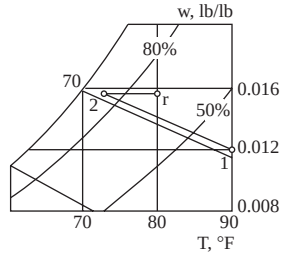
Direct Evaporative Cooler

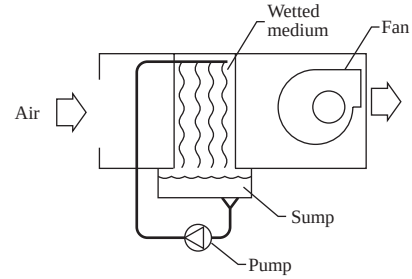
In a *direct evaporative cooler*, the air stream to be cooled directly contacts the water spray or wetted medium as shown in Figure 9.8.3(a). Evaporative pads made of wooden fibers with necessary treatment at a thickness of 2 in., rigid and corrugated plastics, impregnated cellulose, or fiber glass all dripping with water are wetted mediums.

The direct evaporation process 12 takes place along the thermodynamic wet bulb line on the psychrometric chart. Saturation effectiveness ε_{sat} is an index that assesses the performance of a direct evaporative cooler:

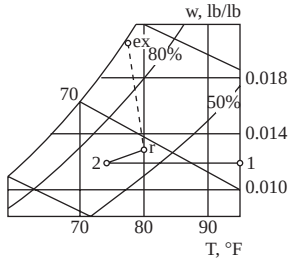
$$\varepsilon_{sat} = \left(T_{ae} - T_{al}\right) \Big/ \left(T_{ae} - T_{ae}^{*}\right) \tag{9.8.6}$$

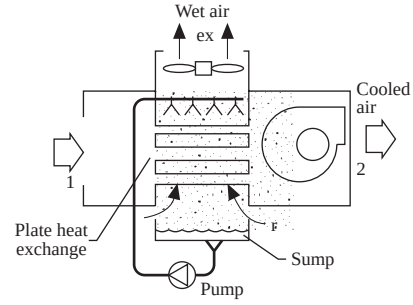
where T, T^* = temperature and thermodynamic wet bulb temperature of air stream, °F. Subscript ae indicates the entering air and al the leaving air. ε_{sat} usually varies between 0.75 and 0.95 at a water–air ratio of 0.1 to 0.4.



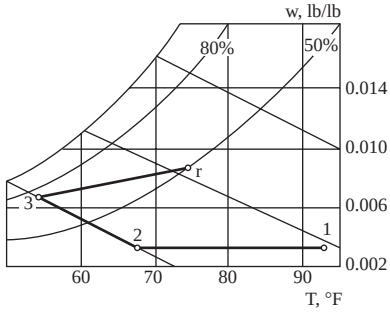


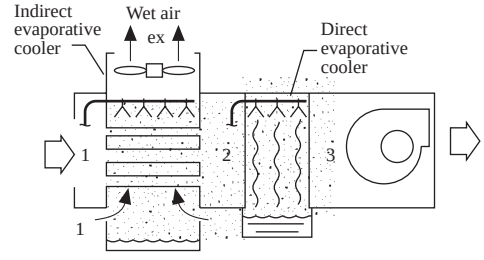
(a)





(b)





(c)

FIGURE 9.8.3 Types of evaporative coolers: (a) direct, (b) indirect, and (c) indirect–direct.

Indirect Evaporative Coolers

In an *indirect evaporative cooler*, the cooled-air stream to be cooled is separated from a wetted surface by a flat plate or tube wall as shown in Figure 9.8.3(b). A wet-air stream flows over the wetted surface so that liquid water is evaporated and extracts heat from the cooled-air stream through the flat plate or tube wall. The cooled-air stream is in contact with the wetted surface indirectly.

The core part of an indirect evaporative cooler is a plate heat exchanger. It is made of thin polyvinyl chloride plates 0.01 in. thick and spaced from 0.08 to 0.12 in. apart to form horizontal passages for cooled air and vertical passages for wet air and water. As in a direct evaporative cooler, there are also fan(s), water sprays, circulating pump, air intake, dampers, controls, etc.

An indirect evaporative cooling process is represented by a horizontal line on a psychrometric chart, which shows that humidity ratio remains constant. If the space air is extracted and used as the wet air intake, the wet air will be exhausted at point x at nearly saturated state.

The performance of an indirect evaporative cooler can be assessed by its performance factor e_{in}, which is calculated as:

$$e_{in} = \left(T_{ca.e} - T_{ca.l}\right) / \left(T_{ca.e} - T_{s.a}\right) \tag{9.8.7}$$

where $T_{ca.e}$, $T_{ca.l}$ = temperature of cooled air entering and leaving the indirect evaporative cooler, °F, and $T_{s.a}$ = temperature of the saturated air film on the wet air side and is about 3°F higher than the wet bulb temperature of the entering air, °F.

An indirect evaporative cooler could be so energy efficient as to provide evaporative cooling with an EER up to 50 instead of 9 to 12 for a reciprocating compression refrigeration system.

Direct–Indirect Evaporative Cooler. A direct–indirect evaporative cooler is a two-stage evaporating cooler, as shown in Figure 9.8.3(c), in which the first-stage indirect evaporative cooler is connected in series with a second-stage direct evaporative cooler for the purpose of increasing the evaporating effect.

Operating Characteristics. The saturation effectiveness ε_{sat} and performance factor e_{in} are both closely related to the air velocity flowing through the air passages. For a direct evaporative cooler, face velocity is usually less than 600 fpm to reduce drift carryover. For an indirect evaporative cooler, face velocity v_s is usually between 400 to 1000 fpm. A higher v_s results at a greater air-side pressure drop.

Scofield et al. (1984) reported the performance of an indirect–direct evaporative cooler in Denver, Colorado. Outdoor air enters the indirect cooler at a dry bulb of 93°F and a wet bulb of 67.5° and was evaporatively cooled to 67.5°F dry bulb and 49.8°F wet bulb with an e_{in} = 0.76 as shown in Figure 9.8.3(c). In the direct cooler, conditioned air was further cooled to a dry bulb of 53.5°F and the wet bulb remained at 49.8°F at a saturation effectiveness ε_{sat} = 0.8.

In locations where outdoor wet bulb $T_o' \leq 60$°F, a direct evaporative can often provide an indoor environment of 78°F and a relative humidity of 60%. In locations $T_o' \leq 68$°F, an indirect–direct evaporative cooler can maintain a comfortable indoor environment. In locations $T_o' \geq 72$°F, an evaporative cooler with a supplementary vapor compression refrigeration may be cost effective. Because the installation cost of an indirect–direct cooler is higher than that of refrigeration, cost analysis is required to select the right choice. Evaporative coolers are not suitable for dehumidification except in locations where $T_o' \leq 60$°F.

9.9 Water Systems

Types of Water Systems

In central and space conditioning air-conditioning systems, water that links the central plant and the air handling units or terminals, that extracts condensing heat, or that provides evaporative cooling may be classified as

- *Chilled water system*, in which chilled water is first cooled in the centrifugal, screw, and reciprocating chillers in a central plant. Chilled water is then used as a cooling medium to cool the air in the cooling coils in AHUs and terminals.
- *Evaporative-cooled water system*, used to cool air directly or indirectly in evaporative coolers.
- *Hot water system*, in which hot water is heated in the boiler and then used to heat the air through heating coils in AHUs, terminals, or space finned-tube heaters.
- *Dual-temperature water system*, in which chilled water and hot water are supplied to and returned from the coils in AHUs and terminals through separate or common main and branch pipes. Using common main and branch pipes requires a lengthy changeover from chilled water to hot water or vice versa for a period of several hours.
- *Condenser water system*, which is a kind of cooling water system used to extract the latent heat of condensation from the condensing refrigerant in a water-cooled condenser and heat of absorption from the absorber.

Water systems can also be classified according to their operating characteristics.

Closed System

In a closed system, water forms a closed loop for water conservation and energy saving when it flows through the coils, chillers, boilers, heaters, or other heat exchangers and water is not exposed to the atmosphere.

Open System

In an open system, water is exposed to the atmosphere.

Once-Through System

In a once-through system, water flows through a heat exchanger(s) only once without recirculation.

Basics

Volume Flow and Temperature Difference

The rate of heat transfer between water and air or water and refrigerant when water flows through a heat exchanger q_w, in Btu/hr, can be calculated as

$$q_w = 500\,\mathring{V}_{gal}\left(T_{wl} - T_{we}\right) = 500\,\mathring{V}_{gal}\,\Delta T_w \tag{9.9.1}$$

where $\mathring{V}_{gal}$ = volume flow rate of water, gpm
T_{wl}, T_{we} = temperature of water leaving and entering the heat exchanger, °F
ΔT_w = temperature rise or drop of water when it flows through a heat exchanger, °F

The temperature of chilled water leaving the water chiller T_{el} should not be lower than 38°F in order to prevent freezing in the evaporator. Otherwise, brine or glycol-water should be used. The T_{el} of chilled water entering the coil T_{we} and the temperature difference of chilled water leaving and entering the coil ΔT_w directly affect the temperature of air leaving the cooling coil T_{cc}. The lower T_{we}, the higher will be the compressor power input. The smaller ΔT_w, the greater will be the water volume flow rate, the pipe

size, and the pump power. For chilled water in conventional comfort systems, T_{we} is usually 40 to 45°F and ΔT_w 12 to 24°F. Only in cold air distribution, T_{we} may drop to 34°F. For a cooling capacity of 1 ton refrigeration, a ΔT_w of 12°F requires a $\mathring{V}_{gal}$ = 2 gpm.

For hot water heating systems in buildings, hot water often leaves the boiler and enters the heating coil or heaters at a temperature T_{we} of 190 to 200°F. It returns at 150 to 180°F. For dual-temperature systems, hot water is usually supplied at 100 to 150°F and returns at a ΔT_w of 20 to 40°F.

Pressure Drop

Usually the pressure drop of water in pipes due to friction for HVAC&R systems, H_f, is in the range 0.75 ft/100 ft length of pipe to 4 ft/100 ft. A pressure loss of 2.5 ft/100 ft is most often used. ASHRAE/IES Standard 90.1-1989 specifies that water piping systems should be designed at a pressure loss of no more than 4.0 ft/100 ft. Figure 9.9.1(a), (b), and (c) shows the friction charts for steel, copper, and plastic pipes for closed water systems.

Water Piping

The piping materials of various water systems for HVAC&R are as follows:

Chilled water	Black and galvanized steel
Hot water	Black steel, hard copper
Condenser water	Black steel, galvanized ductile iron, polyvinyl chloride (PVC)

The pipe thickness varies from Schedule 10, a light wall pipe, to Schedule 160, a very heavy wall pipe. Schedule 40 is the standard thickness for a pipe of up to 10 in. diameter. For copper tubing, type K is the heaviest, and type L is generally used as the standard for pressure copper tubes.

Steel pipes of small diameter are often joined by threaded cast-iron fittings. Steel pipes of diameter 2 in. and over, welded joints, and bolted flanges are often used.

In a water system, the maximum allowable working pressure for steel and copper pipes at 250°F varies from 125 to 400 psig, depending on the pipe wall thickness. Not only pipes, but also their joints and fittings should be considered.

During temperature changes, pipes expand and contract. Both operating and shut-down periods should be taken into consideration. Bends like U-, Z-, and L-bends, loops, and sometimes packed expansion joints, bellows, or flexible metal hose mechanical joints are used.

ASHRAE/IES Standard 90.1-1989 specifies that for chilled water between 40 to 55°F, the minimum thickness of the external pipe insulation varies from 0.5 to 1 in. depending on the pipe diameter. For chilled water temperature below 40°F, the minimum thickness varies from 1 to 1.5 in. For hot water temperatures not exceeding 200°F, the minimum thickness varies from 0.5 to 1.5 in. depending on the pipe diameter and the hot water temperature.

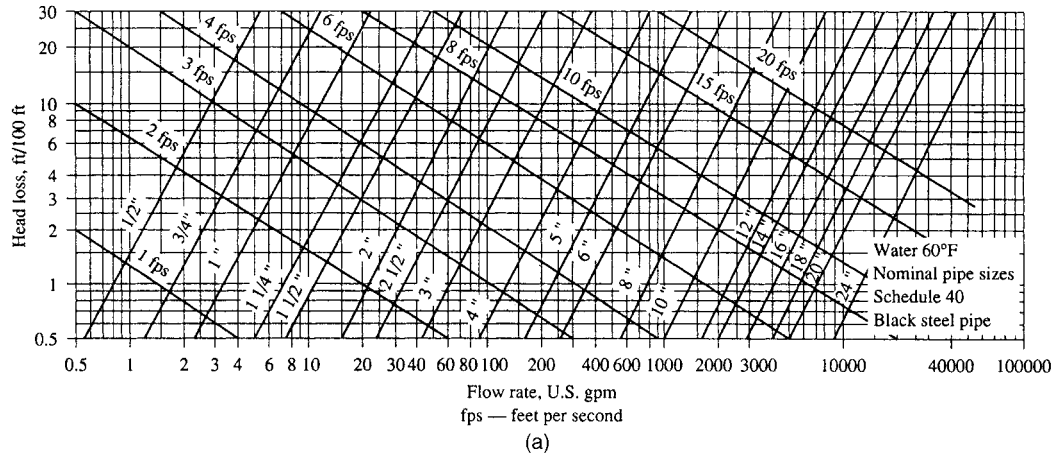
Corrosion, Impurities, and Water Treatments

Corrosion is a destructive process caused by a chemical or electrochemical reaction on metal or alloy. In water systems, dissolved *impurities* cause corrosion and scale and the growth of microbiologicals like algae, bacteria, and fungi. *Scale* is the deposit formed on a metal surface by precipitation of the insoluble constituents. In addition to the dissolved solids, unpurified water may contain suspended solids.

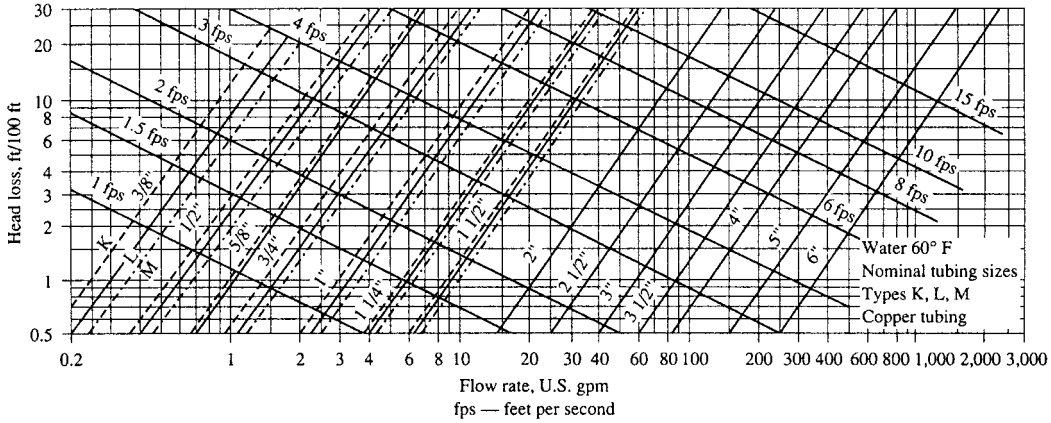
Currently used chemicals include crystal modifiers to change the crystal formation of scale and sequestering chemicals. Growth of bacteria, algae, and fungi is usually treated by biocides to prevent the formation of an insulating layer resulting in lower heat transfer as well as restricted water flow. Chlorine and its compounds are effective and widely used. Blow-down is an effective process in water treatment and should be considered as important as chemical treatments.

Piping Arrangements

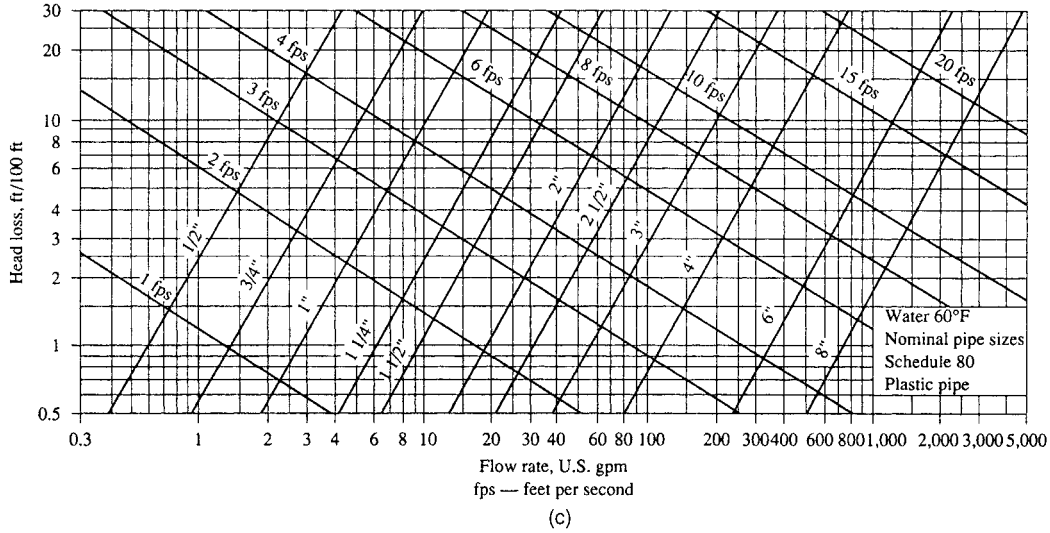
Main and Branch Pipes. In a piping circuit as shown in Figure 9.9.2(a), chilled water from a chiller or hot water from a boiler is often supplied to a *main pipe* and then distributed to *branch pipes* that



(a)



(b)



(c)

FIGURE 9.9.1 Friction chart for water in pipes: (a) steel pipe (schedule 40), (b) copper tubing, and (c) plastic pipe (schedule 80). (Souce: *ASHRAE Handbook 1993 Fundamentals*. Reprinted with permission.)

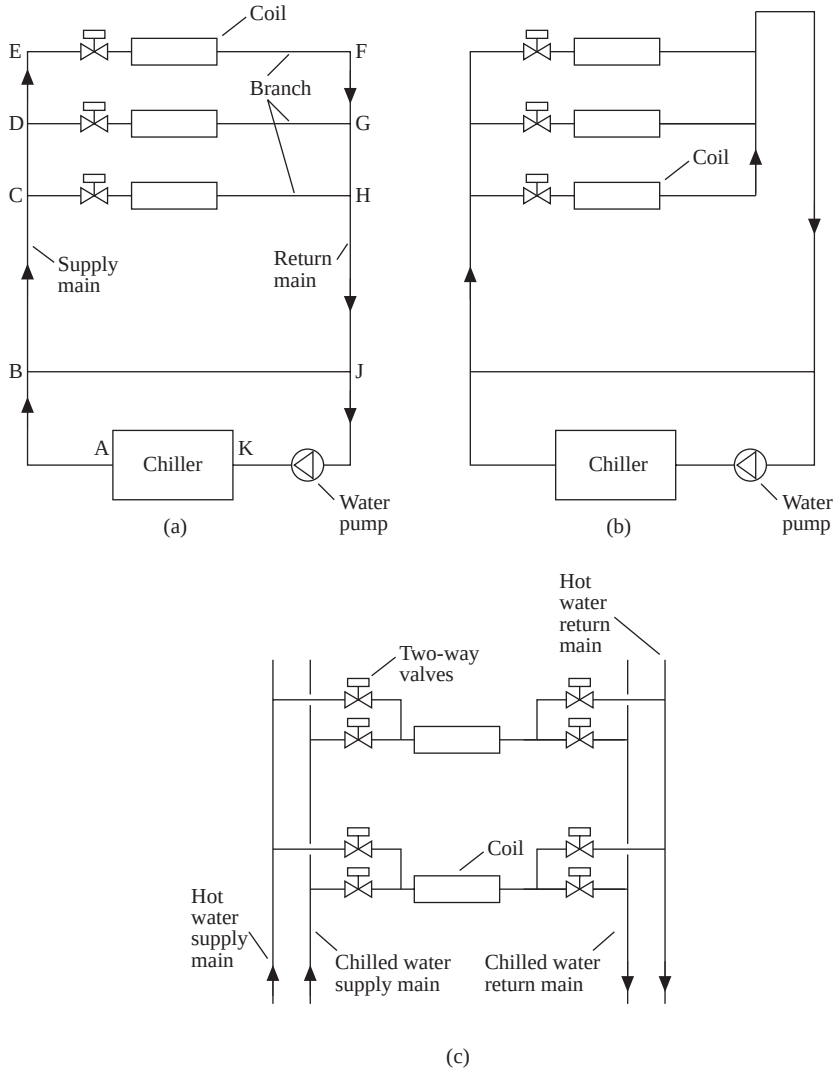


FIGURE 9.9.2 Piping arrangements: (a) two-pipe direct return system, (b) two-pipe reverse system, and (c) four-pipe system.

connect to coils and heat exchangers. Chilled or hot water from the coils and heat exchangers is accumulated by the return main pipe through return branch pipes and then returned to the chiller or boiler.

Constant Flow and Variable Flow. In a constant-flow water system, the volume flow rate at any cross-sectional plane of the supply and return mains remains constant during the entire operating period. In a variable-flow water system, the volume flow rate varies when the system load changes during the operating period.

Direct Return and Reverse Return. In a *direct return* system, the water supplies to and returns from various coils through various piping circuits. ABCHJKA, ... ABCDEFGHJKA are not equal in length, as shown in Figure 9.9.2(a). Water flow must be adjusted and balanced by using balance valves to provide required design flow rates at design conditions. In a *reverse-return* system, as shown in Figure 9.9.2(b), the piping lengths for various piping circuits including the branch and coil are almost equal. Water flow rates to various coils are easier to balance.

Two-Pipe or Four-Pipe. In a dual-temperature water system, the piping from the chiller or boiler to the coils can be either a *two-pipe* system with a supply main and return main as shown in Figure 9.9.2(a) or (b) or a *four-pipe* system with a chilled water supply main, a hot water supply main, a chilled water return main, and a hot water return main as shown in Figure 9.9.2(c). The two-pipe system needs a changeover from chilled to hot water and vice versa. A four-pipe system is more expensive to install.

Plant-Building Loop

System Description

The chillers/boilers in a central plant are often located in the basement, machinery room, or on the rooftop of the building. Generally, a fairly constant-volume water flow is required in the evaporator to protect it from freezing at part load. ASHRAE/IES Standard 90.1-1989 specifies that water systems using control valves to modulate the coil load must be designed for variable flow for energy savings.

Current chilled water systems or dual-temperature water systems often adopt a *plant-building loop* that consists of two piping loops as shown in Figure 9.9.3(a) for reliable and energy-efficient operation:

Plant Loop. A plant loop ABJKA is comprised of chiller(s)/boiler(s); plant chilled/hot water pump(s) usually of split-case, double suction, or end suction type; a diaphragm expansion tank to allow water expansion and contraction during water temperature changes; an air separator to purge dissolved air from water; corresponding piping and fittings; and control systems. The plant loop is operated at constant flow.

Building Loop. A building loop BCDEFGHJB contains coils; building circulating water pumps, often variable-speed pumps, one being a standby pump; corresponding pipes and fittings; and control systems. A differential pressure transmitter is often installed at the farthest end from the building pump between the supply and return mains. The building loop is operated at variable flow.

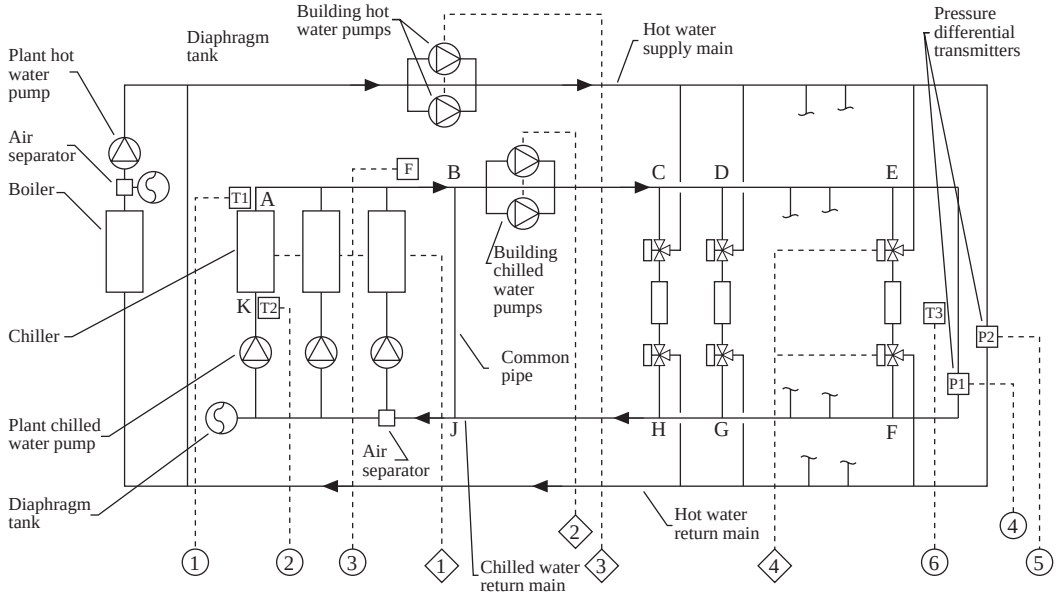
A short common pipe connects these two loops and combines them into a plant-building loop combination. It is also called a *primary-secondary loop*, with the plant loop the primary loop and the building loop the secondary loop. The location of the pump in a water system should be arranged so that the pressure at any point in the system is greater than atmospheric pressure to prevent air leaking into the system.

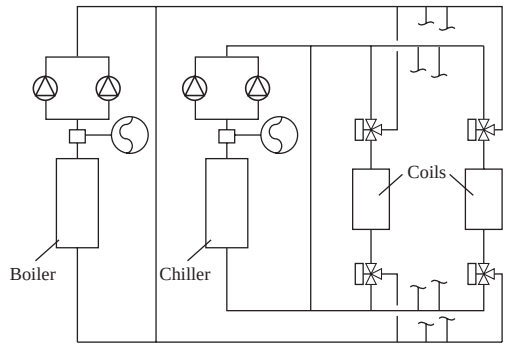
Operating Characteristics

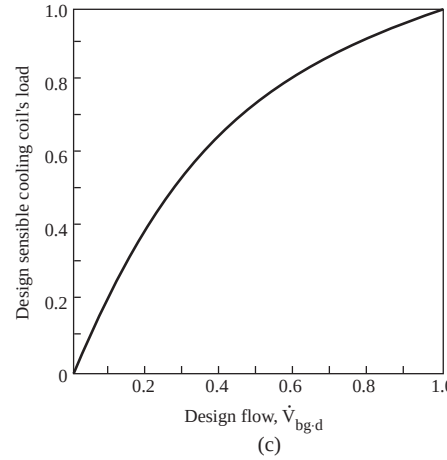
In a dual-temperature water system, when the coil load q_{cc}, in Btu/hr, drops, two-way valves close to a smaller opening. The pressure drop across the coils then increases. As soon as the increase of the pressure differential is sensed by the transmitter, a DDC controller reduces the flow rate of the variable-speed pump to match the reduction of the coil load during part load. The pressure differential transmitter functions similarly to a duct static pressure sensor in a VAV system.

Since the plant loop is at constant flow, excess chilled water bypasses the building loop and flows back to the chiller(s) through the common pipe. When the reduction of coil loads in the building loop is equal to or greater than the refrigeration capacity of a single chiller, the DDC controller will shut down a chiller and its associated chilled water pump. The operating characteristics of the hot water in a dual-temperature water system are similar to those in a chilled water system.

Due to the coil's heat transfer characteristics, the reduction of a certain fraction of the design sensible cooling coil load $q_{cs.d}$ does not equal the reduction of the same fraction of design water volume flow $\mathring{V}_{w.d}$ (Figure 9.9.3[c]). Roughly, a 0.7 $q_{cs.d}$ needs only a 0.45 $\mathring{V}_{w.d}$, and the temperature difference $\Delta T_w = (T_{wl} - T_{we})$ will be about 150% of that at the design condition. When an equal-percentage contour two-way control valve is used, the valve stem displacement of the cooling coil's two-way valve is approximately linearly proportional to the sensible cooling coil's load change.







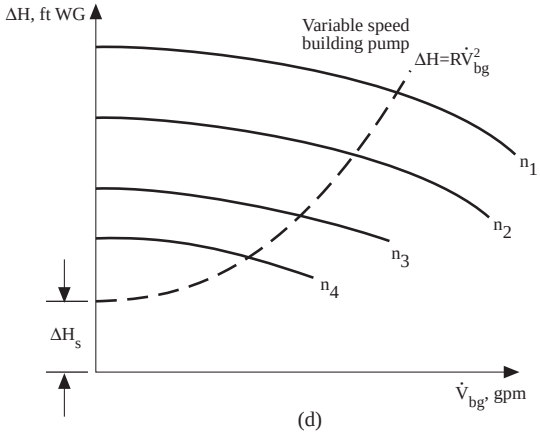


FIGURE 9.9.3 A dual-temperature water system: (a) plant-building loop, (b) single-loop, (c) design sensible load and design volume flow relationship, and (d) variable-speed building pump curves.

Comparison of a Single-Loop and a Plant-Building Loop

Compared with a single-loop water system as shown in Figure 9.9.3(b) that has only a single-stage water pump(s), the plant-building loop:

- Provides variable flow at the building loop and thus saves pump power at reduced flow during part load.
- Separates plant and building loops and makes design, operation, maintenance, and control simpler and more stable as stated in Carlson (1968). The pressure drop across the two-way control valve is considerably reduced as the control valve is only a component of the building loop.

Plant-Distribution-Building Loop

In universities, medical centers, and airports, buildings are often scattered from the central plant. A campus-type chilled water system using a plant-distribution-building loop is often reliable in operation, requires less maintenance, has minimal environmental impact, and sometimes provides energy cost savings.

In a plant-distribution-building loop, plant loop water is combined with many building loops through a distribution loop as shown in Figure 9.9.4(a). The water flow in the plant loop is constant, whereas in both distribution and building loops it is variable. Chilled water often leaves the chiller at a temperature of 40 to 42°F. It is extracted by the distribution pumps and forced into the distribution supply main. At the entrance of each building, chilled water is again extracted by the building pumps and supplied to the cooling coils in AHUs and fan-coil units. From the coils, chilled water is returned through the building return main and the distribution return main and enters the chillers at a temperature around 60°F at design volume flow. System performances of the plant and building loops in a plant-distribution-building loop are similar to those in a plant-building loop.

A campus-type central plant may transport several thousand gallons of chilled water to many buildings, and the farthest building may be several thousand feet away from the central plant. A smaller pressure gradient and end pressure differential between distribution supply and return mains, $\Delta H_{s.d}$, save energy. Meanwhile, a larger diameter of pipes is needed. For a distribution loop, a pressure drop of 0.5 to 1 ft head loss per 100 ft of piping length may be used. A low pressure differential may be offset at the control valves without affecting the normal operation of the coils. Usually, direct return is used for distribution loops.

Using a two-way distribution from the central plant with two separate supply and return loops often reduces the main pipe length and diameter.

A differential pressure transmitter may be located at the farthest end of the distribution mains. As the pressure loss in the building loop is taken care of by the variable-speed building pump(s), a set point of 5 ft WG pressure differential across the supply and return mains seems appropriate.

Chilled water and hot water distribution pipes are often mounted in underground accessible tunnels or trenches. They are well insulated except when chilled water return temperature $T_{ret} > 55$°F. Under such circumstances, the return main may not be insulated, depending on local conditions and cost analysis.

Many retrofits of campus-type chilled water systems required an existing refrigeration plant(s) and a new developed plant(s) connected to the same plant-distribution-building loop. A stand-alone DDC panel is often used to optimize the turning on and off of the chillers in the existing and developed plants according to the system loads and available sources (chillers).

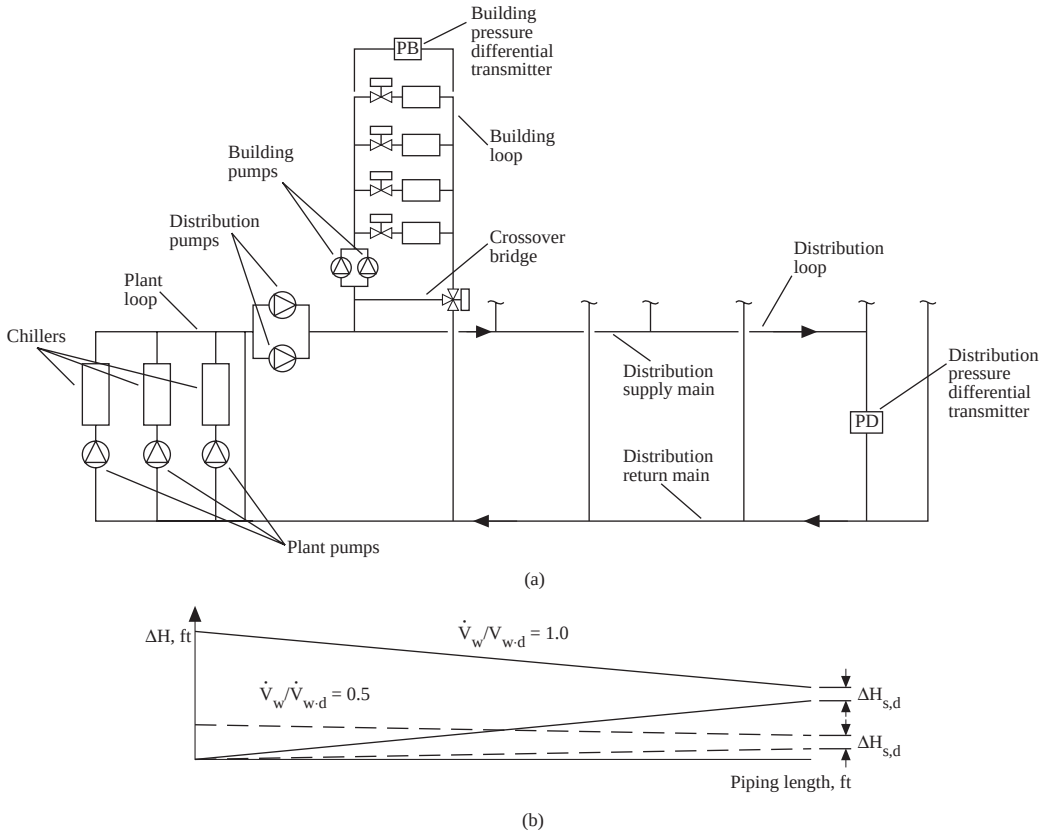

FIGURE 9.9.4 A chilled water system using a plant-distribution-building loop: (a) schematic diagram and (b) pressure gradient for distribution loop.

9.10 Heating Systems

Types of Heating Systems

According to EIA Commercial Buildings Characteristics 1992, for the 57.8 billion ft^2 of heated commercial buildings in the United States in 1992, the following types of heating systems were used:

Warm air heating systems using warm air furnace	27%
Hot water heating systems using boilers	33%
Heat pumps	13%
District heating	8%
Individual space heaters and others heaters	19%

Modera (1989) reported that nearly 50% of U.S. residential houses are using warm air heating systems with direct-fired warm air furnaces.

Warm Air Furnaces

A *warm air furnace* is a device in which gaseous or liquid fuel is directly fired or electric resistance heaters are used to heat the warm supply air. Natural gas, liquefied petroleum gas (LPG), oil, electric energy, or occasionally wood may be used as the fuel or energy input. Among these, natural gas is most widely used. In a warm air furnace, the warm air flow could be *upflow*, in which the warm air is discharged at the top, as shown in Figure 9.10.1(a) and (b); downflow, with the warm air discharged at the bottom; or *horizontal flow*, with the warm air discharged horizontally.

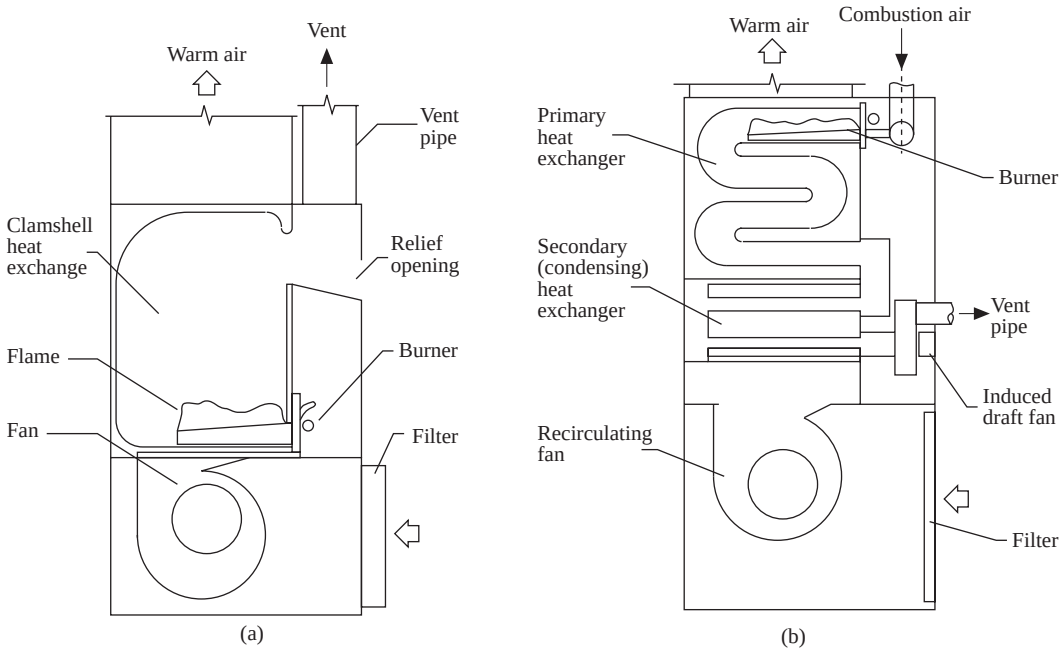

FIGURE 9.10.1 Upflow warm air gas furnace: (a) a natural-vent gas furnace and (b) a power-vent high-efficiency gas furnace.

Natural Vent Combustion Systems. There are two types of combustion systems in a natural gas-fired warm air furnace: natural vent or power vent combustion systems. In a *natural vent* or *atmospheric vent* combustion system, the buoyancy of the combustion products carries the flue gas flowing through the heat exchanger and draft hood, discharging from the chimney or vent pipe. The gas burner is an

atmospheric burner. In an atmospheric burner, air is exracted for combustion by the suction effect of the high-velocity discharged gas and the buoyance effect of the combustion air. An atmospheric burner can be either an in-shot or an up-shot burner or multiple ports. Atmospheric burners are simple, require only a minimal draft of air, and need sufficient gas pressure for normal functioning.

Two types of ignition have been used in burners: standing pilot and spark ignition. In *standing pilot ignition*, the small pilot flame is monitored by a sensor and the gas supply is shut off if the flame is extinguished. *Spark ignition* fires intermittently only when ignition is required. It saves gas fuel if the furnace is not operating.

In a natural vent combustion system, the heat exchanger is often made from cold-rolled steel or aluminized steel in the shape of a clamshell or S. A fan or blower is always used to force the recirculating air flowing over the heat exchanger and distribute the heated air to the conditioned space. A low-efficiency disposable air filter is often located upstream of the fan to remove dust from the recirculating air. A draft hood is also installed to connect the flue gas exit at the top of the heat exchanger to a vent pipe or chimney. A relief air opening is employed to guarantee that the pressure at the flue gas exit is atmospheric and operates safely even if the chimney is blocked. The outer casing of the furnace is generally made of heavy-gauge steel with access panels.

Power Vent Combustion Systems. In a *power vent* combustion system, either a forced draft fan is used to supply the combustion air or an induced draft fan is used to induce the flue gas to the vent pipe or chimney. A power vent is often used for a large gas furnace or a high-efficiency gas furnace with condensing heat exchangers.

Gas burners in a power vent system are called *power burners*. The gas supply to the power burner is controlled by a pressure regulator and a gas valve to control the firing rate. Intermittent spark ignition and *hot surface ignition* that ignites the main burners directly are often used.

Usually, there are two heat exchangers in a power vent combustion system: a primary heat exchanger and a secondary or condensing heat exchanger. The primary heat exchanger constitutes the heating surface of the combustion chamber. When the water vapor in the flue gas is condensed by indirect contact with the recirculating air, part of the latent heat of condensation released is absorbed by the air. Thus the furnace efficiency is increased in the *secondary* or *condensing heat exchanger.* Both primary and secondary heat exchangers are made from corrosion-resistant steel. A fan is also used to force the recirculating air to flow over the heat exchangers and to distribute the heated air to the conditioned space.

Most natural gas furnaces can use LPG. LPG needs a pressure of 10 in. WG at the manifold, compared with 3 to 4 in. for natural gas. It also needs more primary air for gas burners. Oil furnaces are usually of forced draft and installed with pressure-atomizing burners. The oil pressure and the orifice size of the injection nozzle control the firing rate.

Furnace Performance Indices. The performance of a gas-fired furnace is usually assessed by the following indices:

- Thermal efficiency E_t, in percent, is the ratio of the energy output of heated air or water to the fuel energy input during specific test periods using the same units:

$$E_t = 100(\text{fuel energy output})/(\text{fuel energy input}) \tag{9.10.1}$$

- Annual fuel utilization efficiency (AFUE), in percent, is the ratio of the annual output energy from heated air or water to the annual input energy using the same units:

$$\text{AFUE} = (100 \text{ annual output energy})/(\text{annual input energy}) \tag{9.10.2}$$

- Steady-state efficiency (SSE) is the efficiency of a given furnace according to an ANSI test procedure, in percent:

$$\text{SSE} = 100(\text{fuel input} - \text{fuel loss})/(\text{fuel input}) \tag{9.10.3}$$

Jakob et al. (1986) and Locklin et al. (1987), in a report on ASHRAE Special Project SP43, gave the following performance indices based on a nighttime setback period of 8 hr with a setback temperature of 10°F:

Description	AFUE (%)	SSE (%)
Natural vent		
Pilot ignition	64.5	77
Intermittent ignition	69	77
Intermittent ignition plus vent damper	78	77
Power vent		
Noncondensing	81.5	82.5
Condensing	92.5	93

ASHRAE/IES Standard 90.1-1989 specifies a minimum AFUE of 78% for both gas-fired and oil-fired furnaces of heating capacity <225,000 Btu/hr. For a gas-fired warm air furnace ≥225,000 Btu/hr at maximum rating capacity (steady state) the minimum E_t is 80%, and at minimum rating capacity, E_t is 78%.

Operation and Control. Gas is usually brought from the main to the pressure regulator, where its pressure is reduced to 3.5 in. WG. Gas then flows through a valve and mixes with the necessary amount of outside primary air. The mixture mixes again with the ambient secondary air and is burned. The combustion products flow through the heat exchanger(s) due either to natural draft or power vent by a fan. The flue gas is then vented to the outside atmosphere through a vent pipe or chimney.

Recirculating air is pulled from the conditioned space through the return duct and is mixed with the outdoor air. The mixture is forced through the heat exchanger(s) by a fan and is then heated and distributed to the conditioned space. The fan is often started 1 min after the burner is fired in order to prevent a cold air supply.

At part-load operation, the reduction of the heating capacity of the warm air furnace is usually controlled by the gas valve and the ignition device. For small furnaces, the gas valve is often operated at on–off control. For large furnaces, a two-stage gas valve operates the furnace at 100, 50, and 0% heating capacity as required.

Low NO_x Emissions. NO_x means nitrogen oxides NO and NO_2. They are combustion products in the flue gas and become air pollutants with other emissions like SO_2 and CO when they are discharged to the atmosphere. NO_x cause ozone depletion as well as smog.

Southern California regulations required that NO_x emissions should be 30 ppm or less for gas-fired warm air furnaces and boilers. Many gas burner manufactures use induced flue gas recirculation to cool the burner's flame, a cyclonic-type burner to create a swirling high-velocity flame, and other technologies to reduce NO_x and other emissions while retaining high furnace and boiler efficiencies.

Hot Water Boilers

Types of Hot Water Boilers. A *hot water boiler* is an enclosed pressure vessel used as a heat source for space heating in which water is heated to a required temperature and pressure without evaporation. Hot water boilers are fabricated according to American Society of Mechanical Engineers (ASME) codes for boilers and pressure vessels. Boilers are generally rated on the basis of their gross output delivered at the boiler's outlet. Hot water boilers are available in standard sizes from 50 to 50,000 MBtu/hr (1 MBtu/hr = 1000 Btu/hr).

According to EIA Characteristics of Commercial Buildings (1991), the percentages of floor area served by different kinds of fuel used in hot water and steam boilers in 1989 in the United States are gas-fired, 69%; oil-fired, 19%; electric, 7%; others, 5%.

Hot water boilers can be classified as *low-pressure boilers*, whose working pressure does not exceed 160 psig and working temperature is 250°F or less, and *medium-* and *high-pressure boilers*, whose working pressure is above 160 psig and working temperature above 250°F. Most of the hot water boilers are low-pressure boilers except those in campus-type or district water heating systems.

Based on their construction and material, hot water boilers can be classified as fire tube boilers, water tube boilers, cast iron sectional boilers, and electric boilers. Water tube boilers are used mainly to generate steam. Cast iron sectional boilers consist of many vertical inverted U-shaped cast iron hollow sections. They are lower in efficiency and used mainly for residential and small commercial buildings. Electric boilers are limited in applications because of their higher energy cost in many locations in the United States.

Scotch Marine Boiler. In a *fire tube* hot water boiler, the combustion chamber and flue gas passages are in tubes. These tubes are enclosed by an outer shell filled with water. A recently developed fire tube model is the modified Scotch Marine packaged boiler, which is a compact, efficient, and popular hot water boiler used today.

A *Scotch Marine* boiler, as shown in Figure 9.10.2, consists of a gas, oil, or gas/oil burner, a mechanical forced-draft fan, a combustion chamber, fire tubes, flue gas vent, outer shell, and corresponding control system. A packaged boiler is a one-piece factory-assembled boiler.

This figure is not available.

FIGURE 9.10.2 A Scotch Marine packaged boiler.

Gas or oil and air are measured, mixed, and injected into the combustion chamber in which they are initially ignited by an ignition device. The mixture burns and the combustion process is sustained when there is a high enough temperature in the combustion chamber. Because the number of fire tubes decreases continuously in the second, third, and fourth passes due to the volume contraction at lower flue gas temperatures, the gas velocity and heat transfer coefficients are maintained at reasonably high values.

Return water enters the side of the boiler. It sinks to the bottom, rises again after heating, and then discharges at the top outlet.

The dew point of the flue gas is often 130°F. If the temperature of the return water in a *condensing boiler* is below 125°F, it can be used as a condensing cooling medium to condense the water vapor contained in the flue gas. Latent heat of condensation of water vapor can then be recovered. Corrosion in the condensing heat exchanger and the flue gas passage should be avoided.

The *chimney*, or *stack*, is the vertical pipe or structure used to discharge flue gas, which usually has a temperature rise of 300 to 400°F above the ambient temperature. The chimney or stack should be extended to a certain height above adjacent buildings according to local codes.

Operation and Safety Controls. During part-load operation, reduction of heating capacity is achieved by sensing the temperature of return water and controlling the firing rate of the gas burners in on–off, high–low–off, or modulating modes.

For gas burners, two pressure sensors are often provided to maintain the gas pressure within a narrow range. For modulating controls, the ratio of maximum to minimum input is called the *turn-down* ratio. The minimum input is usually 5 to 25% of the maximum input, that is, a turn-down ratio of 20:1 to 4:1. The boiler should be shut off if the input is less than the minimum.

Pressure and temperature relief valves should be installed in each boiler. An additional high limit control is often equipped to shut down the boiler in case the sensed water pressure or temperature exceeds the predetermined limits. A flame detector is often used to monitor the flame and an airflow sensor to verify the combustion airflow. As soon as the flame is extinguished or the combustion airflow is not sensed, the fuel valve closes and the boiler is shut down. ASHRAE/IES Standard 90.1-1989 specifies that gas-fired boilers should have a minimum AFUE of 80%.

Low-Pressure Warm Air Heating Systems

A *low-pressure warm air heating system* is often equipped with an upflow gas-fired furnace having a furnace heat capacity Q_f to air flow $\dot{V}_a$ ratio, $Q_f / \dot{V}_a$, of 50 to 70 Btu/hr.cfm and a temperature rise immediately after the furnace of 50 to 70°F. The external pressure loss of the supply and return duct system is usually not higher than 0.5 in. WG. The supply temperature differential ($T_s - T_r$) is often 20 to 35°F. The heating system is often integrated with a cooling system, forming a heating/cooling system.

Low-pressure warm air heating systems usually have a heating capacity not exceeding 100,000 Btu/hr. They are often used in residences and sometimes in small commercial buildings.

System Characteristics. A low-pressure warm air heating system is equipped with either supply and return ducts or a supply duct and a return plenum. Recirculating air is then returned from living, dining, bed, and study rooms to the return plenum through door undercuts in case the doors are closed.

The location of the furnace has a significant effect on the efficiency of the heating system. According to Locklin et al. (1987), if the gas furnace of a low-pressure warm air heating system is installed in a closet and its supply duct is mounted inside the conditioned space, its system efficiency may be 20% higher than that of installations whose furnace and supply duct are in the attic or basement.

When a low-pressure warm air heating system is operating, the supply duct leakage in the attic or basement raises its pressure to a positive value and promotes exfiltration. Return duct leakage extracts the ambient air, lowers the attic or basement pressure to a negative value, and induces infiltration. Gammage et al. (1986) reported that both types of leakage increase the whole house infiltration to 0.78 ach when the low-pressure warm air heating system is operating. The infiltration rate is only 0.44 ach when the low-pressure warm air heating system is shut off.

If the supply temperature differential $\Delta T_s = (T_s - T_r)$ exceeds 30°F, or if there is a high ceiling, thermal stratification may form in the conditioned space. Greater supply volume flow rates and suitable locations of the supply and return outlets may reduce thermal stratification and vertical temperature difference.

Part-Load Operation and Control. For a low-pressure warm air heating system, a space thermostat is often used to control the gas valve of the furnace operated in on–off or high–low–off mode. The proportion of on and off times in an operating cycle can be varied to meet the change of space heating load. The time period of an on–off operating cycle is usually 5 to 15 min.

A warm-air heating system that has an external pressure higher than 0.5 in. WG is often integrated with a cooling system and becomes a part of an air-conditioning system.

Low-Temperature Hot Water Heating System Using Fin-Tube Heaters

In a *low-temperature hot water heating system*, the operating temperature is 250°F or less with a maximum working pressure not exceeding 150 psig, usually less than 30 psig. Low-temperature hot water heating systems are widely used for space heating in residences and commercial buildings.

Fin-Tube Heaters. A *fin-tube heater* is a device installed directly inside the conditioned space to add heat to the space through radiant and convective heat transfer. A fin-tube heater consists of a finned-tube element and an outer casing as shown in Figure 9.10.3(a). The tubes are often made of copper and steel. Copper tubes are generally 0.75, 1, and 1.25 in. in diameter and steel tubes 1.25 and 2 in. in diameter. The fins are usually made of aluminum for copper tubes and of steel for steel tubes. Fin density may vary from 24 to 60 fins per foot. A fin heater may have a maximum length of 12 ft. The outer casing of a finned-tube heater always has a bottom inlet and top outlet for better convection.

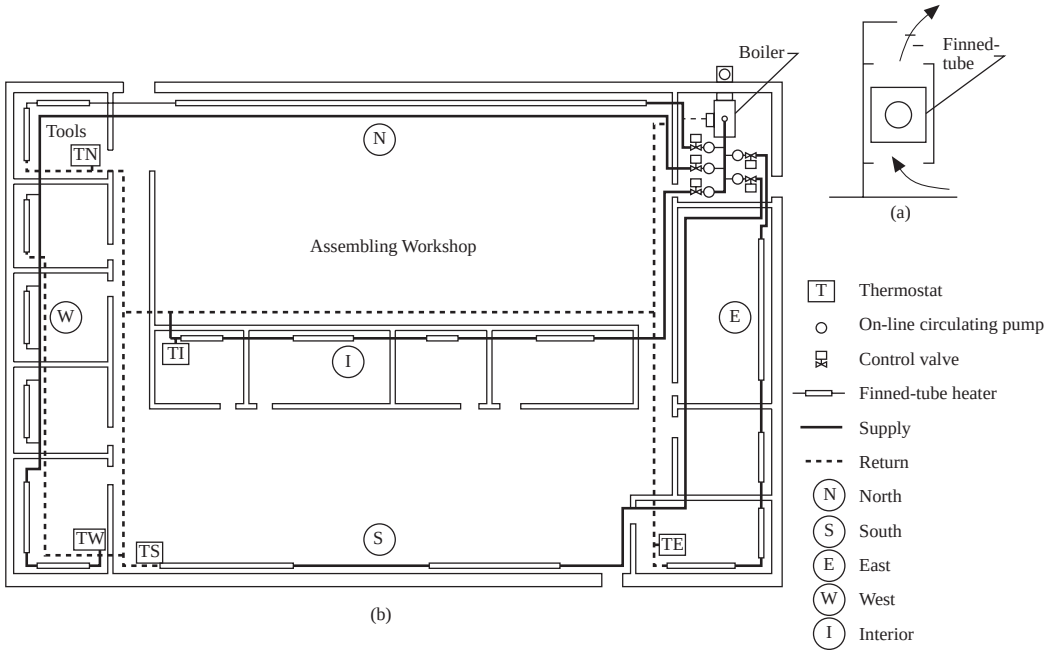

FIGURE 9.10.3 A two-pipe individual-loop low-temperature hot water heating system: (a) finned-tube heater and (b) piping layout.

The most widely used finned-tube heater is the *baseboard heater*, which is often mounted on cold walls at a level 7 to 10 in. from the floor. It is usually 3 in. deep and has one fin-tube row. A wall finned-tube heater has a greater height. A convector has a cabinet-type enclosure and is often installed under the windowsill.

Two-Pipe Individual-Loop Systems. Current low-temperature hot water heating systems using finned-tube heaters are often equipped with zone controls. Zone controls can avoid overheating rooms facing south and underheating rooms facing north because of the effects of solar radiation.

Figure 9.10.3(b) shows the piping layout of a *two-pipe individual-loop system* that is widely used in low-temperature hot water heating systems. Two-pipe means that there are a supply main and a return main pipe instead of one common main for both supply and return. Individual-loop means that there is an individual loop for each control zone. Several finned-tube heaters in a large room can be connected in series, while finned-tube heaters in several small rooms can be connected in reverse return arrangement.

The sizing of low-temperature hot water pipes is usually based on a pressure drop of 1 to 3 ft per 100 ft of pipe length. For a small low-temperature hot water heating system, an open-type expansion tank is often used. A diaphragm tank is often used for a large system. On-line circulating pumps with low head are often used.

Part Load and Control. Usually a hot water sensor located at the exit of the hot water boiler is used to control the firing rate of the boiler at part-load operation. Its set point is usually reset according to the outdoor temperature. Zone control is provided by sensing the return hot water temperature from each individual loop or zone and then varying the water volume flow rate supplied to that zone by modulating the speed of each corresponding on-line circulating pump or its control valve. For hot water heating systems using multiple boilers, on and off for each specific boiler depend not only on the heating demand, but also on minimizing the energy cost.

Infrared Heating

Infrared heating is a process that uses radiant heat transfer from a gas-fired or electrically heated high-temperature device to provide space heating on a localized area for the health and comfort of the occupants or to maintain a suitable indoor environment for a manufacturing process.

An *infrared heater* is a device used to provide infrared heating. Heat radiates from an infrared heater in the form of electromagnetic waves and scatters in all directions. Most infrared heaters have reflectors to focus the radiant beam onto a localized area. Therefore, they are often called *beam radiant heaters.* Infrared heaters are widely used in high-ceiling supermarkets, factories, warehouses, gymnasiums, skating rinks, and outdoor loading docks.

Gas Infrared Heaters. Infrared heaters can be divided into two categories: gas and electric infrared heaters. *Gas infrared heaters* are again divided into porous matrix gas infrared heaters and indirect gas infrared heaters. In a *porous matrix gas infrared heater,* a gas and air mixture is supplied and distributed evenly through a porous ceramic, a stainless steel panel, or a metallic screen, which is exposed to the ambient air and backed by a reflector. Combustion takes place at the exposed surface with a maximum temperature of about 1600°F. An indirect infrared heater consists of a burner, a radiating tube, and a reflector. Combustion takes place inside the radiating tube at a temperature not exceeding 1200°F.

Gas infrared heaters are usually vented and have a small conversion efficiency. Only 10 to 20% of the input energy of an open combustion gas infrared heater is radiated in the form of infrared radiant energy. Usually 4 cfm of combustion air is required for 1000 Btu/hr gas input. A thermostat often controls a gas valve in on–off mode. For standing pilot ignition, a sensor and a controller are used to cut off the gas supply if the flame is extinguished.

Electric Infrared Heaters. An *electric infrared heater* is usually made of nickel–chromium wire or tungsten filaments mounted inside an electrically insulated metal tube or quartz tube with or without inert gas. The heater also contains a reflector that directs the radiant beam to the localized area requiring heating. Nickel–chromium wires often operate at a temperature of 1200 to 1800°F. A thermostat is also used to switch on or cut off the electric current. An electric infrared heater has a far higher conversion efficiency and is cleaner and more easily managed.

Design Considerations. An acceptable radiative temperature increase ($T_{rad} - T_r$) of 20 to 25°F is often adopted for normal clothed occupants using infrared heating. The corresponding required watt density

for infrared heaters is 30 to 37 W/ft^2. At a mounting height of 11 ft, two heaters having a spacing of 6.5 ft can provide a watt density of 33 W/ft^2 and cover an area of 12 × 13 ft. The mounting height of the infrared heaters should not be lower than 10 ft. Otherwise the occupants may feel discomfort from the overhead radiant beam. Refer to Grimm and Rosaler (1990), *Handbook of HVAC Design*, for details.

Gas and electric infrared heaters should not be used in places where there is danger of ignitable gas or materials that may decompose into toxic gases.

9.11 Refrigeration Systems

Classifications of Refrigeration Systems

Most of the refrigeration systems used for air-conditioning are vapor compression systems. Because of the increase in the energy cost of natural gas in the 1980s, the application of absorption refrigeration systems has dropped sharply. According to Commercial Buildings Characteristics 1992, absorption refrigeration system have a weight of less than 3% of the total amount of refrigeration used in commercial buildings in the United States. Air expansion refrigeration systems are used mainly in aircraft and cryogenics.

Refrigeration systems used for air-conditioning can be classified mainly in the following categories:

- Direct expansion (DX) systems and heat pumps
- Centrifugal chillers
- Screw chillers
- Absorption systems

Each can be either a single-stage or a multistage system.

Direct Expansion Refrigeration Systems

A *direct expansion refrigeration (DX) system*, or simply *DX system*, is part of the packaged air-conditioning system. The DX coil in the packaged unit is used to cool and dehumidify the air directly as shown in Figure 9.11.1(a). According to EIA Commercial Buildings Characteristics 1992, about 74% of the floor space of commercial buildings in the United States was cooled by DX refrigeration systems.

Refrigerants R-22 and R-134a are widely used. Azeotropics and near azeotropics are the refrigerants often used for low-evaporating-temperature systems like those in supermarkets. Because of the limitation of the size of the air system, the refrigeration capacity of DX systems is usually 3 to 100 tons.

Components and Accessories. In addition to the DX coil, a DX refrigeration system has the following components and accessories:

- *Compressor(s)* — Both reciprocating and scroll compressors are widely used in DX systems. Scroll compressors are gradually replacing reciprocating compressors because they have fewer parts and comparatively higher efficiency. For large DX systems, multiple compressors are adopted.
- *Condensers* — Most DX systems in rooftop packaged units are air cooled. Water-cooled condensers are adopted mainly for DX systems in indoor packaged units due to their compact volume. Evaporative-cooled condensers are also available.
- *Refrigeration feed* — Thermostatic expansion valves are widely used as the throttling and refrigerant flow control devices in medium and large DX systems, whereas capillary tubes are used in small and medium-sized systems.
- *Oil lubrication* — R-22 is partly miscible with mineral oil. Since R-134a is not miscible with mineral oil, synthetic polyolester oil should be used. For medium and large reciprocating compressors, an oil pump of vane, gear, or centrifugal type is used to force the lubricating oil to the bearings and moving surfaces via grooves. For small reciprocating compressors, splash lubrication using the rotation of the crankshaft and the connecting rod to splash oil onto the bearing surface and the cylinder walls is used.

A scroll compressor is often equipped with a centrifugal oil pump to force the oil to lubricate the orbiting scroll journal bearing and motor bearing. For the scroll contact surfaces, lubrication is provided by the small amount of oil entrained in the suction vapor.

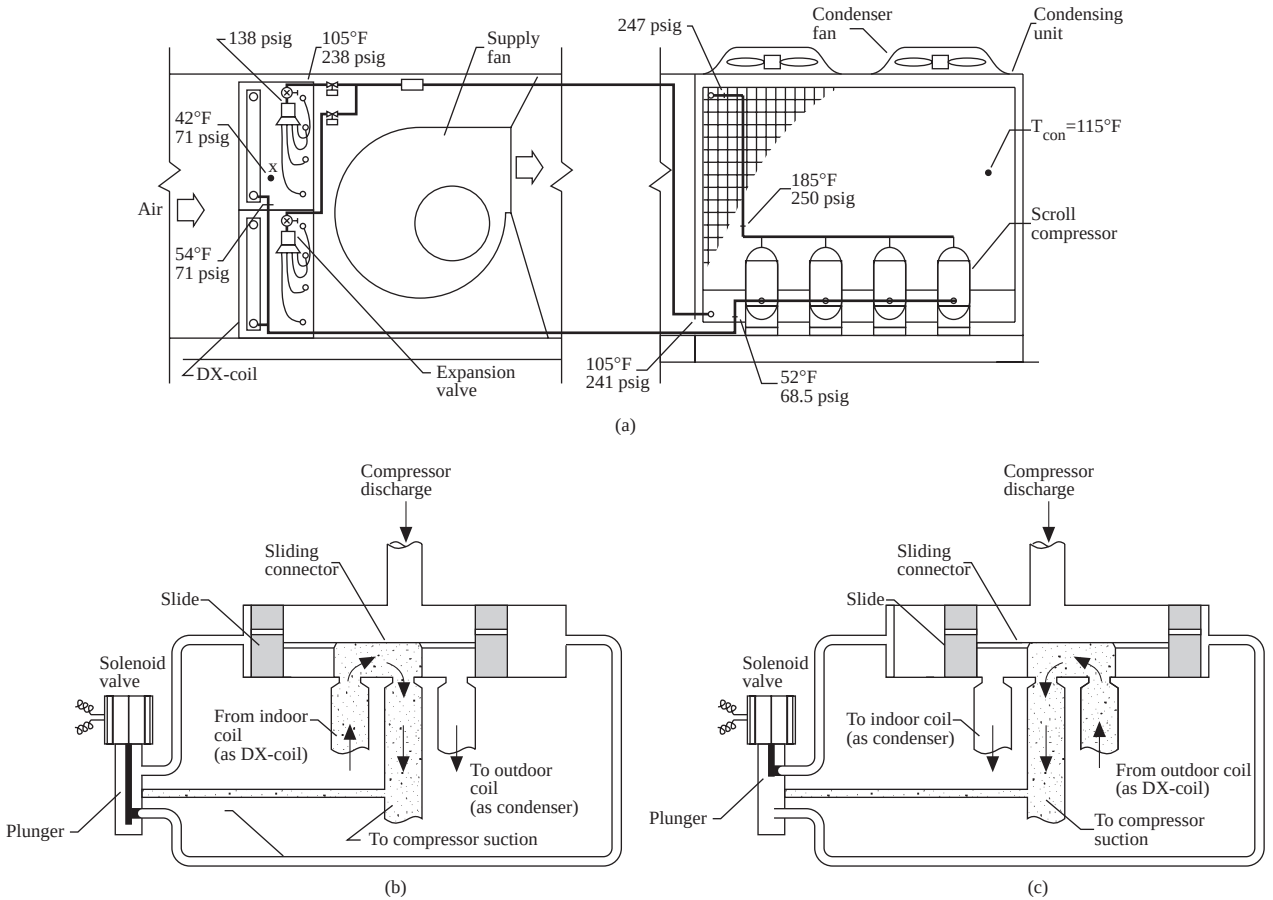

FIGURE 9.11.1 A DX refrigeration system: (a) schematic diagram: (b) four-way reversing valve, cooling mode; and (c) four-way reversing valve, heating mode.

- *Refrigerant piping* — Refrigerant piping transports refrigerant through the compressor, condenser, expansion valve, and DX coil to provide the required refrigeration effect. As shown in Figure 9.11.1(a), from the exit of the DX coil to the inlet of the compressor(s) is the *suction line*. From the outlet of the compressor to the inlet of the air-cooled condenser is the *discharge line*. From the exit of the condenser to the inlet of the expansion valve is the *liquid line*.

Halocarbon refrigerant pipes are mainly made of copper tubes of L type. In a packaged unit, refrigerant pipes are usually sized and connected in the factory. However, the refrigerant pipes in field-built and split DX systems for R-22 are sized on the basis of a pressure drop of 2.91 psi corresponding to a change of saturated temperature ΔT_{suc} of 2°F at 40°F for the suction line and a pressure drop of 3.05 psi corresponding to 1°F at 105°F for the discharge and liquid line. The pressure drop includes pressure losses of pipe and fittings. Refrigerant pipes should also be sized to bring back the entrained oil from the DX coil and condenser through the discharge and suction lines.

Accessories include a filter dryer to remove moisture from the refrigerant, strainer to remove foreign matter, and sight glass to observe the condition of refrigerant flow (whether bubbles are seen because of the presence of flash gas in the liquid line).

Capacity Controls. In DX systems, control of the mass flow rate of refrigerant through the compressor(s) is often used as the primary refrigeration capacity control. Row or intertwined face control at the DX coil is also used in conjunction with the capacity control of the compressor(s).

Three methods of capacity controls are widely used for reciprocating and scroll compressors in DX systems:

- *On–off control* — Starting or stopping the compressor is a kind of step control of the refrigerant flow to the compressor. It is simple and inexpensive, but there is a 100% variation in capacity for DX systems installed with only a single compressor. On–off control is widely used for small systems or DX systems with multiple compressors.
- *Cylinder unloader* — For a reciprocating compressor having multiple cylinders, a cylinder unloader mechanism bypasses the compressed gas from one, two, or three cylinders to the suction chamber to reduce the refrigeration capacity and compressing energy.
- *Speed modulation* — A two-speed motor is often used to drive scroll or reciprocating compressors so that the capacity can be reduced 50% at lower speed.

Safety Controls. In *low- and high-pressure control*, the compressor is stopped when suction pressure drops below a preset value, the cut-in pressure, or the discharge pressure of the hot gas approaches a dangerous level, the cut-out pressure.

In *low-temperature control*, a sensor is mounted on the outer pipe surface of the DX coil. When the surface temperature drops below 32°F, the controller stops the compressor to prevent frosting.

If the pressure of the oil discharged from the pump does not reach a predetermined level within a certain period, a mechanism in *oil pressure failure control* opens the circuit contact and stops the compressor.

In *motor overload control*, a sensor is used to measure the temperature of the electric winding or the electric current to protect the motor from overheating and overloading.

Pump-down control is an effective means of preventing the migration of the refrigerant from the DX coil (evaporator) to the crankcase of the reciprocating compressor. This prevents mixing of refrigerant and oil to form slugs, which may damage the compressor.

When a rise of suction pressure is sensed by a sensor, a DDC controller opens a solenoid valve and the liquid refrigerant enters the DX coil. As the buildup of vapor pressure exceeds the cut-in pressure, the compressor starts. When the DX system needs to shut down, the solenoid valve is closed first; the compressor still pumps the gaseous refrigerant to the condenser. As the suction pressure drops below the cut-in pressure, the compressor stops.

Full- and Part-Load Operations. Consider a DX system in a rooftop packaged unit using four scroll compressors, each with a refrigeration capacity of 10 tons at full load. Performance curves of the condensing unit and the DX coil of this DX system are shown in Figure 9.11.2(a). A DDC controller actuates on–off for these scroll compressors based on the signal from a discharge air temperature T_{dis} sensor.

On a hot summer day, when the rooftop packaged unit starts with a DX coil load or refrigeration capacity, $q_{rc} \approx 40$ tons, all four scroll compressors are operating. The operating point is at A′ with a suction temperature T_{suc} of about 42°F, and the discharge air temperature T_{dis} is maintained around 53°F. As the space cooling load q_{rc} as well as T_{dis} decreases, the required DX coil load q_{rl} drops to 35 tons. Less evaporation in the DX coil causes a decrease of T_{suc} to about 40°F, and the operating point may move downward to point A with a DX coil refrigeration capacity of 39 tons. Since $q_{rc} > q_{rl}$, T_{dis} drops continually until it reaches 50°F, point A in Figure 9.11.2(b), and the DDC controller shuts down one of the scroll compressors. The operating point immediately shifts to B′ on the three-compressor curve.

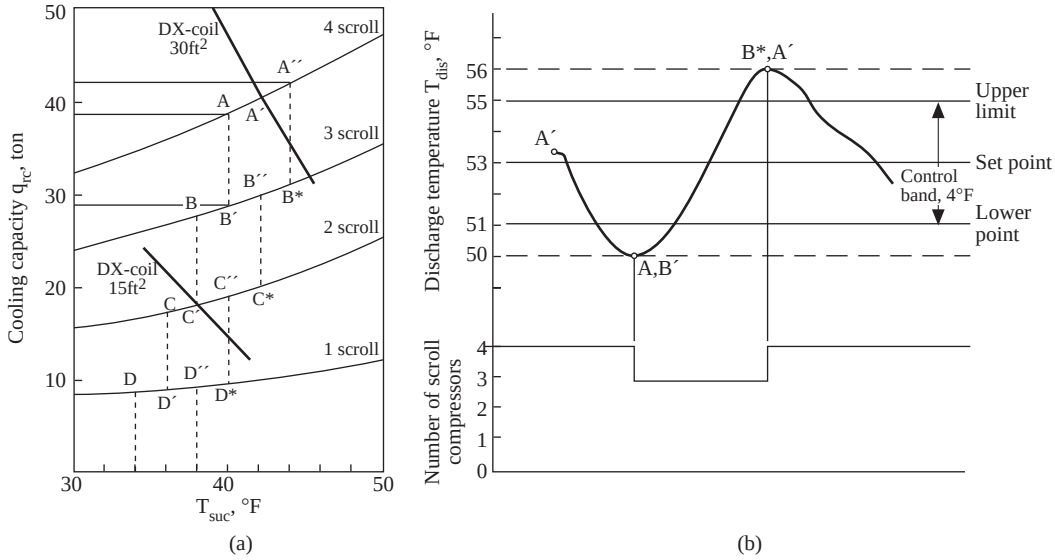

FIGURE 9.11.2 Capacity control of a DX refrigeration system: (a) performance curves and operating points and (b) locus of control point.

Because the refrigeration capacity at point B′ q_{rc} is 29 tons, which is less than the required q_{rl} = 35 tons, both T_{dis} and T_{suc} rise. When the operating point moves up to B* and T_{dis} reaches 56°F, the DDC controller starts all four scroll compressors at operating point A″ with a refrigeration capacity of 42 tons. Since $q_{rc} > q_{rl}$, the operating point again moves downward along the four-compressor curve and forms an operating cycle A″AB′ and B*. The timing of the operating period on four- or three-compressor performance curves balances any required q_{rl} between 29 and 42 tons. Less evaporation at part load in the DX coil results in a greater superheating region and therefore less refrigeration capacity to balance the reduction of refrigeration capacity of the compressor(s) as well as the condensing unit. The condition will be similar when $q_{rl} < 30$ tons, only three- or two-compressor, or two- or one-compressor, or even on–off of one compressor forms an operating cycle.

Main Problems in DX Systems

- *Liquid slugging* is formed by a mixture of liquid refrigerant and oil. It is formed because of the flooding back of liquid refrigerant from the DX coil to the crankcase of the reciprocating compressor due to insufficient superheating. It also may be caused by migration of liquid refrig-

erant from the warmer indoor DX coil to the colder outdoor compressor during the shut-down period in a split packaged unit. Liquid slugging dilutes the lubricating oil and causes serious loss of oil in the crankcase of the reciprocating compressor. Liquid slugging is incompressible. When it enters the compression chamber of a reciprocating compressor, it may damage the valve, piston, and other components. Pump-down control and installation of a crankcase heater are effective means of preventing liquid refrigerant migration and flooding back.

- *Compressor short cycling* — For on–off control, too short a cycle, such as less than 3 min, may pump oil away from the compressor or damage system components. It is due mainly to a too close low-pressure control differential or to reduced air flow.
- *Defrosting* — If the surface of a DX coil is 32°F or lower, frost accumulates on it. Frost blocks the air passage and reduces the rate of heat transfer. It should be removed periodically. The process of removing frost is called defrosting.

  Air at a temperature above 36°F, hot gas inside the refrigerant tubes and an installed electric heating element can be used for defrosting. The defrosting cycle is often controlled by sensing the temperature or pressure difference of air entering the DX coil during a fixed time interval.
- *Refrigerant charge* — Insufficient refrigerant charge causes lower refrigeration capacity, lower suction temperature, and short on–off cycles. Overcharging refrigerant may cause a higher condensing pressure because part of the condensing surface becomes flooded with liquid refrigerant.

Heat Pumps

A *heat pump* in the form of a packaged unit is also a *heat pump system*. A heat pump can either extract heat from a heat source and reject heat to air and water at a higher temperature for heating, or provide refrigeration at a lower temperature and reject condensing heat at a higher temperature for cooling. During summer, the heat extraction, or refrigeration effect, is the useful effect for cooling in a heat pump. In winter, the rejected heat and the heat from a supplementary heater provide heating in a heat pump.

There are three types of heat pumps: air-source, water-source, and ground-coupled heat pumps. Ground-coupled heat pumps have limited applications. Water-source heat pump systems are covered in detail in a later section.

Air-Source Heat Pump. An *air-source heat pump*, or *air-to-air heat pump*, is a DX system with an additional four-way reversing valve to change the refrigerant flow from cooling mode in summer to heating mode in winter and vice versa. The variation in connections between four means of refrigerant flow — compressor suction, compressor discharge, DX coil exit, and condenser inlet — causes the function of the indoor and outdoor coils to reverse. In an air-source heat pump, the coil used to cool or to heat the recirculating/outdoor air is called the *indoor coil*. The coil used to reject heat to or absorb heat from the outside atmosphere is called the *outdoor coil*. A short capillary or restrict tube is often used instead of a thermostatic expansion valve. Both reciprocating and scroll compressors are used in air-source heat pumps. R-22 is the refrigerant widely used. Currently available air-source heat pumps usually have a cooling capacity of $1^1/_2$ to 40 tons.

Cooling and Heating Mode Operation. In *cooling mode operation*, as shown in Figure 9.11.1(b), the solenoid valve is deenergized and drops downward. The high-pressure hot gas pushes the sliding connector to the left end. The compressor discharge connects to the outdoor coil, and the indoor coil connects to the compressor inlet.

In *heating mode operation*, as shown in Figure 9.11.1(c), the solenoid plunger moves upward and pushes the slide connector to the right-hand side. The compressor discharge connects to the indoor coil, and the outdoor coil exit connects to the compressor suction.

System Performance. The performance of an air-source heat pump depends on the outdoor air temperature T_o, in °F as well as the required space heating load q_{rh}. During cooling mode operation, both the refrigeration capacity q_{rc}, in Btu/hr, and EER for the heat pump EER_{hp}, in Btu/hr.W, increase as T_o drops.

During heating mode operation, the heating capacity q_{hp}, in Btu/hr, and COP_{hp} decrease, and q_{rh} increases as the T_o drops. When $q_{rh} > q_{hp}$, supplementary heating is required. If COP_{hp} drops below 1, electric heating may be more economical than a heat pump.

If on–off is used for compressor capacity control for an air-source heat pump in a split packaged unit, refrigerant tends to migrate from the warmer outdoor coil to the cooler indoor coil in summer and from the warmer indoor coil to the cooler outdoor coil in winter during the off period. When the compressor starts again, 2 to 5 min of reduced capacity is experienced before the heat pump can be operated at full capacity. Such a loss is called a *cycling loss*.

In winter, most air-source heat pumps switch from the heating mode to cooling mode operation and force the hot gas to the outdoor coil to melt frost. After the frost is melted, the heat pump is switched back to heating mode operation. During defrosting, supplementary electric heating is often necessary to prevent a cold air supply from the air-source heat pump.

Minimum Performance. ASHRAE/IES Standard 90.1-1989 specifies a minimum performance for air-cooled DX systems in packaged units as covered in Section 9.7. For air-cooled, electrically operated rooftop heat pumps (air-source heat pumps), minimum performance characteristics are:

Cooling EER	8.9
Heating, COP (at T_oF = 47°F)	3.0
Heating, COP (at T_oF = 17°F)	2.0

Centrifugal Chillers

A chiller is a refrigeration machine using a liquid cooler as an evaporator to produce chilled water as the cooling medium in a central air-conditioning system. A *centrifugal chiller*, as shown in Figure 9.11.3(a), is a refrigeration machine using a centrifugal compressor to produce chilled water. It is often a factory-assembled unit with an integrated DDC control system and sometimes may separate into pieces for transportation. A centrifugal chiller is also a *centrifugal vapor compression refrigeration system.*

Refrigerants. According to Hummel et al. (1991), in 1988 there were about 73,000 centrifugal chillers in the United States. Of these, 80% use R-11, 10% use R-12, and the remaining 10% use R-22 and others. As mentioned in Section 9.4, production of CFCs, including R-11 and R-12, ceased at the end of 1995 with limited exception for service. R-123 (HCFC) will replace R-11. The chiller's efficiency may drop 2 to 4%, and a capacity reduction of 5% is possible. R-123 has low toxicity. Its allowable exposure limit was raised to 50 ppm in 1997 from 30 ppm in 1993 by its manufacturers. A monitor and alarm device to detect R-123 in air should be installed in plant rooms and places where there may be refrigerant leaks.

R-134a (HFC) will replace R-12. According to Lowe and Ares (1995), as a result of the changeout from R-12 to R-134a for a 5000-hp centrifugal chiller in Sears Tower, Chicago, its speed increased from 4878 to 5300 rpm, its cooling capacity is 12 to 24% less, and its efficiency is 12 to 16% worse.

System Components. A centrifugal chiller consists of a centrifugal compressor, an evaporator or liquid cooler, a condenser, a flash cooler, throttling devices, piping connections, and controls. A purge unit is optional.

- Centrifugal compressor — According to the number of internally connected impellers, the centrifugal compressor could have a single, two, or more than two stages. A two-stage impeller with a flash cooler is most widely used because of its higher system performance and comparatively simple construction. Centrifugal compressors having a refrigeration capacity less than 1200 tons are often hermetic. Very large centrifugal compressors are of open type. A gear train is often required to raise the speed of the impeller except for very large impellers using direct drive.
- Evaporator — Usually a liquid cooler of flooded shell-and-tube type evaporator is adopted because of its compact size and high rate of heat transfer.
- Condenser — Water-cooled, horizontal shell-and-tube condensers are widely used.

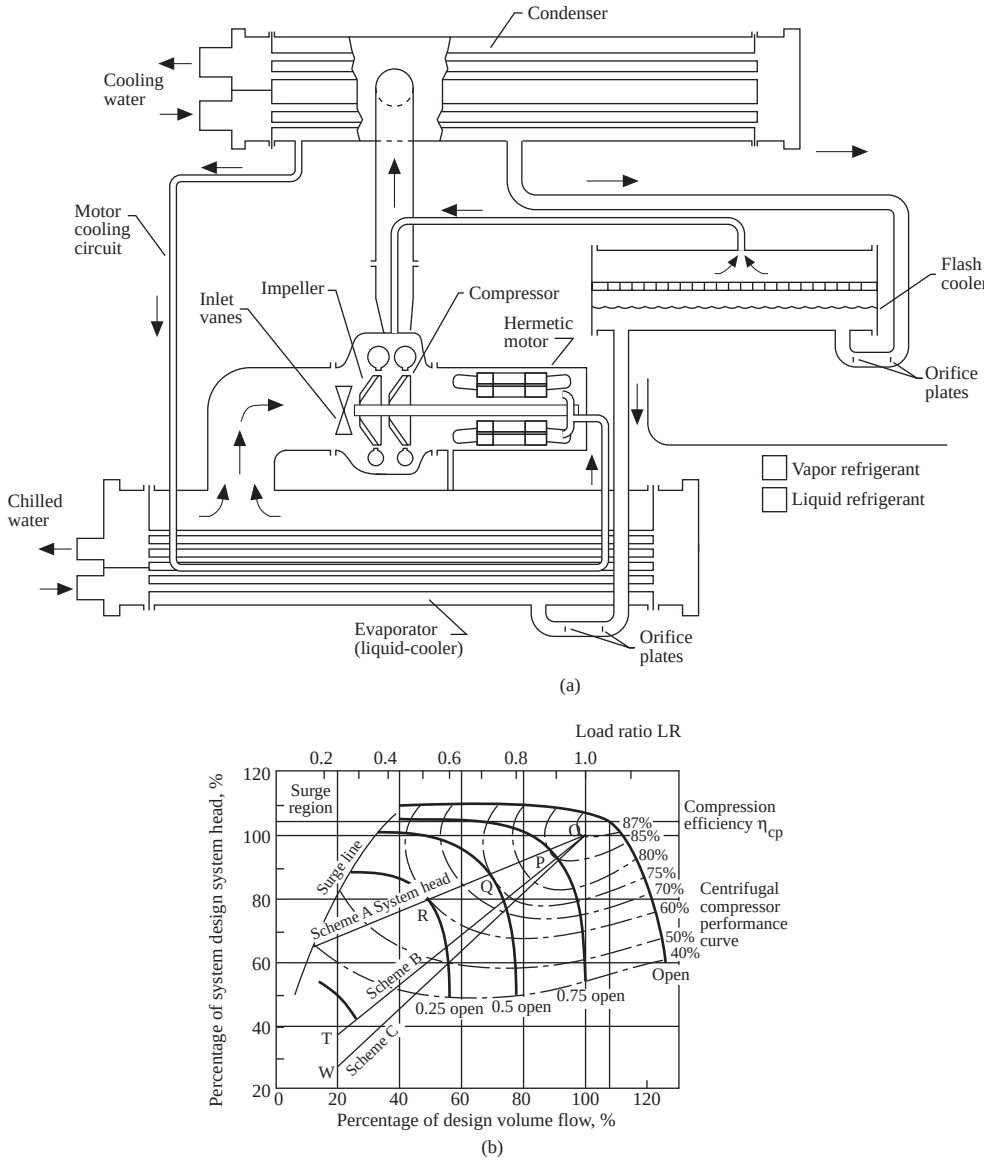

FIGURE 9.11.3 A two-stage water-cooled centrifugal chiller: (a) schematic diagram and (b) centrifugal compressor performance map at constant speed.

- Flash cooler — For a two-stage centrifugal compressor, a single-stage flash cooler is used. For a three-stage compressor, a two-stage flash cooler is used.
- Orifice plates and float valves — Both multiple-orifice plates such as that shown in Figure 9.11.3(a) and float valves are used as throttling devices in centrifugal chillers.
- Purge unit — R-123 has an evaporating pressure p_{ev} = 5.8 psia at 40°F, which is lower than atmospheric pressure. Air and other noncondensable gases may leak into the evaporator through cracks and gaps and usually accumulate in the upper part of the condenser. These noncondensable gases raise the condensing pressure, reduce the refrigerant flow, and lower the rate of heat transfer. A purge unit uses a cooling coil to separate the refrigerant and water from the noncondensable gases and purge the gases by using a vacuum pump.

Performance Ratings. The refrigeration cycle of a typical water-cooled, two-stage centrifugal chiller with a flash cooler was covered in Section 9.4. Centrifugal chillers have the same refrigeration capacity as centrifugal compressors, 100 to 10,000 tons. According to ARI Standard 550-88, the refrigeration capacity of a centrifugal chiller is rated as follows:

Chilled water temperature leaving evaporator T_{el}:	100% load 44°F
	0% load 44°F
Chilled water flow rate:	2.4 gpm/ton
Condenser water temperature entering condenser T_{ce}:	100% load 85°F
	0% load 60°F
Condenser water flow rate:	3.0 gpm/ton
Fouling factor in evaporator and condenser:	0.00025 hr.ft^2.°F/Btu

The integrated part-load value (IPLV) of a centrifugal chiller or other chillers at standard rating conditions can be calculated as:

$$\text{IPLV} = 0.1(A+B)/2 + 0.5(B+C)/2 + 0.3(C+D)/2 + 0.1D \tag{9.11.1}$$

where A, B, C, and D = kW/ton or COP at 100, 75, 50, and 25% load, respectively. If the operating conditions are different from the standard rating conditions, when T_{el} is 40 to 50°F, for each °F increase or decrease of T_{el}, there is roughly a 1.5% difference in refrigeration capacity and energy use; when T_{ce} is between 80 to 90°F, for each °F of increase or decrease of T_{ce}, there is roughly a 1% increase or decrease in refrigeration capacity and 0.6% in energy use.

ASHRAE/IES Standard 90.1-1989 and ARI Standard 550-88 specify the minimum performance for water-cooled water chillers from January 1, 1992:

	COP	**IPLV**
≥300 tons	5.2	5.3
≥150 tons < 300 tons	4.2	4.5
<150 tons	3.8	3.9

COP = 5.0 is equivalent to about 0.70 kW/ton. New, installed centrifugal chillers often have an energy consumption of 0.50 kW/ton.

Air-cooled centrifugal chillers have COPs from 2.5 to 2.8. Their energy performance is far poorer than that of water-cooled chillers. Their application is limited to locations where city water is not allowed to be used as makeup water for cooling towers.

Capacity Control. The refrigeration capacity of a centrifugal chiller is controlled by modulating the refrigerant flow at the centrifugal compressor. There are mainly two types of capacity controls: varying the opening and angle of the inlet vanes, and using an adjustable-frequency AC inverter to vary the rotating speed of the centrifugal compressor.

When the opening of the inlet vanes has been reduced, the refrigerant flow is throttled and imparted with a rotation. The result is a new performance curve at lower head and flow. If the rotating speed of a centrifugal compressor is reduced, it also has a new performance curve at lower volume flow and head. Inlet vanes are inexpensive, whereas the AC inverter speed modulation is more energy efficient at part-load operation.

Centrifugal Compressor Performance Map. Figure 9.11.3(b) shows a single-stage, water-cooled *centrifugal compressor performance map* for constant speed using inlet vanes for capacity modulation. A performance map consists of the compressor's performance curves at various operating conditions. The *performance curve* of a centrifugal compressor shows the relationship of volume flow of refrigerant $\dot{V}_r$

and its head lift Δp or compression efficiency η_{cp} at that volume flow. It is assumed that η_{cp} for a two-stage compressor is equal to the average of the two single-stage impellers having a head of their sum.

On the map, the required *system head curve* indicates the required system head lift at that volume flow of refrigerant. The intersection of the performance curve and the required system head curve is called the *operating point* O, P, Q, R, … as shown in Figure 9.11.3(b). One of the important operating characteristics of a centrifugal chiller (a centrifugal vapor compression refrigeration system as well) is that the required system head lift is mainly determined according to the difference in condensing and evaporating pressure $\Delta p_{c\text{-}e} = (p_{con} - p_{ev})$. The pressure losses due to the refrigerant piping, fittings, and components are minor.

In Figure 9.11.3(b), the abscissa is the percentage of design volume flow of refrigerant, % $\mathring{V}_r$, or load ratio; the ordinate is the percentage of design system head $\Delta H_{s.d}$, or percentage of design temperature lift $(T_{con} - T_{ev})$. Here load ratio LR is defined as the ratio of the refrigeration load to the design refrigeration load $q_{rl}/q_{rl.d}$. There are three schemes of required system head curves:

- Scheme A — T_{ce} = constant and T_{el} = constant
- Scheme B — T_{el} = constant and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio
- Scheme C — A reset of T_{el} of 1°F increase and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio

At design $\mathring{V}_r$ and system head $H_{s.d}$, $\eta_{cp} = 0.87$. As $\mathring{V}_r$, load ratio, and required system head Δp decrease, η_{cp} drops accordingly.

Surge is a unstable operation of a centrifugal compressor or fan resulting in vibration and noise. In a centrifugal chiller, surge occurs when the centrifugal compressor is unable to develop a discharge pressure that satisfies the requirement at the condenser. A centrifugal compressor should never be operated in the surge region.

Part-Load Operation. During part-load operation, if T_{el} and T_{ce} remain constant, the evaporating temperature T_{ev} tends to increase from the design load value because there is a greater evaporating surface and a smaller temperature difference $(T_{el} - T_{ev})$. Similarly, T_{con} tends to decrease.

The ratio of actual compressor power input at part load to the power input at design load may be slightly higher or lower than the load ratios, depending on whether the outdoor wet bulb is constant or varying at part load or whether there is a T_{el} reset; it also depends on the degree of drop of η_{cp} at part load.

Specific Controls. In addition to generic controls, specific controls for a centrifugal chiller include:

- Chilled water leaving temperature T_{el} and reset
- Condenser water temperature T_{ce} control
- On and off of multiple chillers based on actual measured coil load
- Air purge control
- Safety controls like oil pressure, low-temperature freezing protection, high condensing pressure control, motor overheating, and time delaying

Centrifugal Chillers Incorporating Heat Recovery. A *HVAC&R heat recovery system* converts waste heat or waste cooling from any HVAC&R process into useful heat and cooling. A heat recovery system is often subordinate to a parent system, such as a heat recovery system to a centrifugal chiller.

A centrifugal chiller incorporating a heat recovery system often uses a double-bundle condenser in which water tubes are classified as tower bundles and heating bundles. Heat rejected in the condenser may be either discharged to the atmosphere through the tower bundle and cooling tower or used for heating through the heating bundle. A temperature sensor is installed to sense the temperature of return hot water from the heating coils in the perimeter zone. A DDC controller is used to modulate a bypass three-way valve which determines the amount of condenser water supplied to the heating bundle. The tower and heating bundles may be enclosed in the same shell, but baffle sheets are required to guide the water flows.

A centrifugal chiller incorporating a heat recovery system provides cooling for the interior zone and heating for the perimeter zone simultaneously in winter with a higher COP_{hr}. However, it needs a higher condenser water-leaving temperature T_{cl} of 105 to 110°F, compared with 95°F or even lower in a cooling-only centrifugal chiller. An increase of 10 to 12°F of the difference ($T_{con} - T_{ev}$) requires an additional 10 to 15% power input to the compressor. For a refrigeration plant equipped with multiple chillers, it is more energy efficient and lower in first cost to have only part of them equipped with double-bundle condensers.

Screw Chillers

A *screw chiller* or a *helical rotary chiller* is a refrigeration machine using a screw compressor to produce chilled water. A factory-fabricated and assembled screw chiller itself is also a screw vapor compression refrigeration system.

Twin-screw chillers are more widely used than single-screw chillers. A twin-screw chiller consists of mainly a twin-screw compressor, a flooded shell-and-tube liquid cooler as evaporator, a water-cooled condenser, throttling devices, an oil separator, an oil cooler, piping, and controls as shown in Figure 9.11.4(a). The construction of twin-screw compressors has already been covered. For evaporator, condenser, and throttling devices, they are similar to those in centrifugal chillers. Most twin-screw chillers have a refrigeration capacity of 100 to 1000 tons.

Following are the systems characteristics of screw chillers.

Variable Volume Ratio. The ratio of vapor refrigerant trapped within the interlobe space during the intake process V_{in} to the volume of trapped hot gas discharged V_{dis} is called the *built-in volume ratio* of the twin-screw compressor $V_i = V_{in}/V_{dis}$, or simply *volume ratio*, all in ft^3.

There are two types of twin-screw chiller: fixed and variable volume ratio. For a twin-screw chiller of *fixed volume ratio*, the isentropic efficiency η_{isen} becomes maximum when the system required compression ratio $R_{s.com} \approx V_i$. Here $R_{s.com} = p_{con}/p_{ev}$. If $p_{dis} > p_{con}$, overcompression occurs, as shown in Figure 9.11.4(b). The discharged hot gas reexpands to match the condensing pressure. If $p_{dis} < p_{con}$, undercompression occurs (Figure 9.11.4[c]). A volume of gas at condensing pressure reenters the trapped volume at the beginning of the discharge process. Both over- and undercompression cause a reduction of η_{isen}.

For a twin-screw chiller of *variable volume ratio*, there are two slides: a sliding valve is used for capacity control and a second slide. By moving the second slide back and forth, the radial discharge port can be relocated. This allows variation of suction and discharge pressure levels and still maintains maximum efficiency.

Economizer. The hermetic motor shell is connected to an intermediate point of the compression process and maintains an intermediate pressure p_i between p_{con} and p_{ev}. Liquid refrigerant at condensing pressure p_{con} is throttled to p_i, and a portion of the liquid is flashed into vapor. This causes a drop in the temperature of the remaining liquid refrigerant down to the saturated temperature corresponding to p_i. Although the compression in a twin-screw compressor is in continuous progression, the mixing of flashed gas with the compressed gas at the intermediate point actually divides the compression process into two stages. The resulting economizing effect is similar to that of a two-stage compound refrigeration system with a flash cooler: an increase of the refrigeration effect and a saving of the compression power from ($p_{con} - p_{ev}$) to ($p_{con} - p_i$).

Oil Separation, Oil Cooling, and Oil Injection. Oil entrained in the discharged hot gas enters an oil separator. In the separator, oil impinges on an internal perforated surface and is collected because of its inertia. Oil drops to an oil sump through perforation. It is then cooled by condenser water in a heat exchanger. A heater is often used to vaporize the liquid refrigerant in the oil sump to prevent dilution of the oil. Since the oil sump is on the high-pressure side of the refrigeration system, oil is forced to the rotor bearings and injected to the rotors for lubrication.

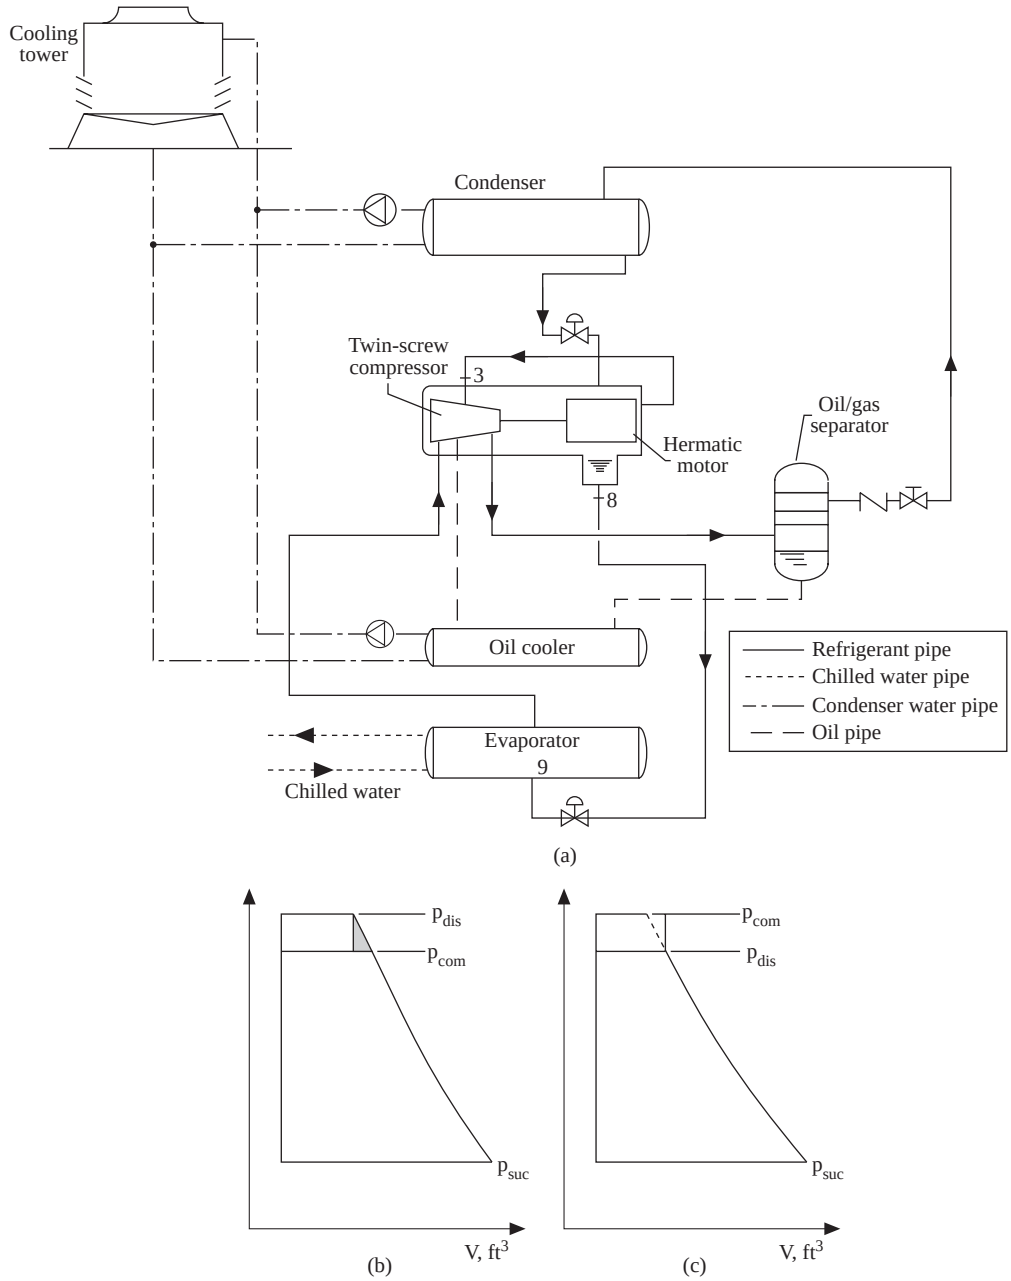

FIGURE 9.11.4 A typical twin-screw chiller: (a) schematic diagram, (b) over-compression, and (c) under-compression.

Oil slugging is not a problem for twin-screw compressors. When suction vapor contains a small amount of liquid refrigerant that carries over from the oil separator, often called *wet suction*, it often has the benefit of scavenging the oil from the evaporator.

Twin-screw compressors are positive displacement compressors. They are critical in oil lubrication, sealing, and cooling. They are also more energy efficient than reciprocating compressors. Twin-screw chillers are gaining more applications, especially for ice-storage systems with cold air distribution.

9.12 Thermal Storage Systems

Thermal Storage Systems and Off-Peak Air-Conditioning Systems

Many electric utilities in the United States have their *on-peak hours* between noon and 8 p.m. during summer weekdays, which include the peak-load hours of air-conditioning. Because the capital cost of a new power plant is so high, from $1200 to $4000 per kW, electric utilities tend to increase their power output by using customers' thermal energy storage (TES) systems, or simply thermal storage systems, which are much less expensive.

A *thermal storage system* as shown in Figure 9.12.1(a) may have the same refrigeration equipment, like chillers, additional storage tank(s), additional piping, pumps, and controls. The electric-driven compressors are operated during off-peak, partial-peak, and on-peak hours. *Off-peak hours* are often nighttime hours. *Partial-peak hours* are hours between on-peak and off-peak hours in a weekday's 24-hr day-and-night cycle. Chilled water or ice is stored in tanks to provide cooling for buildings during on-peak hours when higher electric demand and electric rates are effective. Although thermal storage systems operate during nighttime when outdoor dry and wet bulbs are lower, they are not necessarily energy saving due to lower evaporating temperature, additional pump power, and energy losses. Thermal storage systems significantly reduce the electric energy cost.

Utilities in the United States often use higher electric demand and rates as well as incentive bonus to encourage the shift of electric load from on-peak to off-peak hours by using thermal storage systems and others. Such a shift not only saves expensive capital cost, but also increases the use of base-load high-efficiency coal and nuclear plants instead of inefficient diesel and gas turbine plants.

The air-conditioning systems that operate during off-peak and partial-peak hours for thermal storage, or those that use mainly natural gas to provide cooling to avoid higher electric demand and rates during on-peak hours, are called *off-peak air-conditioning systems*. These systems include ice-storage and chilled-water storage systems, desiccant cooling systems, absorption systems, and gas engine chillers.

Absorption chillers and desiccant cooling systems are covered in other sections. Gas engine-driven reciprocating chillers are often a cogeneration plant with heat recovery from engine jacket and exhaust gas, and will not be covered here.

Full Storage and Partial Storage

Ice and chilled-water storage systems are the two most common thermal energy storage systems today. Knebel (1995) estimated that more than 4000 cool storage systems are operated in various commercial buildings.

The unit of stored thermal energy for cooling is ton-hour, or ton.hr. One *ton.hr* is the refrigeration capacity of one refrigeration ton during a 1-hr period, or 12,000 Btu.

In order to achieve minimum life-cycle cost, thermal storage systems could be either full storage or partial storage. For a *full-storage*, or *load shift*, thermal storage system, all refrigeration compressors cease to operate during on-peak hours. Building refrigeration loads are entirely offset by the chilled water or brine from the thermal storage system within an on-peak period. In a *partial storage*, or *load-leveling*, thermal storage system as shown in Figure 9.12.1(b) all or some refrigeration compressor(s) are operated during on-peak hours.

Direct cooling is the process in which refrigeration compressors produce refrigeration to cool the building directly. During a specific time interval, if the cost of direct cooling is lower than the stored energy, the operation of a thermal storage system is said to be in *chiller priority.* On the contrary, if the cost of direct cooling is higher than the cost of stored energy, the operation is said to be at *storage priority.*

The optimum size of a thermal storage system is mainly determined according to the utility's electric rate structure, especially a time-of-day structure whose electric rates are different between on-peak, partial-peak, and off-peak hours. Not only the design day's instantaneous building peak cooling load is important, but also an hour-by-hour cooling load profile of the design day is required for thermal storage design. A simple payback or a life-cycle cost analysis is usually necessary.

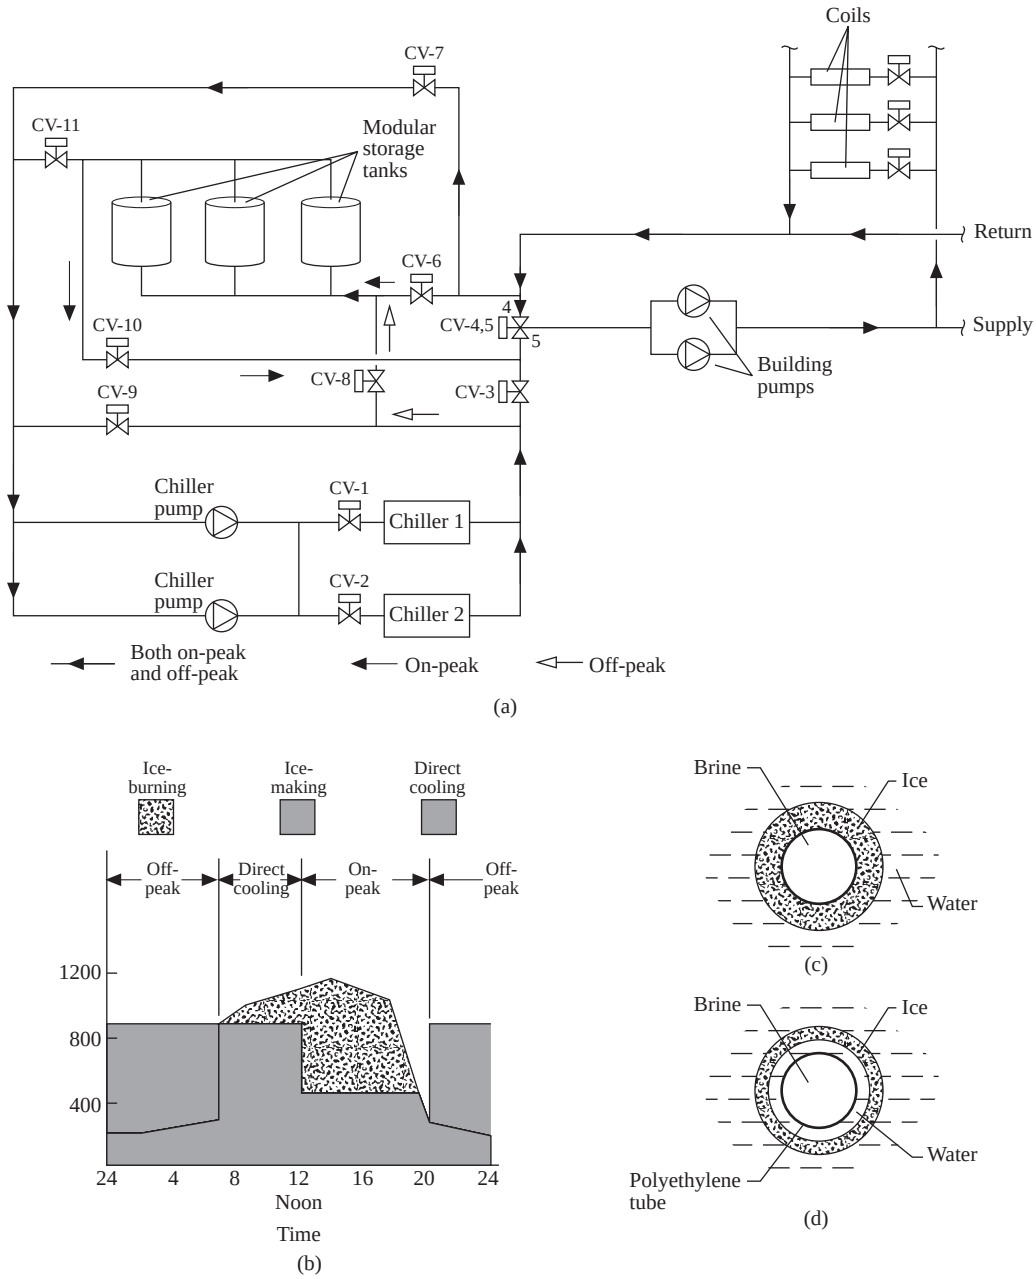

FIGURE 9.12.1 A brine-coil ice-storage system: (a) schematic diagram, (b) partial-storage time schedule, (c) ice making, and (d) ice burning.

Ice-Storage Systems

System Characteristics

In an *ice-thermal-storage* system, or simply an *ice-storage* system, ice is stored in a tank or other containers to provide cooling for buildings in on-peak hours or on- and partial-peak hours. One pound of ice can store [(1 × 144) + (55 – 35)] = 164 Btu instead of (60 – 44) = 16 Btu for chilled water storage. For the same cooling capacity, the storage volume of ice is only about 12% of chilled water. In addition,

an air-conditioning system using ice storage often adopts cold air distribution to supply conditioned air at a temperature typically at 44°F. Cold air distribution reduces the size of air-side equipment, ducts, and investment as well as fan energy use. It also improves the indoor air quality of the conditioned space. Since the late 1980s, ice storage has gained more applications than chilled water storage.

Brine is a coolant without freezing and flashing during normal operation. The freezing point of brine, which has a mass fraction of ethylene glycol of 25%, drops to 10°F, and a mass fraction of propylene glycol of 25% drops to 15°F. Glycol-water, when glycol is dissolved in water, is another coolant widely used in ice-storage systems. Ice crystals are formed in glycol-water when its temperature drops below its freezing point during normal operation.

In an ice-storage system, *ice making* or *charging* is a process in which compressors are operated to produce ice. *Ice burning*, or *discharging*, is a process in which ice is melted to cool the brine or glycol-water to offset refrigeration load.

Brine-Coil Ice-Storage Systems. Currently used ice-storage systems include brine-coil, ice-harvester, and ice-on-coil systems. According to Knebel (1995), the brine-coil ice-storage system is most widely used today because of its simplicity, flexibility, and reliability as well as using modular ice-storage tanks.

In a typical brine-coil ice-storage system, ice is charged in multiple modular factory-fabricated storage tanks as shown in Figure 9.12.1(a). In each storage tank, closely spaced polyethylene or plastic tubes are surrounded by water. Brine, a mixture of 25 to 30% of ethylene glycol by mass and 70 to 75% water, circulates inside the tubes at an entering temperature of 24°F during the ice-making process. The water surrounding the tubes freezes into ice up to a thickness of about 1/2 in. as shown in Figure 9.12.1(c). Brine leaves the storage tank at about 30°F. Water usually at atmospheric pressure is separated from brine by a plastic tube wall. Plastic tubes occupy about one tenth of the tank volume, and another one tenth remains empty for the expansion of ice. Multiple modular storage tanks are always connected in parallel.

During the ice-melting or -burning process, brine returns from the cooling coils in the air-handling units (AHUs) at a temperature of 46°F or higher. It melts the ice on the outer surface of the tubes and is thus cooled to a temperature of 34 to 36°F, as shown in Figure 9.12.1(d). Brine is then pumped to the AHUs to cool and dehumidify the air again.

Case Study of a Brine-Coil Ice-Storage System. In Tackett (1989), a brine-coil ice-storage system cools a 550,000-ft^2 office building near Dallas, TX, as shown in Figure 9.12.1(a). Ethylene glycol water is used as the brine. There are two centrifugal chillers, each of them having a refrigeration capacity of 568 tons when 34°F brine is produced with a power consumption of 0.77 kW/ton for direct cooling. The refrigeration capacity drops to 425 tons if 24°F brine leaves the chiller with a power consumption of 0.85 kW/ton. A demand-limited partial storage is used, as shown in Figure 9.12.1(b). During on-peak hours, ice is melted; at the same time one chiller is also operating. The system uses 90 brine-coil modular storage tanks with a full-charged ice-storaged capacity of 7500 ton.hr.

For summer cooling, the weekdays' 24-hr day-and-night cycle is divided into three periods:

- Off peak lasts from 8 p.m. to AHU's start the next morning. Ice is charged at a maximum capacity of 650 tons. The chillers also provide 200 tons of direct cooling for refrigeration loads that operate 24 hr continuously.
- Direct cooling lasts from AHU's start until noon on weekdays. Chillers are operated for direct cooling. If required refrigeration load exceeds the chillers' capacity, some ice storage will be melted to supplement the direct cooling.
- On peak lasts from noon to 8 p.m. Ice is burning with one chiller in operation. During ice burning, water separates the tube and ice. Water has a much lower thermal conductivity (0.35 Btu/hr.ft.°F) than ice (1.3 Btu/hr.ft.°F). Therefore, the capacity of a brine-coil ice-storage system is dominated by the ice burning.

Ice-Harvester Ice-Storage Systems. In an *ice-harvester* system, glycol-water flows on the outside surface of the evaporator and forms ice sheets with a thickness of 0.25 to 0.40 in. within 20 to 30 min. Ice is harvested in the form of flakes when hot gas is flowing inside the tubes of the evaporator during a time interval of 20 to 30 sec. Ice flakes fall to the glycol-water in the storage tank below. The glycol-water at a temperature of 34°F is then supplied to the cooling coils in AHUs for conditioning. After cooling and dehumidifying the air, glycol-water returns to the storage tank at a temperature of 50 to 60°F and is again cooled to 34°F again.

Ice harvesting is an intermittent process. It has a cycle loss due to harvesting of about 15%. In addition, because of its operating complexity and maintenance, its applications are more suitable for large ice-storage systems.

Ice-on-Coil Ice-Storage Systems. In an ice-on-coil system, refrigerant is evaporated in the coils submerged in water in a storage tank. Ice of a thickness not exceeding 0.25 in. builds up on the outer surface of the coils. The remaining water in the storage tank is used for cooling in AHUs. Ice-on-coil systems need large amounts of refrigerant charge and are less flexible in operation. They are usually used in industrial applications.

Ice-in-Containers Ice-Storage Systems. Ice-in-containers ice-storage systems store ice in enclosed containers. Brine circulating over the containers produces the ice inside containers. Complexity in control of the ice inventory inside the containers limits the application of the ice-in-containers systems.

Chilled-Water Storage Systems

Basics

Chilled-water storage uses the same water chiller and a similar coolant distribution system, except for additional water storage tanks and corresponding piping, additional storage pumps, and controls. The larger the chilled-water storage system, the lower the installation cost per ton.hr storage capacity.

Various types of storage tanks had been used in chilled-water storage systems during the 1970s. A diaphragm tank uses a rubber diaphragm to separate the colder and warmer water. Baffles divide the tank into cells and compartments. Today, stratified tanks have become the most widely used chilled-water storage systems because of their simplicity, low cost, and negligible difference in loss of cooling capacity between stratified tanks and other types of storage tanks.

During the storage of chilled water, the loss in cooling capacity includes direct mixing, heat transfer between warmer return chilled water and colder stored chilled water, and also heat transfer between warmer ambient air and colder water inside the tank. An enthalpy-based easily measured index called *figure of merit* (*FOM*) is often used to indicate the loss in cooling capacity during chilled-water storage. FOM is defined as:

$$\text{FOM} = q_{\text{dis}} / q_{\text{ch}} \tag{9.12.1}$$

where q_{dis} = cooling capacity available in the discharge process, Btu/hr
q_{ch} = theoretical cooling capacity available during charging process, Btu/hr

Charging is the process of filling the storage tank with colder chilled water from the chiller. At the same time, warmer return chilled water is extracted from the storage tank and pumped to the chiller for cooling.

Discharging is the process of discharging the colder stored chilled water from the storage tank to AHUs and terminals. Meanwhile, the warmer return chilled water from the AHUs and terminals fills the tank.

Stratified Tanks. *Stratified tanks* utilize the buoyancy of warmer return chilled water to separate it from the colder stored chilled water during charging and discharging, as shown in Figure 9.12.2(a). Colder stored chilled water is always charged and discharged from bottom diffusers, and the warmer return chilled water is introduced to and withdrawn from the top diffusers.

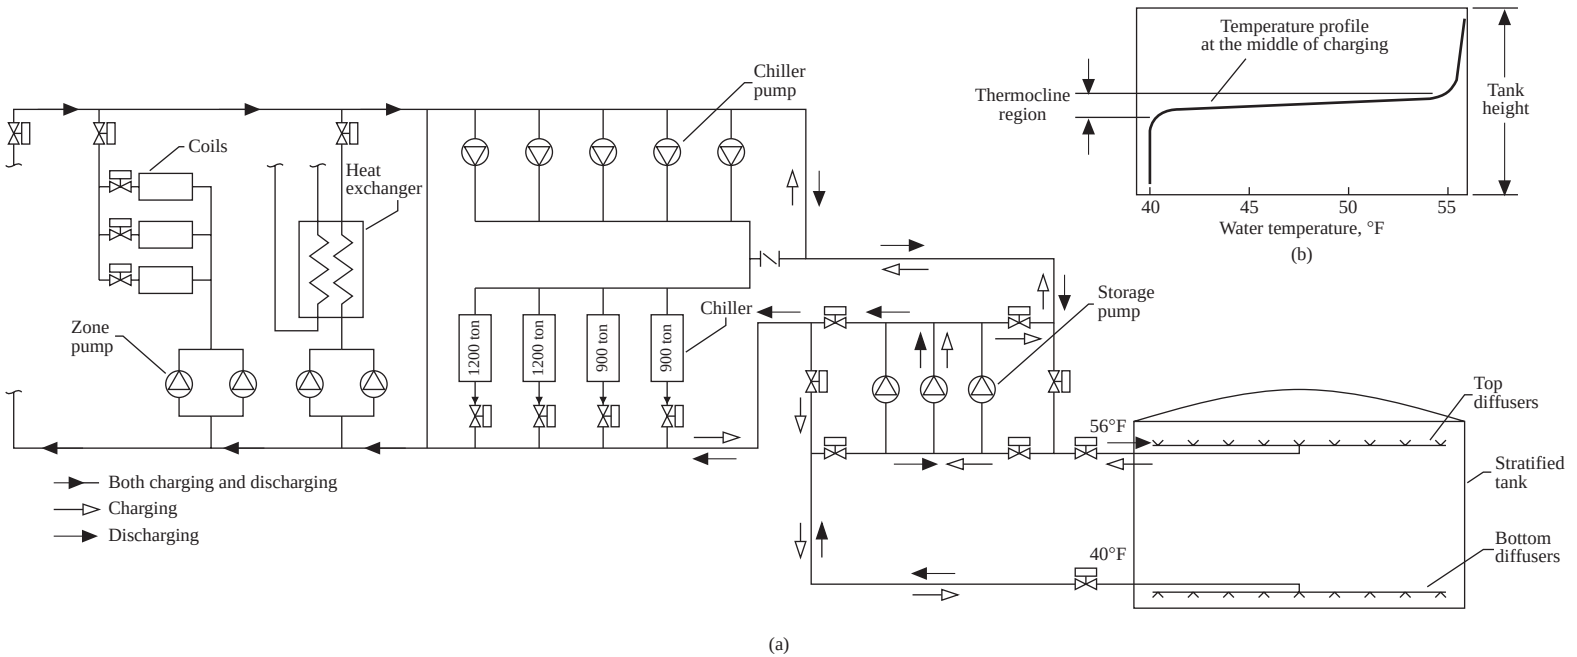

FIGURE 9.12.2 A chilled-water storage system using stratified tanks: (a) schematic diagram of a chilled-water storage system and (b) thermocline at the middle of charging process.

Chilled-water storage tanks are usually vertical cylinders and often have a height-to-diameter ratio of 0.25:0.35. Steel is the most commonly used material for above-grade tanks, with a 2-in.-thick spray-on polyurethane foam, a vapor barrier, and a highly reflective coating. Concrete, sometimes precast, prestressed tanks are widely used for underground tanks.

A key factor to reduce loss in cooling capacity during chilled water storage is to reduce mixing of colder and warmer water streams at the inlet. If the velocity pressure of the inlet stream is less than the buoyancy pressure, the entering colder stored chilled water at the bottom of tank will stratify. Refer to Wang's handbook (1993) and Knebel (1995) for details.

A *thermocline* is a stratified region in a chilled-water storage tank of which there is a steep temperature gradient as shown in Figure 9.12.2(b). Water temperature often varies from 42°F to about 60°F. Thermocline separates the bottom colder stored chilled water from the top warmer return chilled water. The thinner the thermocline, the lower the mixing loss.

Diffusers and symmetrical connected piping are used to evenly distribute the incoming water streams with sufficient low velocity, usually lower than 0.9 ft/sec. Inlet stream from bottom diffusers should be downward and from the top diffusers should be upward or horizontal.

Field measurements indicate that stratified tanks have a FOM between 0.85 to 0.9.

9.13 Air System Basics

Fan-Duct Systems

Flow Resistance

Flow resistance is a property of fluid flow which measures the characteristics of a flow passage resisting the fluid flow with a corresponding total pressure loss Δp, in in. WG, at a specific volume flow rate $\mathring{V}$, in cfm:

$$\Delta p = R\mathring{V}^2 \tag{9.13.1}$$

where R = flow resistance (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in series, its flow resistance R_s, in in. WG/(cfm)^2, can be calculated as

$$R_s = R_1 + R_2 + \ldots + R_n \tag{9.13.2}$$

where R_1, R_2, … R_n = flow resistance of duct section 1, 2, … n in the duct system (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in parallel, its flow resistance R_p, in in. WG/(cfm)^2, is:

$$1/\sqrt{R_p} = 1/\sqrt{R_1} + 1/\sqrt{R_2} + \ldots + 1/\sqrt{R_n} \tag{9.13.3}$$

Fan-Duct System

In a *fan-duct system*, a fan or several fans are connected to ductwork or ductwork and equipment. The volume flow and pressure loss characteristics of a duct system can be described by its performance curve, called *system curve*, and is described by $\Delta p = R\,\mathring{V}^2$.

An *air system* or an air handling system is a kind of fan-duct system. In addition, an outdoor ventilation air system to supply outdoor ventilation air, an exhaust system to exhaust contaminated air, and a smoke control system to provide fire protection are all air systems, that is, fan-duct systems.

Primary, Secondary, and Transfer Air

Primary air is the conditioned air or makeup air. Secondary air is often the induced space air, plenum air, or recirculating air. Transfer air is the indoor air that moves to a conditioned space from an adjacent area.

System-Operating Point

A *system-operating point* indicates the operating condition of an air system or fan-duct system. Since the operating point of a fan must lie on the fan performance curve, and the operating point of a duct system on the system curve, the system operating point of an air system must be the intersection point P_s of the fan performance curve and system curve as shown in Figure 9.13.1(a).

Fan-Laws

For the same air system operated at speeds n_1 and n_2, both in rpm, their relationship of $\mathring{V}$ volume flow rate, in cfm, system total pressure loss, in in. WG, and fan power input, in hp, can be expressed as

$$\begin{aligned} \mathring{V}_2/\mathring{V}_1 &= n_2/n_1 \\ \Delta p_{t2}/\Delta p_{t1} &= (n_2/n_1)^2(\rho_2/\rho_1) \\ P_2/P_1 &= (n_2/n_1)^3(\rho_2/\rho_1) \end{aligned} \tag{9.13.4}$$

where ρ = air density (lb/ft^3). Subscripts 1 and 2 indicate the original and the changed operating conditions. For air systems that are geometrically and dynamically similar:

$$\begin{aligned} \mathring{V}_2 / \mathring{V}_1 &= \left(D_2/D_1\right)^3 \left(n_2/n_1\right) \\ \Delta p_{t2}/\Delta p_{t1} &= \left(D_2/D_1\right)^2 \left(n_2/n_1\right)^2 \left(\rho_2/\rho_1\right) \\ P_2/P_1 &= \left(D_2/D_1\right)^5 \left(n_2/n_1\right)^3 \left(\rho_2/\rho_1\right) \end{aligned} \tag{9.13.5}$$

where D = diameter of the impeller (ft).

Geometrically similar means that two systems are similar in shape and construction. For two systems that are dynamically similar, they must be geometrically similar, and in addition, their velocity distribution or profile of fluid flow should also be similar. When fluid flows in the air systems are at high Reynolds number, such as Re > 10,000, their velocity profiles can be considered similar to each other.

System Effect

The system effect Δp_{se}, in in. WG, of an air system is its additional total pressure loss caused by uneven or nonuniform velocity profile at the fan inlet, or at duct fittings after fan outlet, due to the actual inlet and outlet connections as compared with the total pressure loss of the fan test unit during laboratory ratings. The selected fan total pressure which includes the system effect Δp_{ts}, in in. WG, as shown in Figure 9.13.1(a), can be calculated as

$$\begin{aligned} \Delta p_{ts} &= \Delta p_{sy} + \Delta p_{se} = \Delta p_{sy} + \Delta p_{s.i} + \Delta p_{s.o} \\ &= \Delta p_{sy} + C_{s.i}\left(v_{fi}/4005\right)^2 + C_{s.o}\left(v_{fo}/4005\right)^2 \end{aligned} \tag{9.13.6}$$

where Δp_{sy} = calculated total pressure loss of the air system, in WG
$\Delta p_{s.i}$, $\Delta p_{s.o}$ = fan inlet and outlet system effect loss, in WG
$C_{s.i}$, $C_{s.o}$ = local loss coefficient of inlet and outlet system effect, in WG
v_{fi}, v_{fo} = velocity at fan inlet (fan collar) and fan outlet, fpm

Both $C_{s.i}$ and $C_{s.o}$ are mainly affected by the length of connected duct between the duct fitting and fan inlet or outlet, by the configuration of the duct fitting, and by the air velocity at the inlet or outlet. Because v_{fi} and v_{fo} are often the maximum velocity of the air system, system effect should not be overlooked. According to AMCA Fan and Systems (1973), a square elbow (height to turning radius ratio R/H = 0.75) connected to a fan inlet with a connected duct length of 2 D_e (equivalent diameter) and v_{fi} = 3000 fpm may have a 0.67 in. WG $\Delta p_{i.o}$ loss. Refer to AMCA Fan and Systems (1973) or Wang's handbook (1993) for details.

Modulation of Air Systems

Air systems can be classified into two categories according to their operating volume flow: constant volume and variable-air-volume systems. The volume flow rate of a *constant volume system* remains constant during all the operating time. Its supply temperature is raised during part load. For a *variable-air-volume* (*VAV*) *system*, its volume flow rate is reduced to match the reduction of space load at part-load operation. The system pressure loss of a VAV system can be divided into two parts: variable part Δp_{var} and fixed part Δp_{fix}, which is the set point of the duct static pressure control as shown in Figure 9.13.1(b) and (c). The *modulation curve* of a VAV air system its its operating curve, or the locus of system operating points when its volume flow rate is modulated at full- and part-load operation.

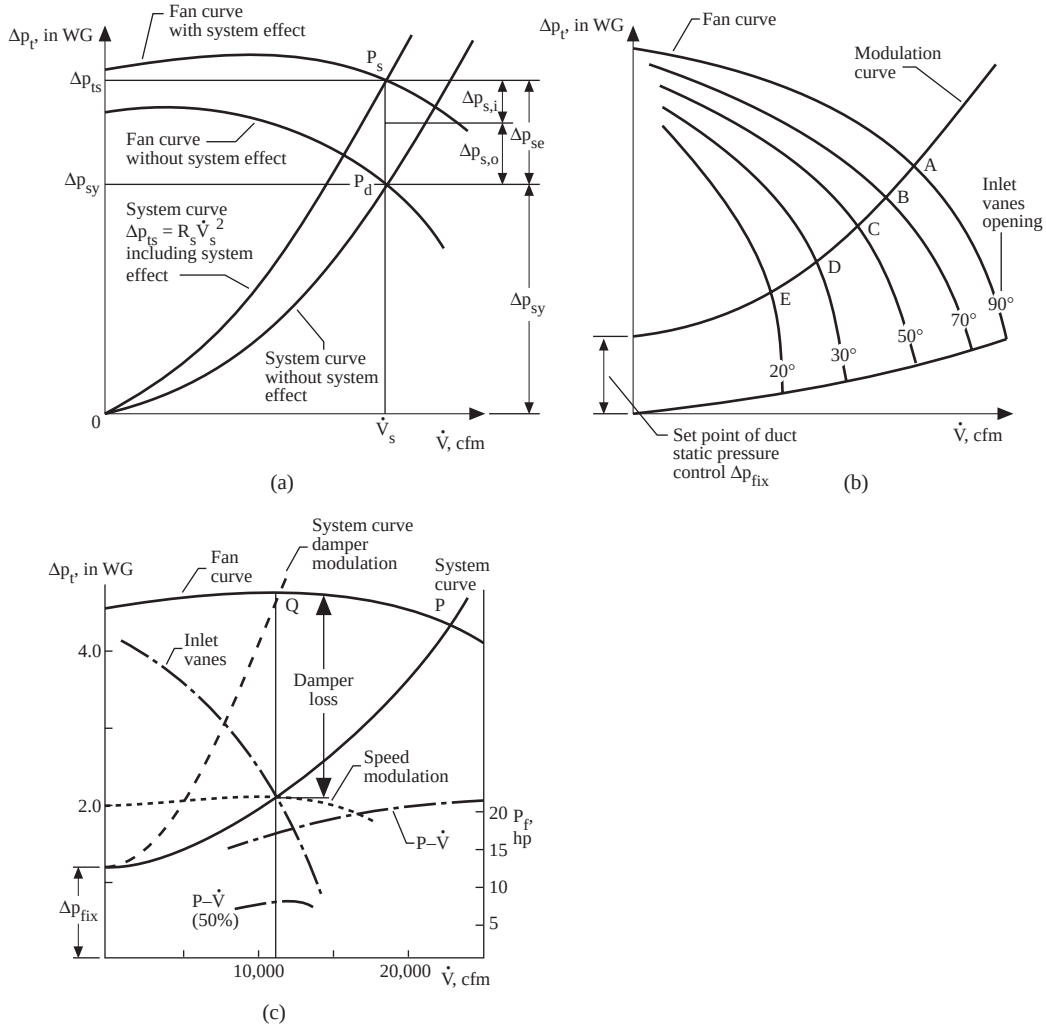

FIGURE 9.13.1 Air system $\dot{V}$-Δp_t performance: (a) system operating point and system effect, (b) modulation curve, and (c) damper, inlet vanes, and fan speed modulation.

The volume flow and system pressure loss of an air system can be modulated either by changing its fan characteristics or by varying its flow resistance of the duct system. Currently used types of modulation of volume flow rate of VAV air systems are

1. *Damper modulation* uses an air damper to vary the opening of the air flow passage and therefore its flow resistance.
2. *Inlet vanes modulation* varies the opening and the angle of inlet vanes at the centrifugal fan inlet and then gives different fan performance curves.
3. *Inlet cone modulation* varies the peripheral area of the fan impeller and therefore its performance curve.
4. *Blade pitch modulation* varies the blade angle of the axial fan and its performance curve.
5. *Fan speed modulation* using *adjustable frequency AC drives* varies the fan speed by supplying a variable-frequency and variable-voltage power source. There are three types of AC drives: adjustable voltage, adjustable current, and pulse width modulation (PWM). The PWM is universally applicable.

Damper modulation wastes energy. Inlet vanes are low in cost and are not so energy efficient compared with AC drives and inlet cones. Inlet cone is not expensive and is suitable for backward curved centrifugal fans. Blade pitch modulation is energy efficient and is mainly used for vane and tubular axial fans. AC drive is the most energy-efficient type of modulation; however, it is expensive and often considered cost effective for air systems using large centrifugal fans.

Example 9.13.1

A multizone VAV system equipped with a centrifugal fan has the following characteristics:

$\mathring{V}$ (cfm)	5,000	10,000	15,000	20,000	25,000
Δp_t, in. WG	4.75	4.85	4.83	4.60	4.20
P, hp		17.0	18.6	20.5	21.2

At design condition, it has a volume flow rate of 22,500 cfm and a fan total pressure of 4.45 in. WG. The set point of duct static pressure control is 1.20 in. WG.

When this VAV system is modulated by inlet vanes to 50% of design flow, its fan performance curves show the following characteristics:

$\mathring{V}$ (cfm)	5,000	10,000	11,250
Δp_t, in. WG	3.6	2.5	2.1
P, hp		7.5	7.8

Determine the fan power input when damper, inlet vanes, or AC drive fan speed modulation is used. Assume that the fan total efficiency remains the same at design condition when the fan speed is reduced.

Solutions

1. At 50% design flow, the volume flow of this VAV system is $0.5 \times 22{,}500 = 11{,}250$ cfm. The flow resistance of the variable part of this VAV system is

$$R_{var} = \Delta p_{va} = R\mathring{V}^2 = (4.45 - 1.20)/(22{,}500)^2 = 6.42 \times 10^{-9} \text{ in. WG}/(\text{cfm})^2$$

   When damper modulation is used, the system operating point Q must be the intersection of the fan curve and the system curve that has a higher flow resistance and a $\mathring{V}$ = 11,250 cfm. From Figure 9.13.1(c), at point Q, the fan power input is 17.0 hp.
2. From the given information, when inlet vane modulation is used, the fan power input is 7.8 hp.
3. The total pressure loss of the variable part of the VAV system at 50% volume flow is

$$\Delta p_{var} = R_{var}\mathring{V}^2 = 6.42 \times 10^{-9}(11{,}250)^2 = 0.81 \text{ in. WG}$$

   From Figure 9.13.1(c), since the fan power input at design condition is 21.2 hp, then its fan total efficiency is:

$$\eta_f = \mathring{V}\Delta p_{tf}/(6356P_f) = 22{,}500 \times 4.45/(6356 \times 21.2) = 74.3\%$$

   The fan power input at 50% design volume flow is:

$$P = \mathring{V}\Delta p_{tf}/(6356\eta_f) = 11{,}250(0.81 + 1.20)/(6356 \times 0.743) = 4.8 \text{ hp}$$

   Damper modulation has a energy waste of (17 – 4.8) = 12.2 hp

Fan Combinations in Air-Handling Units and Packaged Units

Currently used fan combinations in air-handling units (AHUs) and packaged units (PUs) (except dual-duct VAV systems) are shown in Figure 9.13.2(a), (b), and (c):

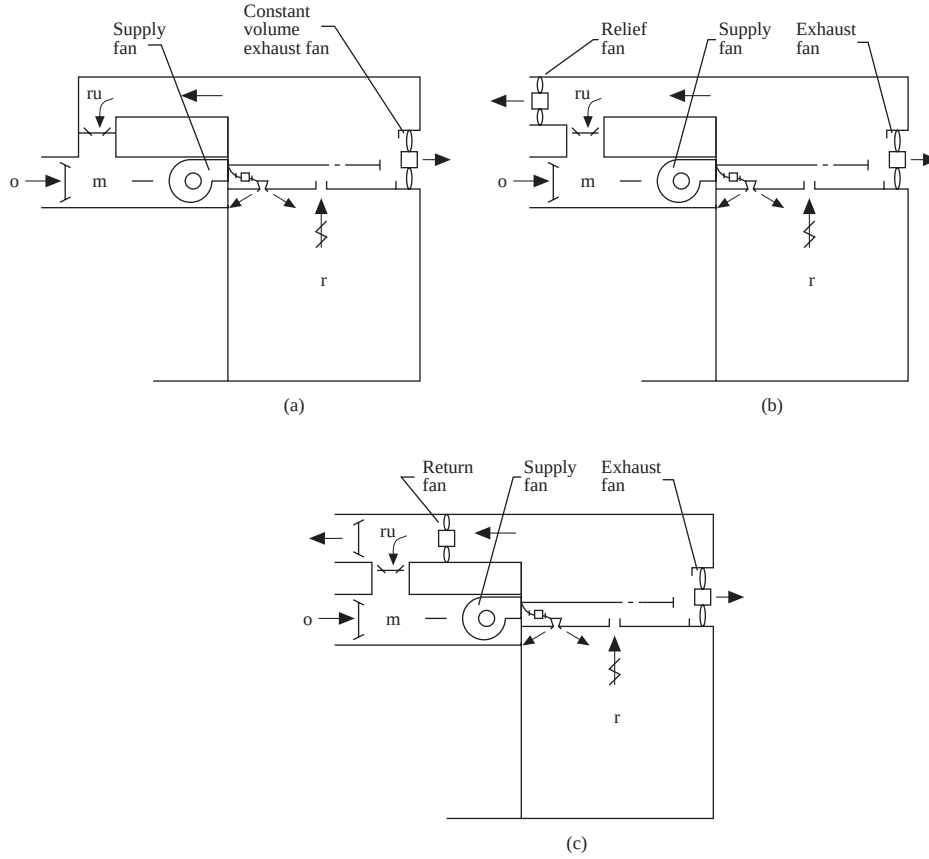

FIGURE 9.13.2 Fan combinations: (a) supply and exhaust fan, (b) supply and relief fan, and (c) supply and return fan.

Supply and Exhaust Fan/Barometric Damper Combination

An air system equipped with a single supply fan and a constant-volume exhaust fan, or a supply fan and a barometric damper combination as shown in Figure 9.13.2(a), is often used in buildings where there is no return duct or the pressure loss of the return duct is low. An all-outdoor air economizer cycle is usually not adopted due to the extremely high space pressure. A barometric relief damper is often installed in or connected to the conditioned space to prevent excessively high space pressure. When the space-positive pressure exerted on the barometric damper is greater than the weight of its damper and/or a spring, the damper is opened and the excessive space pressure is relieved.

Consider a VAV rooftop packaged system using a supply fan and a constant-volume exhaust system to serve a typical floor in an office building. This air system has the following design parameters:

During minimum outdoor ventilation air *recirculating mode* at summer design volume flow and at 50% of design volume flow, the outdoor damper is at its minimum opening. The recirculating damper is fully opened. The outdoor air intake at the PU must be approximately equal to the exfiltration at the conditioned space due to the positive space pressure p_r, in in. WG. By using the iteration method, the calculated pressure characteristics and the corresponding volume flow rates are shown below:

Supply volume flow rate:		20,000 cfm
Total pressure loss:	Across the recirculating damper	0.1 in. WG
	Filter and coils	2.5 in. WG
	Supply main duct	0.85 in. WG
	Return system between point r and ru	0.2 in. WG
Effective leakage area on the building shell		3.35 ft^2
Minimum outdoor ventilation air		3000 cfm
Space pressure at design flow		+0.05 in. WG

Point	**o**	**m**	**r**	**ru**
Design flow:				
p_o, in. WG	0	–0.20	+0.05	–0.15
$\dot{V}$, cfm	3,000	20,000	20,000	17,000
50% design:				
p_o, in. WG	0	–0.092	+0.0225	–0.052
$\dot{V}$, cfm	2,025	10,000	10,000	7,975

Here, o represents outdoor, m the mixing box, r the space, and ru the recirculating air inlet to the PU.

When the supply volume flow is reduced from the design volume flow to 50% of design flow during the recirculating mode, the total pressure in the mixing box increases from –0.20 to –0.092 in. WG and the outdoor air intake reduces from 3000 to 2025 cfm. Refer to Wang's (1993) *Handbook of Air Conditioning and Refrigeration* for details.

Supply and Relief Fan Combination

Figure 9.13.2(b) shows the schematic diagrams of an air system of supply fan and relief fan combination. A relief fan is used to relieve undesirable high positive space pressure by extracting space air and relieving it to the outside atmosphere. A relief fan is always installed in the relief flow passage after the junction of return flow, relief flow, and recirculating flow passage, point ru. It is usually energized only when the air system is operated in air economizer mode. A relief fan is often an axial fan. Since the relief fan is not energized during recirculating mode operation, the volume flow and pressure characteristics of a supply fan and relief fan combination are the same as that in a single supply fan and barometric damper combination when they have the same design parameters.

During air economizer mode, the outdoor air damper(s) are fully opened and the recirculating damper closed. The space pressure p_r = +0.05 in. WG is maintained by modulating the relief fan speed or relief damper opening. The pressure and volume flow characteristics of a supply and relief fan combination at design volume flow and 50% of design flow are as follows:

Point	**o**	**m**	**r**	**ru**
Design flow:				
p_o, in. WG	0	–0.20	+0.05	–0.15
$\dot{V}$, cfm	20,000	20,000	20,000	17,000

Point	**o**	**m**	**r**	**ru**
50% design:				
p_o, in. WG	0	–0.057	+0.05	+0.007
$\dot{V}$, cfm	10,000	10,000	10,000	7,000

Supply Fan and Return Fan Combination

A *return fan* is always installed at the upstream of the junction of return, recirculating, and exhaust flow passage, point ru as shown in Figure 9.13.2(c). A supply and return fan combination has similar pressure and volume flow characteristics as that of a supply and relief fan combination, except a higher total

pressure at point ru. If the return fan is improperly selected and has an excessive fan total pressure, total pressure at point m may be positive. There will be no outdoor intake at the PU or AHU, and at the same time there will also be a negative space pressure and an infiltration to the space.

Comparison of These Three Fan Combination Systems

A supply fan and barometric damper combination is simpler and less expensive. It is suitable for an air system which does not operate at air economizer mode and has a low pressure drop in the return system.

For those air systems whose pressure drop of return system is not exceeding 0.3 in. WG, or there is a considerable pressure drop in relief or exhaust flow passage, a supply and relief fan combination is recommended. For air systems whose return system has a pressure drop exceeding 0.6 in. WG, or those requiring a negative space pressure, a supply and return fan combination seems more appropriate.

Year-Round Operation and Economizers

Consider a typical single-duct VAV reheat system to serve a typical floor whose indoor temperature is 75°F with a relative humidity of 50%, as shown in Figure 9.13.3(a). During summer, the off-coil temperature is 55°F. The year-round operation of this air system can be divided into four regions on the psychrometric chart, as shown in Figure 9.13.3(b):

- *Region I — Refrigeration/evaporative cooling.* In this region, the enthalpy of the outdoor air h_o is higher than the enthalpy of the recirculating air h_{ru}, $h_o > h_{ru}$. It is more energy efficient to condition the mixture of recirculating air and minimum outdoor air.
- *Region II — Free cooling and refrigeration.* In this region, $h_o \le h_{ru}$. It is more energy efficient and also provides better indoor air quality to extract 100% outdoor air.
- *Region III — Free cooling evaporative cooling, and refrigeration.* In this region, extract 100% outdoor air for free cooling because $h_o \le h_{ru}$. Use evaporative cooling and refrigeration to cool and humidify if necessary.
- *Region IV — Winter heating.* Maintain a 55°F supply temperature by mixing the recirculating air with the outdoor air until the outdoor air is reduced to a minimum value. Provide heating if necessary.

An economizer is a device consisting of dampers and control that uses the free cooling capacity of either outdoor air or evaporatively cooled water from the cooling tower instead of mechanical refrigeration. An air economizer uses outdoor air for free cooling. There are two kinds of air economizers: enthalpy-based, in which the enthalpy of outdoor and recirculating air is compared, and temperature-based, in which temperature is compared. A water economizer uses evaporatively cooled water.

Fan Energy Use

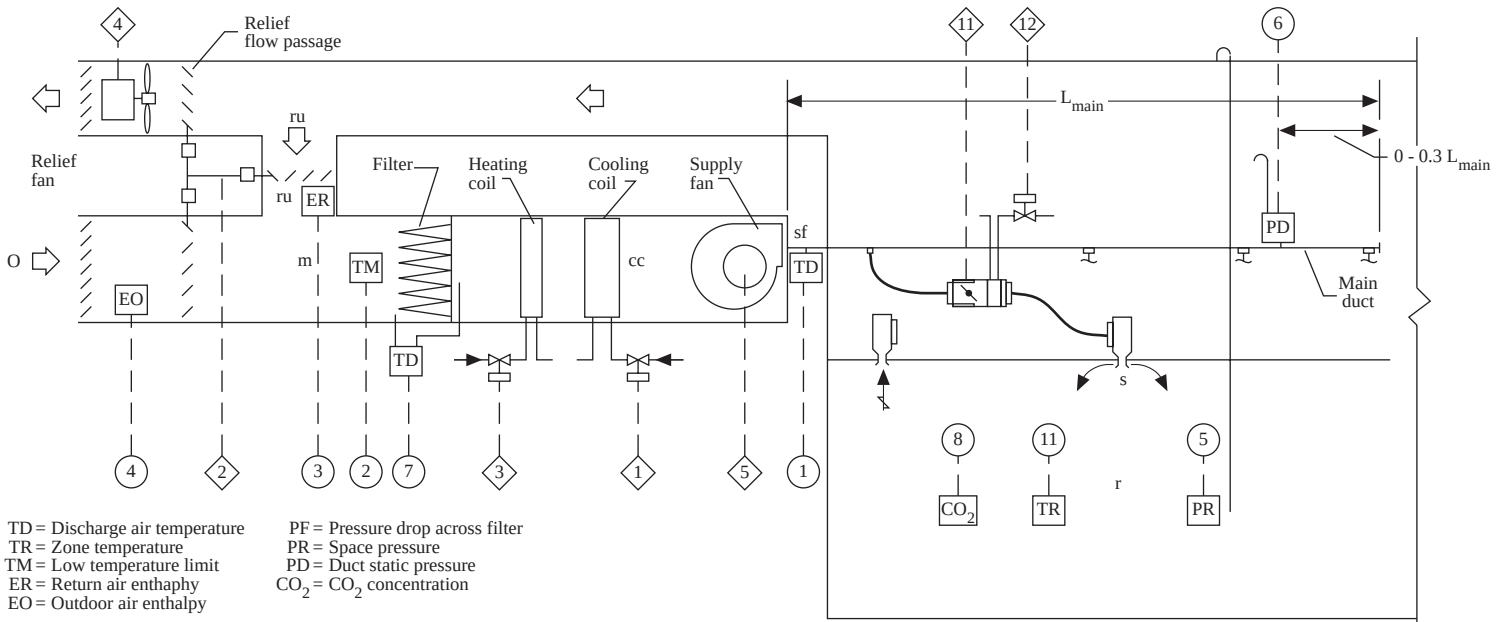
For an air system, fan energy use for each cfm of conditioned air supplied from the AHUs and PUs to the conditioned space within a certain time period, in W/cfm, can be calculated as

$$\text{W/cfm} = 0.1175\Delta p_{sy} / (\eta_f \eta_m) \tag{9.13.7}$$

where Δp_{sy} = mean system total pressure loss during a certain time period, in. WG
η_f = fan total efficiency
η_m = combined motor and drive (direct drive or belt drive) efficiency

For an air system using a separate outdoor ventilation system, its fan energy use, in W/cfm, is then calculated as

$$\text{W/cfm} = (1 + R_{o.s})\left[0.1175\Delta p_{sy} / (\eta_f \eta_m)\right] \tag{9.13.8}$$



(a)

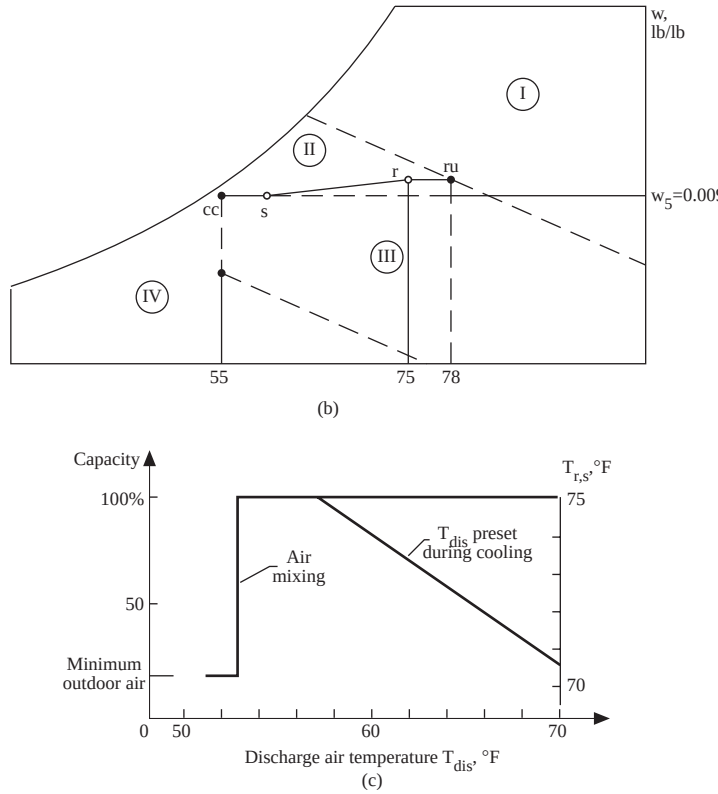

FIGURE 9.13.3bc

where $R_{o.s}$ = ratio of outdoor air volume flow rate to supply volume flow rate.

Outdoor Ventilation Air Supply

Basics

- An adequate amount of outdoor ventilation air supply is the key factor to provide acceptable indoor air quality (IAQ) for a conditioned space. Although an inadequate amount of outdoor ventilation air supply causes poor IAQ, an oversupply of outdoor ventilation air other than in an air economizer cycle is often a waste of energy.
- According to local codes and ANSI/ASHRAE Standard 62-1989, the minimum outdoor ventilation rate for each person must be provided at the outdoor air intake of AHU or PU, or by an outdoor air ventilation system. If the minimum outdoor ventilation air rate is reduced by using higher efficiency filters to remove air contaminants in the recirculating air, then indoor air contaminant concentration must be lower than the specified level in ANSI/ASHRAE Standard 62-1989.
- For a multizone air system, although the ratio of outdoor ventilation air rate to supply air volume flow rate required may be varied from zone to zone, the excessive outdoor air supply to a specified zone will increase the content of unused outdoor air in the recirculating air in AHU or PU. This helps to solve the problem in any zone that needs more outdoor air.
- Since the occupancy in many buildings is often variable and intermittent, a demand-based variable amount of outdoor ventilation air control should be used instead of time-based constant volume outdoor ventilation air control, except during the air economizer cycle.

- Carbon dioxide (CO_2) is a gaseous body effluent. CO_2 is an indicator of representative odor and an indicator of adequate outdoor ventilation rate at specific outdoor and indoor air concentration in a control zone at steady state. For most of the comfort air-conditioning systems, it is suitable to use CO_2 as a key parameter to control the intake volume flow rate of outdoor ventilation air to maintain an indoor CO_2 concentration not exceeding 800 to 1000 ppm in a critical or representative zone. As mentioned in Section 9.5, Persily (1993) showed that the actual measured indoor daily maximum CO_2 concentration levels in five buildings were all within 400 to 820 ppm.

If a field survey finds that a specific indoor air contaminant exceeds a specified indoor concentration, then a gas sensor for this specific contaminant or a mixed gas sensor should be used to control this specific indoor concentration level.

Types of Minimum Outdoor Ventilation Air Control. There are four types of minimum outdoor ventilation air control that are currently used:

- Type I uses a CO_2 sensor or a mixed gas sensor and a DDC controller to control the volume flow rate of outdoor ventilation air for a separate outdoor ventilation air system on the demand-based principle.
- Type II uses a CO_2 or mixed gas sensor and a DDC controller to control the ratio of the openings between outdoor and recirculating dampers and, therefore, the volume flow rates of outdoor air and recirculating air in AHUs or PUs on the demand-based principle.
- Type III uses a flow sensor or a pressure sensor and a DDC controller to control the openings of outdoor and recirculating dampers to provide a nearly constant volume outdoor air intake in VAV AHUs or VAV PUs.
- Type IV adjusts the opening of the outdoor damper manually to provide a constant volume of outdoor air in constant-volume AHUs and PUs. If the outdoor intake is mounted on the external wall without a windshield, the volume flow of outdoor ventilation air intake will be affected by wind force and direction.

Type I is the best minimum outdoor ventilation air control for the air system. For a VAV system, it is expensive. Type II is a better choice. Type III is more complicated and may cause energy waste. Type IV has the same result as Type III and is mainly used in constant-volume systems.

Outdoor intake must be located in a position away from the influence of exhaust outlets. Fans, control dampers, and filters should be properly operated and maintained in order to provide a proper amount of outdoor ventilation air as well as an acceptable IAQ.

9.14 Absorption System

Absorption systems use heat energy to produce refrigeration as well as heating if it is required. Water is the refrigerant and aqueous lithium bromide (LiBr) is widely used as the carrier to absorb the refrigerant and provide a higher coefficient of performance.

The mixture of water and anhydrous LiBr is called *solution*. The composition of a solution is usually expressed by its mass fraction, or percentage of LiBr, often called *concentration*. When the water vapor has boiled off from the solution, it is called *concentration solution*. If the solution has absorbed the water vapor, it is called *diluted solution*.

Absorption systems can be divided into the following categories:

- *Absorption chillers* use heat energy to produce refrigeration.
- *Absorption chiller/heaters* use direct-fired heat input to provide cooling or heating separately.
- *Absorption heat pumps* extract heat energy from the evaporator, add to the heat input, and release them both to the hot water for heating.
- *Absorption heat transformers* raise the temperature of the waste heat source to a required level.

Most recently installed absorption chillers use direct-fired natural gas as the heat source in many locations in the United States where there are high electric demand and electric rate at on-peak hours. Absorption chillers also are free from CFC and HCFC. An energy cost analysis should be done to determine whether an electric chiller or a gas-fired absorption chiller is the suitable choice.

Absorption heat pumps have only limited applications in district heating. Most absorption heat transformers need industrial waste heat. Both of them will not be covered here.

Double-Effect Direct-Fired Absorption Chillers

Figure 9.14.1(a) shows a double-effect direct-fired absorption chiller. *Double effect* means that there are two generators. *Direct fired* means that gas is directly fired at the generator instead of using steam or hot water. A single-effect absorption chiller using steam as the heat input to its single generator has a COP only from 0.7 to 0.8, whereas a double-effect direct-fired absorption chiller has a COP approximately equal to 1 and therefore is the mot widely used absorption chiller in the United States for new and retrofit projects today. The refrigeration capacity of double-effect direct-fired absorption chillers varies from 100 to 1500 tons.

A double-effect direct-fired absorption chiller mainly consists of the following components and controls:

- Evaporator — An *evaporator* is comprised of a tube bundle, spray nozzles, a water trough, a refrigerant pump, and an outer shell. Chilled water flows inside the tubes. A refrigerant pump sprays the liquid refrigerant over the outer surface of the tube bundle for a higher rate of evaporation. A water trough is located at the bottom to maintain a water level for recirculation.
- Absorber — In an *absorber*, there are tube bundles in which cooling water flows inside the tubes. Solution is sprayed over the outer surface of the tube bundle to absorb the water vapor. A solution pump is used to pump the diluted solution to the heat exchanger and low-temperature generator.
- Heat exchangers — There are two heat exchangers: *low-temperature heat exchanger* in which the temperature of hot concentrated solution is lower, and *high-temperature heat exchanger* in which the temperature of hot concentrated solution is higher. In both heat exchangers, heat is transferred from the hot concentrated solution to the cold diluted solution. Shell-and-tube or plate-and-frame heat exchangers are most widely used for their higher effectiveness.
- Generators — *Generators* are also called *desorbers*. In the *direct-fired generator*, there are the fire tube, flue tube, vapor/liquid separator, and flue-gas economizer. Heat is supplied from the gas burner or other waste heat source. The *low-temperature generator* is often of the shell-and-tube type. The water vapor vaporized in the direct-fired generator is condensed inside the tubes. The

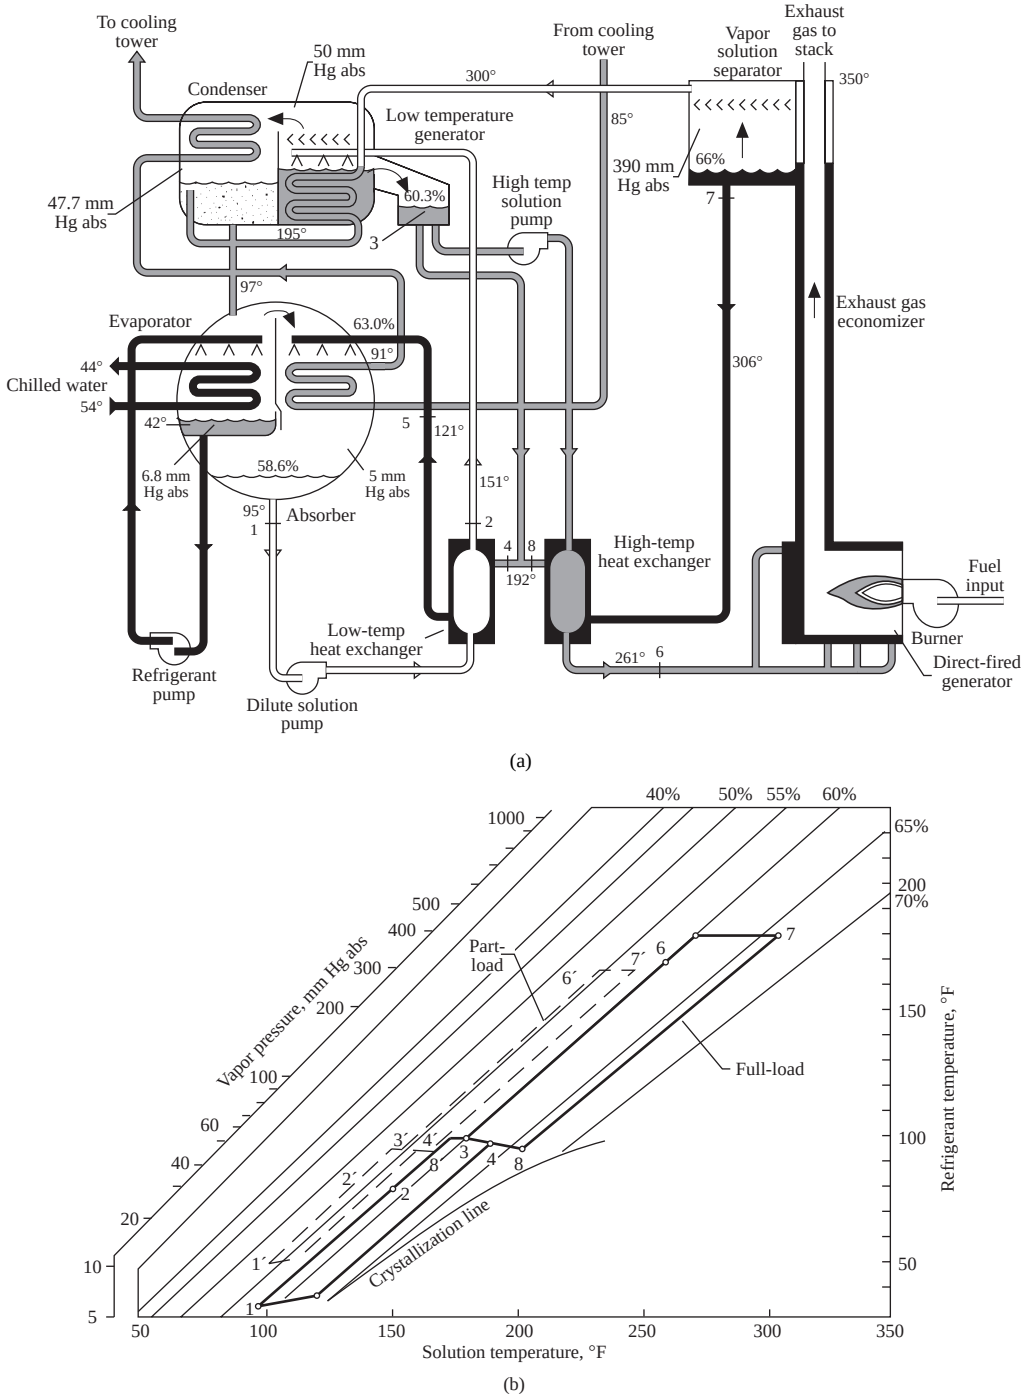

FIGURE 9.14.1 A double-effect direct-fired reverse-parallel-flow absorption chiller: (a) schematic diagram (reprinted by permission from the Trane catalog) and (b) absorption cycle.

latent heat of condensation thus released is used to vaporize the dilute solution in the low-temperature generator.

- Condenser — A condenser is usually also of the shell-and-tube type. Cooling water from the absorber flows inside the tubes.
- Throttling devices — Orifices and valves are often used as throttling devices to reduce the pressure of refrigerant and solution to the required values.
- Air purge unit — Since the pressure inside the absorption chiller is below atmospheric pressure, air and other noncondensable gases will leak into it from the ambient air. An *air purge unit* is used to remove these noncondensable gases from the chiller. A typical air purge unit is comprised of a pickup tube, a purge chamber, a solution spray, cooling water tubes, a vacuum pump, a solenoid valve, and a manual shut-off valve.

When noncondensable gases leak into the system, they tend to migrate to the absorber where pressure is lowest. Noncondensable gases and water vapor are picked from the absorber through the pickup tube. Water vapor is absorbed by the solution spray and returned to the absorber through a liquid trap at the bottom of the purge chamber. Heat of absorption is removed by the cooling water inside the tubes. Noncondensable gases are then evacuated from the chamber periodically by a vacuum pump to the outdoor atmosphere.

Palladium cells are used to continuously remove a small amount of hydrogen that is produced due to corrosion. Corrosion inhibitors like lithium chromate are needed to protect the machine parts from the corrosive effect of the absorbent when air is present.

Absorption Cycles, Parallel-, Series-, and Reverse-Parallel Flow

An *absorption* cycle shows the properties of the solution and its variation in concentrations, temperature, and pressure during absorbing, heat exchanging, and concentration processes on an equilibrium chart as shown in Figure 9.14.1(b). The ordinate of the equilibrium chart is the saturated temperature and pressure of water vapor, in °F and mm Hg abs. The abscissa is the temperature of the solution, in °F. Concentration lines are incline lines. At the bottom of the concentration lines, there is a *crystallization line* or *saturation line*. If the mass of fraction of LiBr in a solution which remains at constant temperature is higher than the saturated condition, that part of LiBr exceeding the saturation condition tends to form solid crystals.

Because there are two generators, the flow of solution from the absorber to generators can be in series flow, parallel flow, or reverse-parallel flow. In a series-flow system, the diluted solution from the absorber is first pumped to the direct-fired generator and then to the low-temperature generator. In a parallel-flow system, diluted solution is pumped to both direct-fired and low-temperature generators in parallel. In a reverse-parallel-flow system as shown in Figure 9.14.1(a), diluted solution is first pumped to the low-temperature generator. After that, the partly concentrated solution is then sent to the direct-fired generator as well as to the intermediate point 4 between high- and low-temperature heat exchangers in parallel. At point 4, partly concentrated solution mixes with concentrated solution from a direct-fired generator. A reverse-parallel-flow system is more energy efficient.

Solution and Refrigerant Flow

In a typical double-effect direct-fired reverse-parallel-flow absorption chiller operated at design full load, water is usually evaporated at a temperature of 42°F and a saturated pressure of 6.8 mm Hg abs in the evaporator. Chilled water returns from the AHUs or fan coils at a temperature typically 54°F, cools, and leaves the evaporator at 44°F. A refrigeration effect is produced due to the vaporization of water vapor and the removal of latent heat of vaporization from the chilled water.

Water vapor in the evaporator is then extracted to the absorber due to its lower vapor pressure. It is absorbed by the concentrated LiBr solution at a pressure of about 5 mm Hg abs. After absorption, the solution is diluted to a concentration of 58.6% and its temperature increases to 95°F (point 1). Most of the heat of absorption and the sensible heat of the solution is removed by the cooling water inside the

tube bundle. Diluted solution is then pumped by a solution pump to the low-temperature generator through a low-temperature heat exchanger.

In the low-temperature generator, the dilute solution is partly concentrated to 60.3% at a solution temperature of 180°F (point 3). It then divides into two streams: one of them is pumped to the direct-fired generator through a high-temperature heat exchanger, and the other stream having a slightly greater mass flow rate is sent to the intermediate point 4. In the direct-fired generator, the concentrated solution leaves at a concentration of 66% and a solution temperature of 306°F (point 7).

The mixture of concentrated and partly concentrated solution at point 4 has a concentration of 63% and a temperature of 192°F. It enters the low-temperature heat exchanger. Its temperature drops to 121°F before entering the absorber (point 5).

In the direct-fired generator, water is boiled off at a pressure of about 390 mm Hg abs. The boiled-off water vapor flows through the submerged tube in the low-temperature generator. The release of latent heat of condensation causes the evaporation of water from the dilution solution at a vapor pressure of about 50 mm Hg abs. The boiled-off water vapor in the low-temperature generator flows to the condenser through the top passage and is condensed into liquid water at a temperature of about 99°F and a vapor pressure of 47.7 mm Hg abs. This condensed liquid water is combined with the condensed water from the submerged tube at the trough. Both of them return to the evaporator after its pressure is throttled by an orifice plate.

Part-Load Operation and Capacity Control

During part-load operation, a double-effect direct-fired reverse-parallel-flow absorption chiller adjusts its capacity by reducing the heat input to the direct-fired generator through the burner. Lower heat input results at less water vapor boiled off from the solution in the generators. This causes the drop in solution concentration, the amount of water vapor extracted, the rate of evaporation, and the refrigeration capacity. Due to less water vapor being extracted, both evaporating pressure and temperature will rise. Since the amount of water vapor to be condensed is greater than that boiled off from the generators, both the condensing pressure and condensing temperature decrease.

Coefficient of Performance (COP)

The COP of an absorption chiller can be calculated as

$$\text{COP} = 12{,}000/q_{1g} \tag{9.14.1}$$

where q_{lg} = heat input to the direct-fired generator per ton of refrigeration output (Btu/hr.ton).

Safety Controls

Safety controls in an absorption chiller include the following:

- Crystallization controls are devices available to prevent crystallization and dissolve crystals. Absorption chillers are now designed to operate in a region away from the crystallization line. It is no longer a serious problem in newly developed absorption systems. One such device uses a bypass valve to permit refrigerant to flow to the concentration solution line when crystallization is detected. Condenser water temperature is controlled by using a three-way bypass valve to mix the recirculating water with the evaporated cooled water from the tower to avoid the sudden drop of the temperature of concentrated solution in the absorber.
- Low-temperature cut-out control shuts down the absorption chiller if the temperature of the refrigerant in the evaporator falls below a preset limit to protect the evaporator from freezing.
- Chilled and cooling water flow switches stop the absorption chiller when the mass flow rate of chilled water or the supply of cooling water falls below a preset value.
- A high-pressure relief valve is often installed on the shell of the direct-fired generator to prevent its pressure from exceeding a predetermined value.

- Monitoring of low and high pressure of gas supply and flame ignition are required for direct-fired burner(s).
- Interlocked controls between absorption chiller and chilled water pumps, cooling water pumps, and cooling tower fans are used to guarantee that they are in normal operation before the absorption chiller starts.

Absorption Chiller/Heater

A double-effect direct-fired reverse-parallel-flow absorption chiller/heater has approximately the same system components, construction, and flow process as the absorption chiller. The cooling mode operation is the same as in an absorption chiller. During the heating mode of an absorption chiller/heater, its evaporator becomes the condenser and is used to condense the water vapor that has been boiled off from the direct-fired generator. At design condition, hot water is supplied at a temperature of 130 to 140°F. The condenser and the low-temperature generator are not in operation. (See Figure 9.14.1.)

In order to increase the coefficient of performance of the absorption chiller, a triple-effect cycle with three condensers and three desorbers has been proposed and is under development. A triple-effect absorption chiller is predicted to have a coefficient of performance of around 1.5. Its initial cost is also considerably increased due to a greater number of condensers and desorbers.

9.15 Air-Conditioning Systems and Selection

Basics in Classification

The purpose of classifing air-conditioning or HVAC&R systems is to distinguish one type from another so that an optimum air-conditioning system can be selected according to the requirements. Proper classification of air-conditioning systems also will provide a background for using knowledge-based expert systems to help the designer to select an air-conditioning system and its subsystems.

Since air system characteristics directly affect the space indoor environmental parameters and the indoor air quality, the characteristics of an air system should be clearly designated in the classification.

The system and equipment should be compatible with each other. Each system has its own characteristics which are significantly different from others.

Individual Systems

As described in Section 9.1, air conditoning or HVAC&R systems can be classified as individual, space, packaged, and central systems.

Individual systems usually have no duct and are installed only in rooms that have external walls and external windows. Individual systems can again be subdivided into the following.

Room Air-Conditioner Systems

A room air conditioner is the sole factory-fabricated self-contained equipment used in the room air-conditioning system. It is often mounted on or under the window sill or on a window frame as shown in Figure 9.1.1. A room air-conditioner consists mainly of an indoor coil, a small forward-curved centrifugal fan for indoor coil, a capillary tube, a low-efficiency dry and reusable filter, grilles, a thermostat or other controls located in the indoor compartment, and a rotary, scroll, or reciprocating compressor, an outdoor coil, and a propeller fan for the outdoor coil located in the outdoor compartment. There is an outdoor ventilation air intake opening and a manually operated damper on the casing that divides the indoor and outdoor compartments. Room air-conditioners have a cooling capacity between 1/2 to 2 tons.

The following are system characteristics of a room air-conditioner system:

Room heat pump system is a room air-conditioner plus a four-way reversing valve which provides both the summer cooling and winter heating.
Air system: single supply fan
Fan, motor, and drive combined efficiency: 25%
Fan energy use: 0.3 to 0.4 W/cfm
Fan speed: HI-LO 2-speed or HI-MED-LO 3-speed
Outdoor ventilation air system: type IV
Cooling system: DX system, air-cooled condenser
EER 7.5 to 9.5 Btu/hr.W
Evaporating temperature T_{ev} at design load: typically 45°F
Heating system: electric heating (if any)
Part-load: on–off of refrigeration compressor
Sound level: indoor NC 45 to 50
Maintenance: More maintenance work is required.

Summer and winter mode air-conditioning cycles of a room air-conditioning system are similar to that shown in Figure 9.3.4.

All fan, motor, and drive combined efficiencies for various air-conditioning systems are from data in ASHRAE Standard 90.1-1989.

Packaged Terminal Air-Conditioner (PTAC) Systems

A packaged terminal air-conditioner is the primary equipment in a PTAC system. A PTAC system is similar to a room air-conditioner system. Their main differences are

- A PTAC uses a wall sleeve and is intended to be mounted through the wall.
- Heating is available from hot water, steam, heat pump, electric heater, and sometimes even direct-fired gas heaters.

PTACs are available in cooling capacity between 1/2 to 1 1/2 tons and a heating capacity of 2500 to 35,000 Btu/hr.

Space (Space-Conditioning) Systems

Most space conditioning air-conditioning systems cool, heat, and filtrate their recirculating space air above or in the conditioned space. Space conditioning systems often incorporate heat recovery by transferring the heat rejected from the interior zone to the perimeter zone through the condenser(s). Space systems often have a separate outdoor ventilation air system to supply the required outdoor ventilation air.

Space systems can be subdivided into four-pipe fan-coil systems and water-source heat pump systems.

Four-Pipe Fan-Coil Systems

In a four-pipe fan-coil unit system, space recirculating air is cooled and heated at a fan coil by using four pipes: one chilled water supply, one hot water supply, one chilled water return, and one hot water return. Outdoor ventilation air is conditioned at a make-up AHU or primary AHU. It is then supplied to the fan coil where it mixes with the recirculating air, as shown in Figure 9.15.1(a), or is supplied to the conditioned space directly.

A *fan-coil unit* or a *fan coil* is a *terminal* as shown in Figure 9.15.1(b). Fan-coil units are available in standard sizes 02, 03, 04, 06, 08, 10, and 12 which correspond to 200 cfm, 400 cfm, and so on in volume flow.

The following are system characteristics of a four-pipe fan-coil system:

A *two-pipe fan-coil system* has a supply and a return pipe only. Because of the problems of changeover from chilled water to hot water and vice versa, its applications are limited.

A *water-cooling electric heating fan-coil system* uses chilled water for cooling and an electric heater for heating as shown in Figure 9.1.2. This system is often used in a location that has a mild winter.

Air system:

Fan-coil, space air recirculating
Fan, motor, and drive combined efficiency: 25%
Fan speed: HI-LO 2-speed and HI-MED-LO 3-speed
External pressure for fan coil: 0.06 to 0.2 in. WG
System fan(s) energy use: 0.45 to 0.5 W/cfm
No return air and return air duct
Outdoor ventilation air system: type I
An exhaust system to exhaust part of the outdoor ventilation air

Cooling system: chilled water from centrifugal or screw chiller

Water-cooled chiller energy use: 0.4 to 0.65 kW/ton

Heating system: hot water from boiler, electric heater

Part load: control the flow rate of chilled and hot water supplied to the coil. Since air leaving coil temperature T_{cc} rises during summer mode part load, space relative humidity will be higher.

Sound level: indoor NC 40 to 45

Maintenance: higher maintenance cost

System fan(s) energy use: 0.45 to 0.55 W/cfm (includes all fans in the four-pipe fan-coil system)

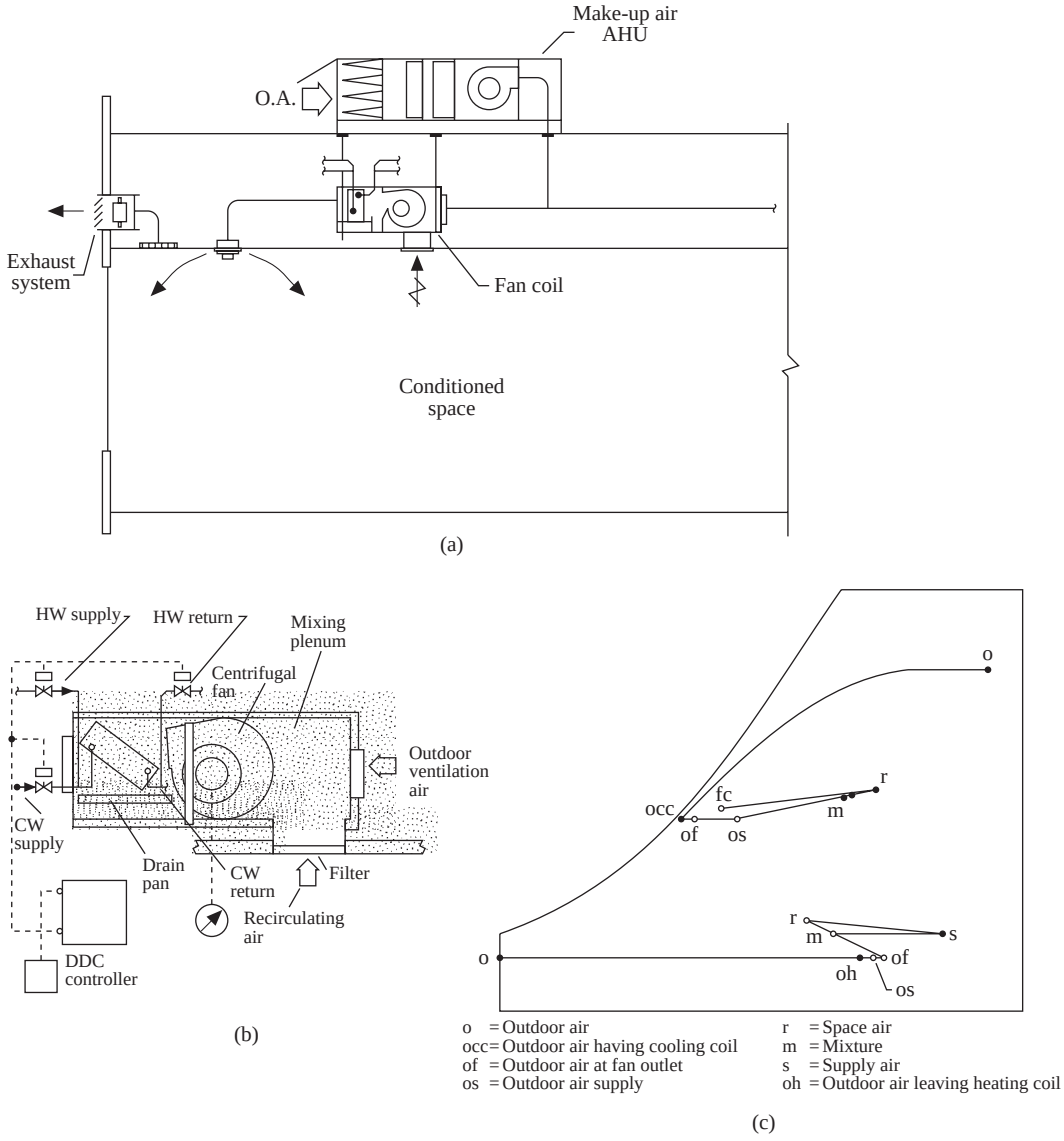

FIGURE 9.15.1 A four-pipe fan-coil system: (a) schematic diagram, (b) fan-coil unit, and (c) air-conditioning cycle.

An air-conditioning cycle for a four-pipe fan-coil system with outdoor ventilation air delivered to the suction side of the fan coil is shown in Figure 9.15.1(c). A part of the space cooling and dehumidifying load is usually taken care by the conditioned outdoor ventilation air from the make-up AHU. A double-bundle condenser is often adopted in a centrifugal chiller to incorporate heat recovery for providing winter heating.

Water-Source Heat Pump Systems

Water-source heat pumps (WSHPs) are the primary equipment in a water-source heat pump system as shown in Figure 9.15.2(a). A *water-source heat pump* usually consists of an air coil to cool and heat the air; a water coil to reject and extract heat from the condenser water; a forward-curved centrifugal fan; reciprocating, rotary, or scroll compressor(s); a short capillary tube; a reversing valve; controls; and an outer casing. WSHPs could be either a horizontal or vertical unit. WSHPs usually have cooling

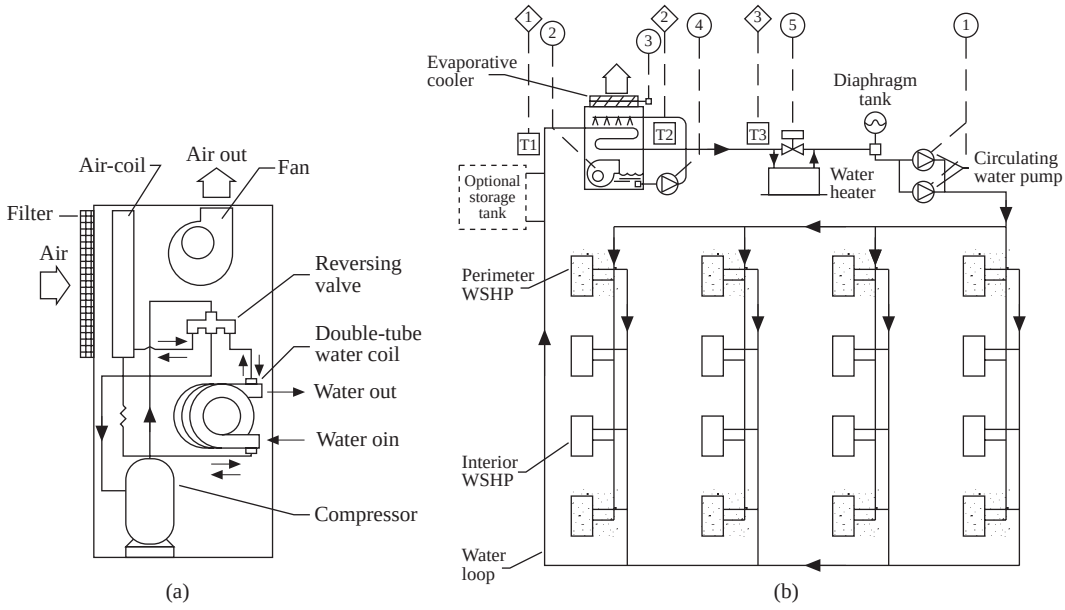

FIGURE 9.15.2 A water-source heat pump system: (a) vertical system and (b) system schematic diagram..

capacities between 1/2 to 26 tons. Small-capacity WSHPs of 3 tons or less without ducts are used in perimeter zones, whereas large-capacity WSHPs with ductwork are used only in interior zones.

In addition to the WSHPs, a WSHP system usually is also comprised of an evaporative cooler or cooling tower to cool the condenser water; a boiler to provide the supplementary heat for the condenser water if necessary; two circulating pumps, one of them being standby; and controls, as shown in Figure 9.15.2(b). A separate outdoor ventilation air system is required to supply outdoor air to the WSHP or directly to the space.

During hot weather, such as outdoor wet bulb at 78°F, all the WSHPs are operated in cooling mode. Condenser water leaves the evaporative cooler at a temperature typically 92°F and absorbs condensing heat rejected from the condensers — the water coils in WSHPs. Condenser water is then raised to 104°F and enters the evaporative cooler. In an evaporative cooler, condenser water is evaporatively cooled indirectly by atmospheric air, so that it would not foul the inner surface of water coils in WSHPs.

During moderate weather, the WSHPs serving the shady side of a building may be in heating mode, and while serving the sunny side of the building and the interior space in cooling mode. During cold weather, most of the WSHPs serving perimeter zones are in heating mode, while serving interior spaces are in cooling mode except morning warm-up. Cooling WSHPs reject heat to the condenser water loop; meanwhile heating WSHPs absorb heat from the condenser water loop. The condenser water is usually maintained at 60 to 90°F. If its temperature rises above 90°F, the evaporative cooler is energized. If it drops below 60°F, the boiler or electric heater is energized. A WSHP system itself is a combination of WSHP and a heat recovery system to transfer the heat from the interior space and sunny side of the building to the perimeter zone and shady side of building for heating in winter, spring, and fall.

System characteristics of air, cooling, and heating in a WSHP system are similar to a room conditioner heat pump system. In addition:

Outdoor ventilating air system: type I and IV
Water system: two-pipe, close circuit
Centrifugal water circulating pump
Water storage tank is optional

To prevent freezing in locations where outdoor temperature may drop below 32°F, isolate the outdoor portion of the water loop, outdoor evaporative cooler, and the pipe work from the indoor portion by using a plate-and-frame heat exchanger. Add ethylene or propylene glycol to the outdoor water loop for freezing protection.

There is another space system called a panel heating and cooling system. Because of its higher installation cost and dehumidification must be performed in the separate ventilation systems, its applications are very limited.

A space conditioning system has the benefit of a separate demand-based outdoor ventilation air system. A WSHP system incorporates heat recovery automatically. However, its indoor sound level is higher; only a low-efficiency air filter is used for recirculating air, and more space maintenance is required than central and packaged systems. Because of the increase of the minimum outdoor ventilation air rate to 15 cfm/person recently, it may gain more applications in the future.

Packaged Systems

In packaged systems, air is cooled directly by a DX coil and heated by direct-fired gas furnace or electric heater in a packaged unit (PU) instead of chilled and hot water from a central plant in a central system. Packaged systems are different from space conditioning systems since variable-air-volume supply and air economizer could be features in a packaged system. Packaged systems are often used to serve two or more rooms with supply and return ducts instead of serving individual rooms only in an individual system.

As mentioned in Section 9.7, packaged units are divided according to their locations into rooftop, split, or indoor units. Based on their operating characteristics, packaged systems can be subdivided into the following systems:

Single-Zone Constant-Volume (CV) Packaged Systems

Although a single-zone CV packaged system may have duct supplies to and returns from two or more rooms, there is only a single zone sensor located in the representative room or space. A CV system has a constant supply volume flow rate during operation except the undesirable reduction of volume flow due to the increase of pressure drop across the filter.

A single-zone CV packaged system consists mainly of a centrifugal fan, a DX coil, a direct-fired gas furnace or an electric heater, a low or medium efficiency filter, mixing box, dampers, DDC controls, and an outer casing. A relief or a return fan is equipped for larger systems.

A single-zone CV packaged system serving a church is shown in Figure 9.1.3. This system operates on basic air-conditioning cycles as shown in Figure 9.3.4 during cooling and heating modes.

The system characteristics of a single-zone CV packaged system are

Air system: single supply fan, a relief or return fan for a large system
- Fan, motor, and drive combined efficiency: 40 to 45%
- Fan total pressure: 1.5 to 3 in. WG
- Fan(s) energy use: 0.45 to 0.8 W/cfm
- Outdoor ventilation air system: type IV and II
- Enthalpy or temperature air economizer

Cooling systems: DX system, air cooled
- Compressor: reciprocating or scroll
- EER: 8.9 to 10.0 Btu/hr.W

Heating system: direct-fired gas furnace, air-source heat pump, or electric heating

Part load: on–off or step control of the compressor capacity, DX-coil effective area, and the gas flow to the burner

Sound level: indoor NC 35 to 45

Maintenance: higher maintenance cost than central systems

Single-zone, CV packaged systems are widely used in residences, small retail stores, and other commercial buildings.

Constant-Volume Zone-Reheat Packaged Systems

System construction and system characteristics of a CV zone-reheat system are similar to the single-zone CV packaged systems except:

1. It serves multizones and has a sensor and a DDC controller for each zone.
2. There is a reheating coil or electric heater in the branch duct for each zone.

A CV zone-reheat packaged system cools and heats simultaneously and therefore wastes energy. It is usually used for the manufacturing process and space needs control of temperature and humidity simultaneously.

Variable-Air-Volume Packaged Systems

A variable-air-volume (VAV) system varies its volume flow rate to match the reduction of space load at part load. A VAV packaged system, also called a *VAV cooling packaged system*, is a multizone system and uses a VAV box in each zone to control the zone temperature at part load during summer cooling mode operation, as shown in Figure 9.15.3(a).

A *VAV box* is a terminal in which the supply volume flow rate of the conditioned supply air is modulated by varying the opening of the air passage by means of a single blade damper, as shown in Figure 9.15.3(b), or a moving disc against a cone-shaped casing.

The following are the system characteristics of a VAV packaged system:

Single-zone VAV packaged system which serves a single zone without VAV boxes. A DDC controller modulates the position of the inlet vanes or the fan speed according to the signal of the space temperature sensor.

Air system: a supply/relief fan or supply/return fan combination. Space pressurization control by a relief/return fan
Fan, motor, and drive combined efficiency: 45%
Supply fan total pressure: 3.75 to 4.5 in. WG
Fan(s) energy use at design condition: 1 to 1.25 W/cfm
VAV box minimum setting: 30% of peak supply volume flow
Outdoor ventilation air system: type II and III
Economizer: enthalpy air economizer or water economizer
Cooling system: DX coil, air-, water-, or evaporative-cooled condenser
Compressor: reciprocating, scroll, and screw
EER: 8.9 to 12 Btu/hr.W
Capacity: 20 to 100 tons
Part load: zone volume flow modulation by VAV box; step control of compressor capacity; modulation of gas flow to burner; and discharge air temperature reset
Smoke control: exhausts smoke on the fire floor, and supplies air and pressurizes the floors immediately above or below the fire floor
Diagnostics: a diagnostic module displays the status and readings of various switches, dampers, sensors, etc. and the operative problems by means of expert system
Maintenance: higher than central system
Sound level: indoor NC 30 to 45

Heating system characteristics as well as the air-conditioning cycles are similar as that in a single-zone CV packaged system.

VAV Reheat Packaged Systems

A VAV reheat packaged system has its system construction and characteristics similar to that in a VAV packaged system except in each VAV box there is an additional reheating coil. Such a VAV box is called

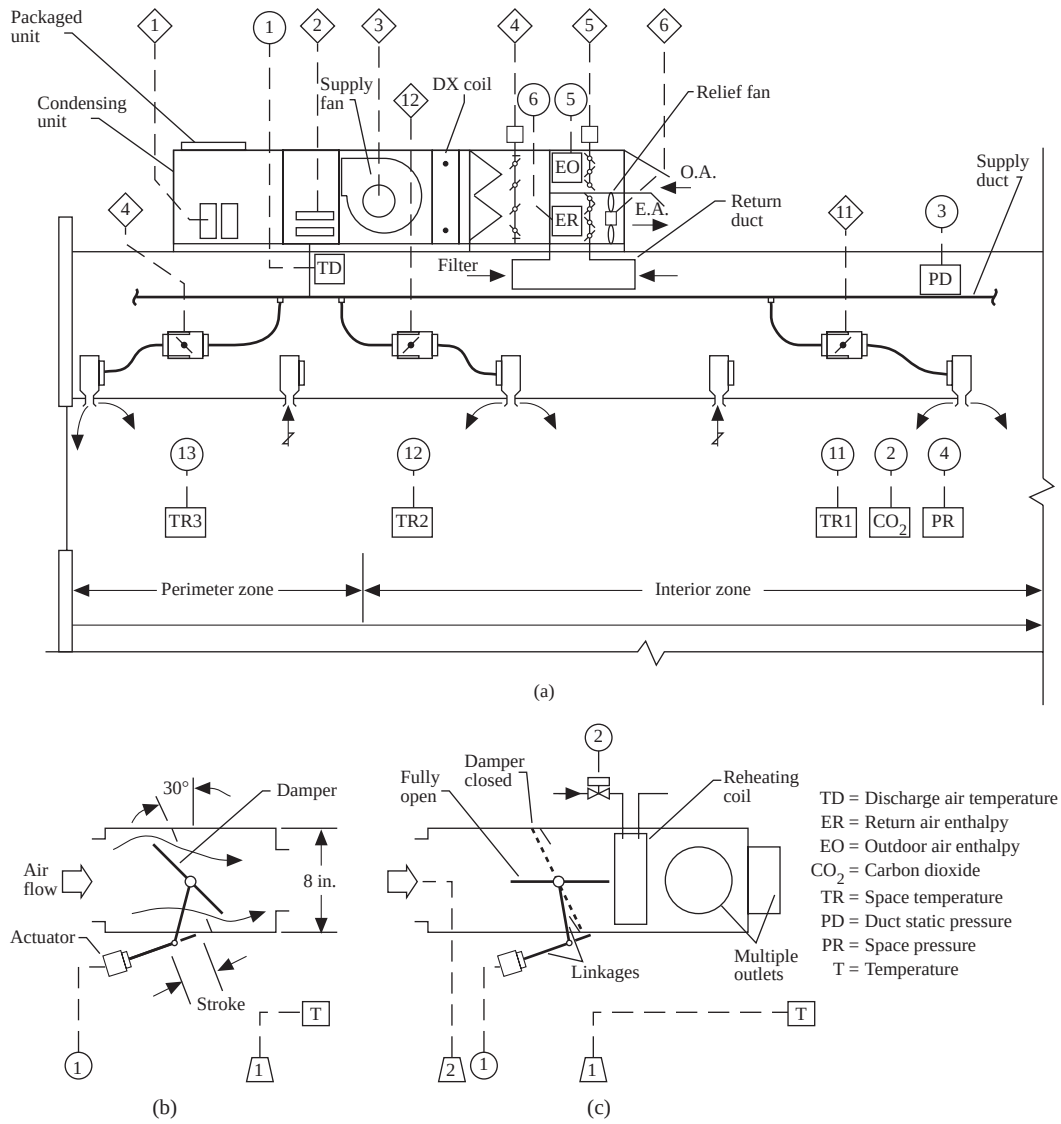

FIGURE 9.15.3 A variable-air-volume (VAV) package system: (a) schematic diagram, (b) VAV box, (c) reheating box, (d) parallel-flow fan-powered VAV box.

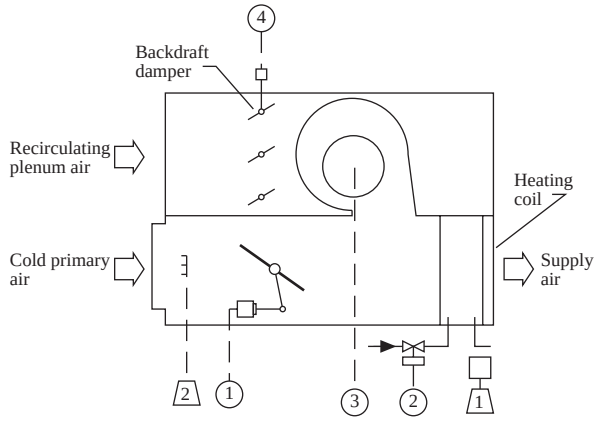
a *reheating VAV box*, as shown in Figure 9.15.2(a) and 9.15.3(c). VAV reheat packaged systems are used to serve perimeter zones where winter heating is required.

Fan-Powered VAV Packaged Systems

A fan-powered VAV packaged system is similar to that of a VAV packaged system except *fan-powered VAV boxes* as shown in Figure 9.15.3(d) are used instead of VAV boxes.

There are two types of fan-powered VAV boxes: parallel-flow and series-flow boxes. In a *parallel-flow* fan-powered box, the plenum air flow induced by the fan is parallel with the cold primary air flow through the VAV box. These two air streams are then combined and mixed together. In a *series-flow* box, cold primarily from the VAV box is mixed with the induced plenum air and then flows through the small fan. The parallel-flow fan-powered VAV box is more widely used.



(d)

FIGURE 9.15.3d

In a fan-powered VAV box, volume flow dropping to minimum setting, extracting of ceiling plenum air, and energizing of reheating coil will actuate in sequence to maintain the space temperature during part-load/heating mode operation. A fan-powered VAV box can also mix the cold primary air from cold air distribution with the ceiling plenum air and provides greater space air movements during minimum space load.

Packaged systems are lower in installation cost and occupy less space than central systems. During the past two decades, DDC-controlled packaged systems have evolved into sophisticated equipment and provide many features that only a built-up central system could provide before.

Central Systems

Central systems use chilled and hot water that comes from the central plant to cool and heat the air in the air-handling units (AHUs). Central systems are built-up systems. The most clean, most quiet thermal-storage systems, and the systems which offer the most sophisticated features, are always central systems. Central systems can be subdivided into the following.

Single-Zone Constant-Volume Central Systems

A single-zone CV central system uses a single controller to control the flow of chilled water, hot water, or the opening of dampers to maintain a predetermined indoor temperature, relative humidity, or air contaminants. They are often used in manufacturing factories. The system characteristics of a single-zone CV central system are

Single-zone CV air washer central system uses air washer to control both space relative humidity and temperature. This system is widely used in textile mills. The reason to use constant volume is to dilute the fiber dusts produced during manufacturing. A rotary filter is often used for high dust-collecting capacity.

Air system: supply and return fan combination
- Fan, motor, and drive combined efficiency: 45 to 50%
- Outdoor ventilation air system: type II and IV

Economizer: air or water economizer
Smoke control: exhaust smoke on the fire floor, and pressurize adjacent floor(s) or area
Cooling system: centrifugal or screw chiller, water-cooled condenser
- Cooling energy use: 0.4 to 0.65 kW/ton

Heating system: hot water from boiler or from heat recovery system

Part load: modulate the water mass flow to cooling and heating coils in AHUs, and discharge air temperature reset
Sound level: indoor NC 30 to 45. Silencers are used both in supply and return air systems if they are required
Maintenance: in central plant and fan rooms, lower maintenance cost

Single-Zone CV Clean Room Systems

This is the central system which controls the air cleanliness, temperature, and relative humidity in Class 1, 10, 100, 1000, and 10,000 clean rooms for electronic, pharmaceutical, and precision manufacturing and other industries. Figure 9.15.4(a) shows a schematic diagram of this system. The recirculating air unit (RAU) uses prefilter, HEPA filters, and a water cooling coil to control the space air cleanliness and required space temperature, whereas a make-up air unit (MAU) supplies conditioned outdoor air, always within narrow dew point limits to the RAU at any outside climate, as shown in Figure 9.15.4(b). A unidirectional air flow of 90 fpm is maintained at the working area. For details, refer to *ASHRAE Handbook 1991 HVAC Applications* and Wang's *Handbook of Air Conditioning and Refrigeration.*

CV Zone-Reheat Central Systems

These systems have their system construction and characteristics similar to that for a single-zone CV central system, except they serve multizone spaces and there is a reheating coil, hot water, or electric heating in each zone. CV zone-reheat central systems are often used for health care facilities and in industrial applications.

VAV Central Systems

A VAV central system is used to serve multizone space and is also called *VAV cooling central system.* Its schematic diagram is similar to that of a VAV packaged system (Figure 9.15.3) except air will be cooled or heated by water cooling or heating coils in the AHUs. The same VAV box shown in Figure 9.15.3(b) will be used in a VAV central system. The system characteristics of VAV central systems are as follows:

Single-zone VAV central system differs from a VAV central system only because it serves a single zone, and therefore there is no VAV box in the branch ducts. Supply volume flow is modulated by inlet vanes and AC inverter.

Air system: supply and relief/return fan combination
Fan, motor, and drive combined efficiency for airfoil centrifugal fan with AC inverter fan speed modulation: 55%
Fan(s) energy use: 0.9 to 1.2 W/cfm
VAV box: minimum setting 30% of peak supply volume flow
Outdoor ventilation air system: type I, II, and III
Cooling system: centrifugal, screw, and reciprocating chillers, water-cooled condenser, with energy use 0.4 to 0.65 kW/ton; or sometimes absorption chiller
Heating system: hot water from boiler or electric heating at the terminals
Economizer: air and water economizer
Part load: zone volume flow modulation, discharge air temperature reset, and chilled water temperature reset
Smoke control: exhausts smoke from the fire floor and pressurizes the immediate floors above and below
Sound level: indoor NC 20 to 40. Silencers are often used both in supply and return systems.
Maintenance: less space maintenance

VAV central systems are widely used for interior zone in buildings.

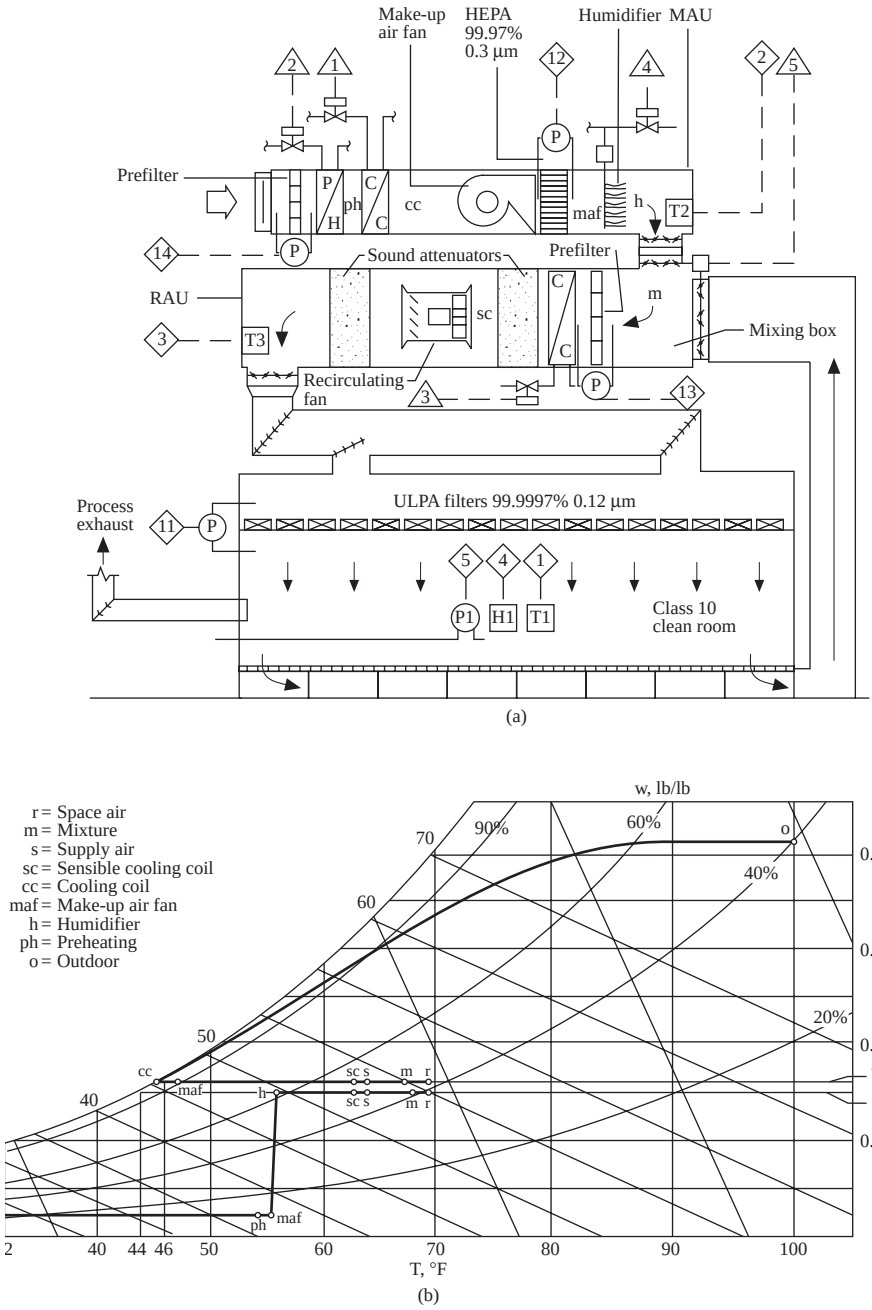


FIGURE 9.15.4 A single-zone CV clean room system: (a) schematic diagram and (b) air-conditioning cycle.

VAV Reheat Central Systems

A VAV reheat system is similar in system construction and characteristics to that in a VAV central system except that reheating boxes are used instead of VAV boxes in a VAV central system.

Fan-Powered VAV Central Systems

A fan-powered VAV central system is similar in system construction and characteristics to that in a VAV central system except that fan-powered VAV boxes are used instead of VAV boxes.

Dual-Duct VAV Central Systems

A dual-duct VAV system uses a warm air duct and a cold air duct to supply both warm and cold air to each zone in a multizone space, as shown in Figure 9.15.5(a). Warm and cold air are first mixed in a mixing VAV box, and are then supplied to the conditioned space. Warm air duct is only used for perimeter zones.

A *mixing VAV box* consists of two equal air passages, one for warm air and one for cold air, arranged in parallel. Each of them has a single blade damper and its volume flow rate is modulated. Warm and cold air are then combined, mixed, and supplied to the space.

A dual-duct VAV system is usually either a single supply fan and a relief/return fan combination, or a warm air supply fan, a cold air supply fan, and a relief/return fan. A separate warm air fan and cold air supply fan are beneficial in discharge air temperature reset and fan energy use.

During summer cooling mode operation, the mixture of recirculating air and outdoor air is used as the warm air supply. The heating coil is not energized. During winter heating mode operation, mixture of outdoor and recirculating air or 100% outdoor air is used as the cold air supply; the cooling coil is not energized.

Because there is often air leakage at the dampers in the mixing VAV box, more cold air supply is needed to compensate for the leaked warm air or leaked cold air.

Other system characteristics of a dual-duct VAV central system are similar to a VAV central system.

Dual-Duct CV Central System

This is another version of a dual-duct VAV central system and is similar in construction to a dual-duct VAV system, except that a mixing box is used instead of a mixing VAV box. The supply volume flow rate from a mixing box is nearly constant. Dual-duct CV central systems have only limited applications, like health care facilities, etc.

An ice- or chilled-water storage system is always a central system plus a thermal storage system. The thermal storage system does not influence the system characteristics of the air distribution, and air cooling and heating — except for a greater head lift for a refrigeration compressor — is needed for ice-storage systems. Therefore, the following central systems should be added:

- VAV ice-storage or chilled-water systems
- VAV reheat ice-storage or chilled-water storage systems
- Fan-powered VAV ice-storage systems

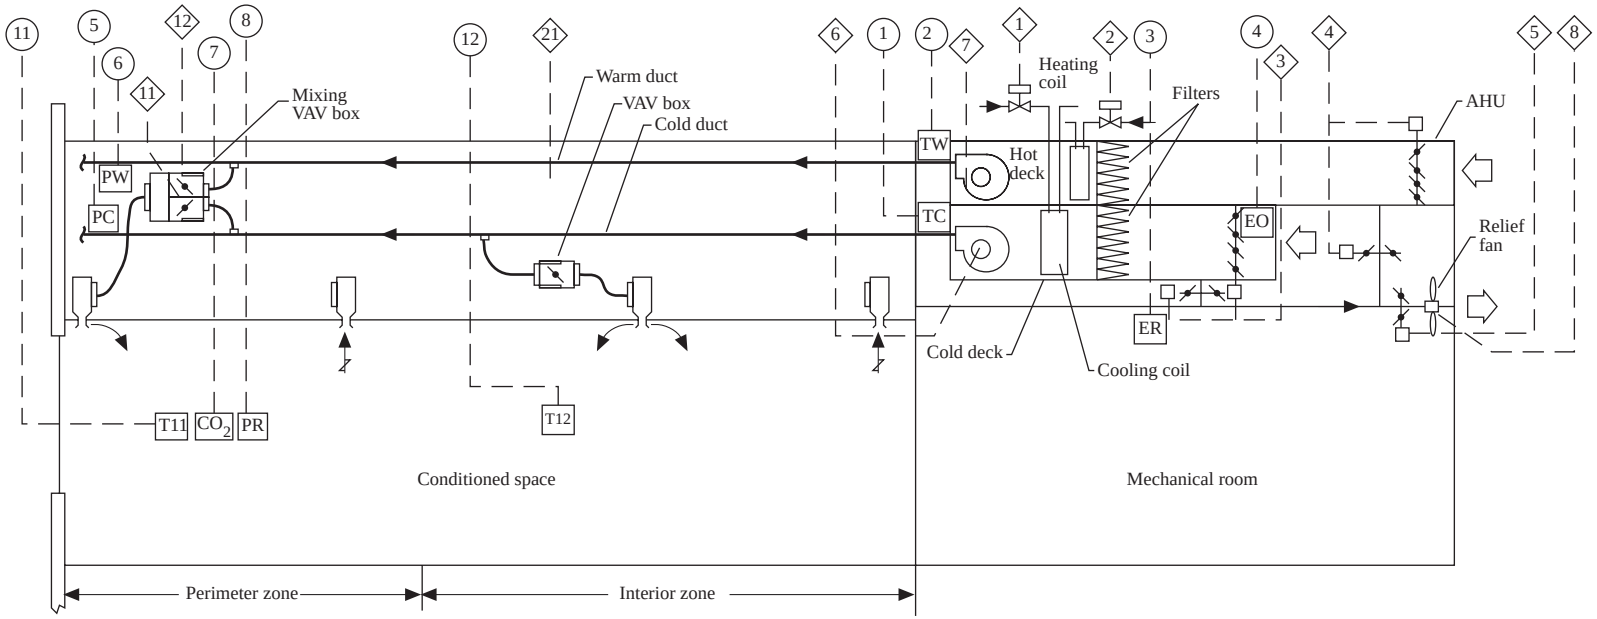
Some of the air-conditioning systems are not listed because they are not effective or are a waste of energy, and therefore rarely used in new and retrofit projects such as:

- High-velocity induction space conditioning systems which need a higher pressure drop primary air to induce recirculating air in the induction unit and use more energy than fan-coil systems
- Multizone central systems which mix warm and cool air at the fan room and use a supply duct from fan room to each control zone
- Air skin central systems which use a warm air heating system to offset transmission loss in the perimeter zone and overlook the effect of the solar radiation from variation building orientations

In the future, there will be newly developed systems added to this classification list.

Air-Conditioning System Selection

As described in Section 9.1, the goal of an air-conditioning or HVAC&R system is to provide a healthy, comfortable, manufacturable indoor environment at acceptable indoor air quality, keeping the system



(a)

FIGURE 9.15.5 A dual-duct VAV central system: (a) schematic diagram.

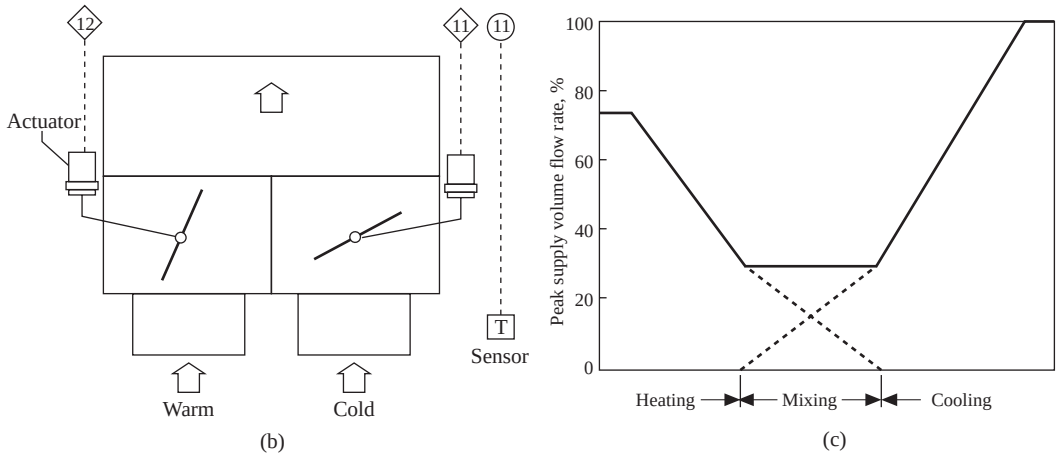


FIGURE 9.15.5 A dual-duct VAV central system: (b) mixing VAV box and (c) volume flow-operating mode diagram.

energy efficient. Various occupancies have their own requirements for their indoor environment. The basic considerations to select an air-conditioning system include:

1. The selection of an air-conditioning system must satisfy the required space temperature, relative humidity, air cleanliness, sound level, and pressurization. For a Class 100 clean room, a single-zone CV clean room system is always selected. A four-pipe fan-coil space conditioning system is usually considered suitable for guest rooms in hotels for operative convenience, better privacy, and a guaranteed outdoor ventilation air system. A concert hall needs a very quiet single-zone VAV central system for its main hall and balcony.
2. The size of the project has a considerable influence on the selection. For a small-size residential air-conditioning system, a single-zone constant-volume packaged system is often the first choice.
3. Energy-efficient measures are specified by local codes. Comparison of alternatives by annual energy-use computer programs for medium and large projects is often necessary. Selection of energy source includes electricity or gas, and also using electrical energy at off-peak hours, like thermal storage systems is important to achieve minimum energy cost.

   For a building whose sound level requirement is not critical and conditioned space is comprised of both perimeter and interior zones, a WSHP system incorporating heat recovery is especially suitable for energy saving.
4. First cost or investment is another critical factor that often determines the selection.
5. Selection of an air-conditioning system is the result of synthetical assessment. It is difficult to combine the effect of comfort, reliability, safety, and cost. Experience and detailed computer program comparisons are both important.

The selection procedure usually begins whether an individual, space conditioning, packaged, central system, or CV, VAV, VAV reheat, fan-powered VAV, dual-duct VAV, or thermal storage system is selected. Then the air, refrigeration, heating, and control subsystems will be determined. After that, choose the option, the feature, the construction, etc. in each subsystem.

Comparison of Various Systems

The sequential order of system performance — excellent, very good, good, satisfactory — regarding temperature and relative humidity control (T&HC), outdoor ventilation air (OA), sound level, energy use, first cost, and maintenance for individual, space conditioning (SC), packaged, and central systems is as follows:

	Excellent (low or less)	Very good	Good	Satisfactory
T&HC	Central	Packaged	Space	Individual
IAQ	Space	Central	Packaged	Individual
Sound	Central	Packaged	Space	Individual
Energy use	Individual	Space	Packaged	Central
First cost	Individual	Packaged	Space	Central
Maintenance	Central	Packaged	Space	Individual

Among the packaged and central systems, VAV cooling systems are used only for interior zones. VAV reheat, fan-powered VAV, and dual-duct VAV central systems are all for perimeter zones. VAV reheat systems are simple and effective, but have a certain degree of simultaneous cooling and heating when their volume flow has been reduced to minimum setting. Fan-powered VAV systems have the function of mixing cold primary air with ceiling plenum air. They are widely used in ice-storage systems with cold air distribution. Fan-powered VAV is also helpful to create a greater air movement at minimum cold primary air flow. Dual-duct VAV systems are effective and more flexible in operation. They are also more complicated and expensive.

Subsystems

Air Systems

The economical size of an air system is often 10,000 to 25,000 cfm. A very large air system always has higher duct pressure loss and is more difficult to balance. For highrise buildings of four stories and higher, floor-by-floor AHU(s) or PU(s) (one or more AHU or PU per floor) are often adopted. Such an arrangement is beneficial for the balance of supply and return volume flow in VAV systems and also for fire protection. A fan-powered VAV system using a riser to supply less cold primary to the fan-powered VAV box at various floors may have a larger air system. Its risers can be used as supply and exhaust ducts for a smoke-control system during a building fire.

In air systems, constant-volume systems are widely used in small systems or to dilute air contaminants in health care facilities and manufacturing applications. VAV systems save fan energy and have better operating characteristics. They are widely used in commercial buildings and in many factories.

Refrigeration Systems

For comfort air-conditioning systems, the amounts of required cooling capacity and energy saving are dominant factors in the selection of the refrigeration system. For packaged systems having cooling capacity less than 100 tons, reciprocating and scroll vapor compression systems with air-cooled condensers are most widely used. Evaporative-cooled condensers are available in many packaged units manufactured for their lower energy use. Scroll compressors are gradually replacing the reciprocating compressors for their simple construction and energy saving. For chillers of cooling capacity of 100 tons and greater, centrifugal chillers are still most widely used for effective operation, reliability, and energy efficiency. Screw chillers have become more popular in many applications, especially for ice-storage systems.

Heating Systems

For locations where there is a cold and long winter, a perimeter baseboard hot water heating system or dual-duct VAV systems are often a suitable choice. For perimeter zones in locations where winter is mild, winter heating is often provided by using warm air supply from AHU or PU from terminals with electric or hot water heaters. Direct-fired furnace warm air supply may be used for morning warm-up. For interior or conditioned zones, a cold air supply during occupied periods in winter and a warm air supply from the PUs or AHUs during morning warm-up period is often used.

Control Systems

Today, DDC microprocessor-based control with open data communication protocol is often the choice for medium- and large-size HVAC&R projects. For each of the air, cooling, and heating systems, carefully select the required generic and specific control systems. If a simple control system and a more complicated control system can provide the same required results, the simple one is always the choice.

Energy Conservation Recommendations

1. Turn off electric lights, personal computers, and office appliances when they are not needed. Shut down AHUs, PUs, fan coils, VAV boxes, compressors, fans, and pumps when the space or zone they serve is not occupied or working.
2. Provide optimum start and stop for the AHUs and PUs and terminals daily.
3. Temperature set point should be at its optimum value. For comfort systems, provide a dead band between summer and winter mode operation. Temperature of discharged air from the AHU or PU and chilled water leaving the chiller should be reset according to space or outdoor temperature or the system load.
4. Reduce air leakages from ducts and dampers. Reduce the number of duct fittings and pipe fittings and their pressure loss along the design path if this does not affect the effectiveness of the duct system. The maximum design velocity in ducts for comfort systems should not exceed 3000 fpm, except that a still higher velocity is extremely necessary.
5. Adopt first the energy-efficient cooling methods: air and water economizer, evaporative cooler, or ground water instead of refrigeration.
6. Use cost-effective high-efficiency compressors, fans, pumps, and motors as well as evaporative-cooled condensers in PUs. Use adjustable-frequency fan speed modulation for large centrifugal fans. Equipment should be properly sized. Over-sized equipment will not be energy efficient.
7. Use heat recovery systems and waste heat for winter heating or reheating. Use a heat-pump system whenever its COP_{hp} is greater than 1.
8. For medium- and large-size air-conditioning systems, use VAV systems instead of CV systems except for health care or applications where dilution of air contaminant is needed. Use variable flow for building-loop and distribution-loop water systems.
9. Use double- and triple-pane windows with low emissive coatings. Construct low U-value roofs and external walls.

9.16 Desiccant Dehumidification and Air-Conditioning

Zalman Lavan

Introduction

Desiccant air-conditioning is a promising emerging technology to supplement electrically driven vapor compression systems that rely almost exclusively on R22 refrigerant that causes depletion of the ozone layer. To date, this technology has only a limited market, e.g., in supermarkets where the latent heat loads are very high, in specialized manufacturing facilities that require very dry air, and in hospitals where maximum clean air is required. However, recent emphasis on increased air change requirements (see ASHRAE standards, ANSI 62-1989), improved indoor air quality, and restriction on use of CFC refrigerants (see The Montreal Protocol Agreement, as amended in Copenhagen in 1992, United Nations Environmental Programme, 1992) may stimulate wider penetration of desiccant-based air-conditioning which can be used as stand-alone systems or in combination with conventional systems. (See Table 9.4.1 for properties of some refrigerants.)

Sorbents and Desiccants

Sorbents are materials which attract and hold certain vapor or liquid substances. The process is referred to **absorption** if a chemical change takes place and as **adsorption** if no chemical change occurs. **Desiccants**, in both liquid and solid forms, are a subset of sorbents that have a high affinity to water molecules. Liquid desiccants *absorb* water molecules, while solid desiccants *adsorb* water molecules and hold them on their vast surfaces (specific surface areas are typically hundreds of square meters per gram).

While desiccants can sorb water in both liquid and vapor forms, the present discussion is limited to **sorption** of water vapor from adjacent air streams. The sorption driving force for both liquid and solid desiccants is a vapor pressure gradient. Adsorption (in solid desiccants) and absorption (in liquid desiccants) occur when the water vapor partial pressure of the surrounding air is larger than that at the desiccant surface. When an air stream is brought in contact with a desiccant, water vapor from the air is attracted by the desiccant, the air is **dehumidified**, and the water content of the desiccant rises. As the water sorbed by the desiccant increases, the sorption rate decreases and finally stops when *sorption equilibrium* is reached. For dehumidification to be resumed, water must be removed from the desiccant by heating. This process is referred to as **desorption**, **reactivation**, or **regeneration**. The heat of sorption (or desorption) is generally higher than the latent heat of vaporization of water; it approaches the latter as sorption equilibrium is reached.

Some typical *liquid desiccants* are water solutions of calcium chloride (CaCl), lithium chloride (LiCl), lithium bromide (LiBr), and triethylene glycol. The equilibrium water vapor pressure at the solution surface as a function of temperature and water content is shown in Figure 9.16.1 for water-lithium chloride solution. The surface vapor pressure (and dew point) increases with increasing solution temperature and decreases with increasing moisture content.

Common *solid desiccants* are silica gel, molecular sieves (zeolites), activated alumina, and activated carbon. The equilibrium sorption capacity (or moisture content) at a constant temperature, referred to as an **isotherm**, is usually presented as percent water (mass of water divided by mass of dry desiccant) vs. percent relative humidity (vapor pressure divided by saturation vapor pressure). Sorption capacity decreases with increasing temperature, but the spread of isotherms is relatively small (especially for concave down isotherms). Figure 9.16.2 shows normalized loading (sorption capacity divided by sorption capacity at 100% relative humidity) vs. relative humidity for silica gel, molecular sieve, and a generic desiccant, type 1 (modified) or simply 1-M (Collier et al., 1986).

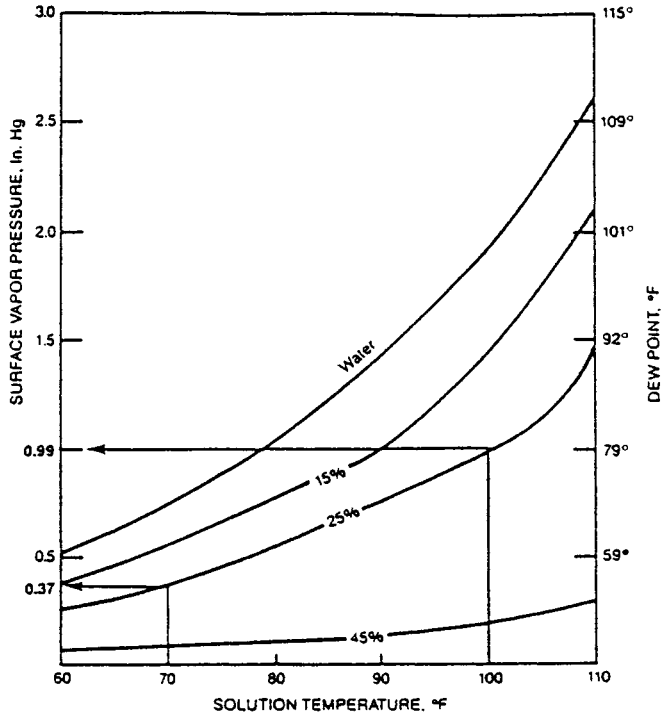

FIGURE 9.16.1 Surface vapor pressure of water-lithium chloride solutions. (Source: ASHRAE 1993, *Fundamentals Handbook*, chap. 19. With permission.)

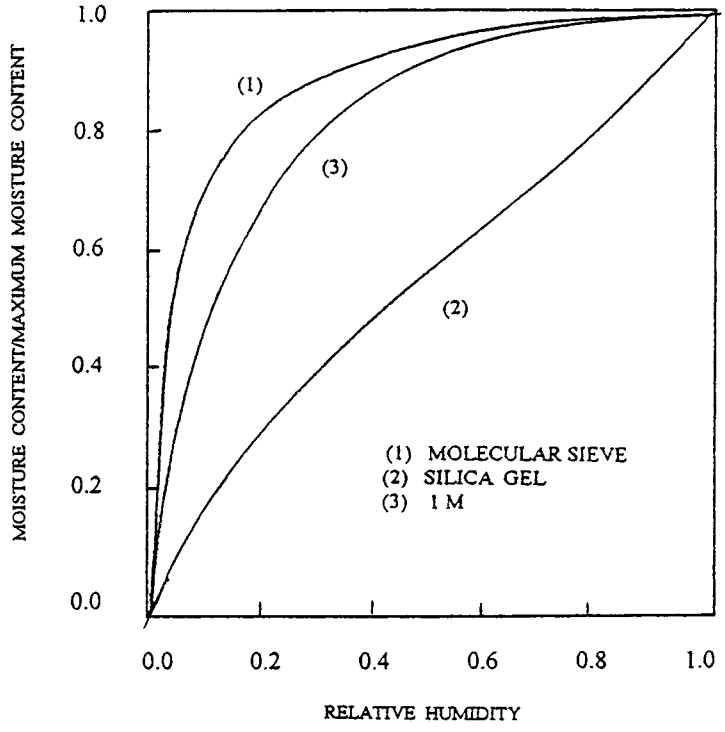

FIGURE 9.16.2 Normalized solid desiccant isotherms.

Dehumidification

Dehumidification by vapor compression systems is accomplished by cooling the air below the dew point and then reheating it. The performance is greatly hindered when the desired outlet dew point is below 40°F due to frost formation on the cooling coils (*ASHRAE, Systems and Equipment Handbook*, 1992).

Desiccant dehumidification is accomplished by direct exchange of water vapor between an air stream and a desiccant material due to water vapor pressure difference. Figure 9.16.3 shows the cyclic operation of a desiccant dehumidification system.

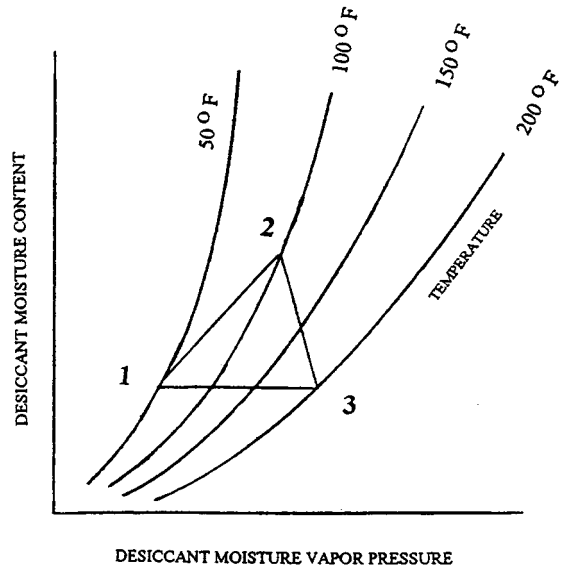

FIGURE 9.16.3 Cyclic dehumidification processes.

In *sorption (1–2)*, dry and cold desiccant (point 1) sorbs moisture since the vapor pressure at the surface is lower than that of the air stream. During this process the moisture content (loading or uptake) increases, the surface vapor pressure increases, and the liberated heat of sorption raises the desiccant temperature. During *desorption (2–3)*, the desiccant is subjected to a hot air stream, and moisture is removed and transferred to the surrounding air. The surface vapor pressure is increased and the desiccant temperature rises due to the added heat. The cycle is closed by *cooling (3–1)*. The desiccant is cooled while its moisture content is constant and the surface vapor pressure is lowered. The above cycle of sorption, desorption, and cooling can be modified by combining the sorption process with cooling to approach isothermal rather than adiabatic sorption.

Desirable Characteristics for High-Performance Liquid and Solid Desiccant Dehumidifiers

High equilibrium moisture sorption capacity
High heat and mass transfer rates
Low heat input for regeneration
Low pressure drop
Large contact transfer surface area per unit volume
Compatible desiccant/contact materials
Inexpensive materials and manufacturing techniques
Minimum deterioration and maintenance

Additional Requirements for Liquid Desiccant Dehumidifiers

Small liquid side resistance to moisture diffusion

Minimum crystallization

Additional Requirements for Solid Desiccant Dehumidifiers

The desiccant should not deliquesce even at 100% relative humidity.
The airflow channels should be uniform.
The desiccant should be bonded well to the matrix.
The material should not be carciogenic or combustible.

Liquid Spray Tower

Figure 9.16.4 is a schematic of a liquid spray tower. A desiccant solution from the sump is continuously sprayed downward in the absorber, while air, the process stream, moves upward. The air is dehumidified and the desiccant solution absorbs moisture and is weakened. In order to maintain the desired solution concentration, a fraction of the solution from the sump is passed through the regenerator, where it is heated by the heating coil and gives up moisture to the desorbing air stream. The strong, concentrated solution is then returned to the sump. The heat liberated in the absorber during dehumidification is removed by the cooling coil to facilitate continuous absorption (see Figures 9.16.1 and 9.16.3). The process air stream exits at a relatively low temperature. If sufficiently low water temperature is available (an underground well, for example), the process stream could provide both sensible and latent cooling.

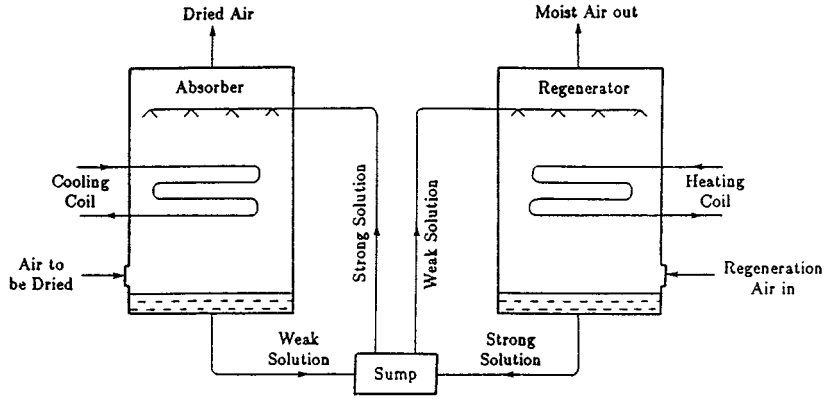

FIGURE 9.16.4 Liquid desiccant dehumidifier with heating and cooling coils.

The heating and cooling coils, shown in Figure 9.16.4, are often eliminated and the liquid solutions are passed through heating and cooling heat exchangers before entering the spray towers.

Advantages

The system is controlled to deliver the desired level of dry air by adjusting the solution concentration.

Uniform exit process stream conditions can be maintained.
A concentrated solution can be economically stored for subsequent drying use.
The system can serve as a humidifier when required by simply weakening the solution.
When used in conjunction with conventional A/C systems, humidity control is improved and energy is conserved.

Disadvantages

Some desiccants are corrosive.
Response time is relatively large.
Maintenance can be extensive.
Crystallization may be a problem.

Solid Packed Tower

The dehumidification system, shown in Figure 9.16.5, consists of two side-by-side cylindrical containers filled with solid desiccant and a heat exchanger acting as a desiccant cooler. The air stream to be processed is passed through dry desiccant in one of the containers, while a heated air stream is passed over the moist desiccant in the other. Adsorption (1–2) takes place in the first container, desorption (2–3) in the other container, and cooling (3–1) occurs in the desiccant cooler. The function of the two containers is periodically switched by redirecting the two air streams.

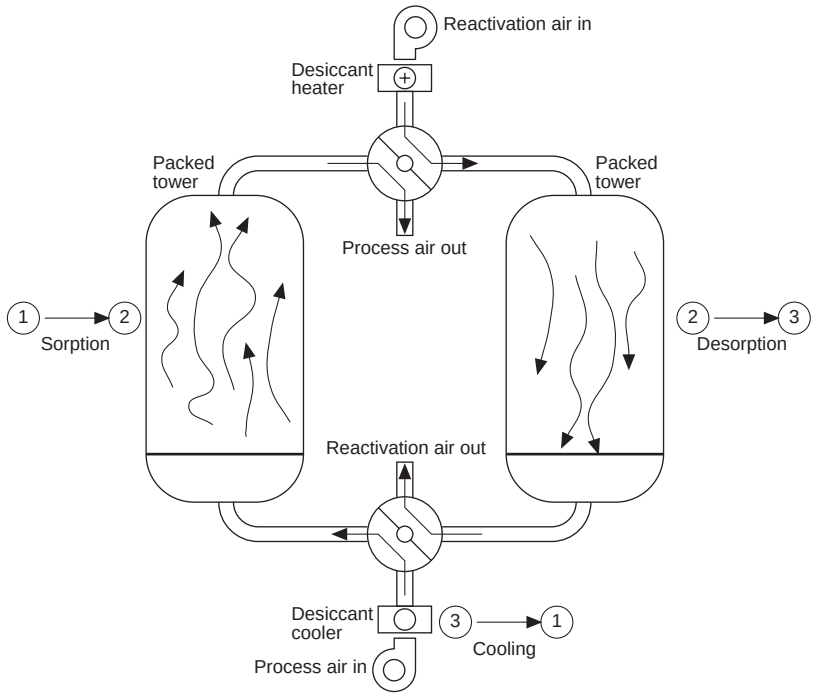

FIGURE 9.16.5 Solid packed tower dehumidification.

Advantages

No corrosion or crystallization
Low maintenance
Very low dew point can be achieved

Disadvantages

The air flow velocity must be low in order to maintain uniform velocity through the containers and to avoid dusting.
Uniform exit process stream dew point cannot be maintained due to changing moisture content in the adsorbing desiccant.

Rotary Desiccant Dehumidifiers

A typical rotary solid desiccant dehumidifier is shown in Figure 9.16.6. Unlike the intermittent operation of packed towers, rotary desiccant dehumidifiers use a wheel (or drum) that rotates continuously and delivers air at constant humidity levels.

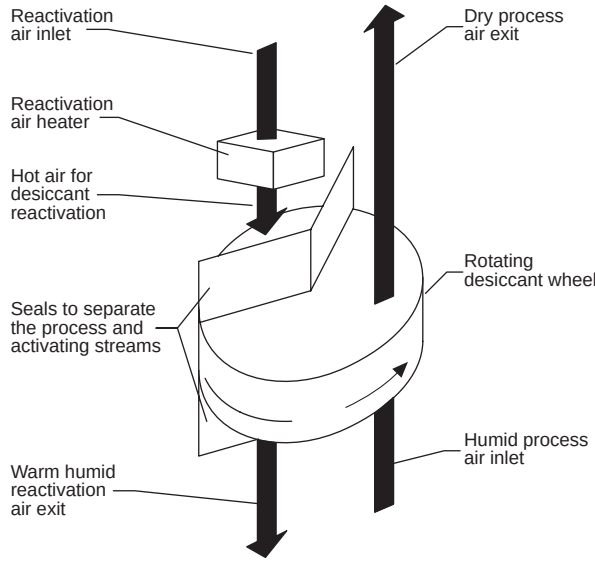

FIGURE 9.16.6 Rotary desiccant dehumidification wheel.

Desiccant wheels typically consist of very fine desiccant particles dispersed and impregnated with a fibrous or ceramic medium shaped like a honeycomb or fluted corrugated paper. The wheel is divided into two segments. The process stream flows through the channels in one segment, while the regenerating (or reactivating) stream flows through the other segment.

Desiccant Material

The desired desiccant properties for optimum dehumidification performance are a suitable isotherm shape and a large moisture sorption capacity. The isotherms of silica gel are almost linear. The moisture sorption capacity is high; the desiccant is reactivated at relatively low temperatures and is suitable for moderate dehumidification. Molecular sieves have very steep isotherms at low relative humidity. The desiccant is reactivated at relatively high temperatures and is used for deep dehumidification. The isotherm of the type 1-M yields optimum dehumidification performance (Collier et al., 1986), especially when used in conjunction with high regeneration temperatures.

The Desiccant Wheel

Some considerations for selection of desiccant wheels are:

Appropriate desiccant materials
Large desiccant content
Wheel depth and flute size (for large contact surface area and low pressure drop)
Size and cost

The actual performance depends on several additional factors that must be addressed. These include:

Inlet process air temperature and humidity
Desired exit process air humidity
Inlet reactivating air temperature and humidity
Face velocity of the two air streams
Size of reactivation segment

It should be noted that:

Higher inlet process air humidity results in higher exit humidity and temperature (more heat of sorption is released).
Lower face velocity of the process stream results in lower exit humidity and higher temperature.
Higher regeneration temperatures result in deeper drying, hence lower exit process air humidity and higher temperature.
When lower exit air temperature is required, the exit process air should be cooled by a heat exchanger.
Final cooling of the exit process air can be achieved by partial humidification (this counteracts in part previous dehumidification).

The following is a range of typical parameters for rotary desiccant wheels:

Rotation speed: 4 to 10 rpm
Desiccant fraction: 70 to 80%
Flute size: 1 to 2 mm
Reactivation segment: 25 to 30% of wheel
Face velocity: 300 to 700 fpm
Reactivating temperature: 100 to 300°F

Hybrid Cycles

A limited number of hybrid systems consisting of desiccant dehumidifiers and electrically driven vapor compression air-conditioners are presently in use in supermarkets. This application is uniquely suited for this purpose since the latent heat loads are high due to the large number of people and frequent traffic through doors. Also, low relative humidity air is advantageous for open-case displays.

Vapor compression systems are inefficient below a dew point of 45 to 50°F. When used in supermarkets, they require high airflow rates, the air must be reheated for comfort, and the evaporator coils must be defrosted frequently. Hybrid systems offer improved performance and lower energy cost in these cases.

Figure 9.16.7 shows a typical hybrid air-conditioning system for supermarkets. A mixture of outdoor and recirculated air is first passed through the desiccant and sensible heat exchanger wheels, where it is dehumidified and precooled. It then enters the conventional chiller before it is introduced to the interior of the supermarket. The sensible heat exchanger wheel is cooled by outdoor air and the desiccant wheel is regenerated by air heated with natural gas. Energy cost can be further reduced by preheating the reactivating air stream with waste heat rejected from the condenser of the refrigeration and/or air-conditioning systems.

The advantages of these hybrid systems are

Air-conditioning requirement is reduced by up to 20%.
The vapor compression system operates at a higher coefficient of performance (COP) since the evaporator coils are at a higher temperature.
Airflow requirements are reduced; electric fan energy is saved and duct sizes are reduced.
The refrigeration cases run more efficiently since the frequency of defrost cycles is greatly reduced.

Solid Desiccant Air-Conditioning

Several stand-alone desiccant air-conditioning systems were suggested and extensively studied. These systems consist of a desiccant wheel, a sensible heat exchanger wheel, and evaporating pads. Sorption can be adiabatic or cooled (if cooling is combined with sorption). When room air is dehumidified and recirculated, the system is said to operate in the **recirculating** mode. When 100% outside air is used as the process stream, the system operates in the **ventilating mode**.

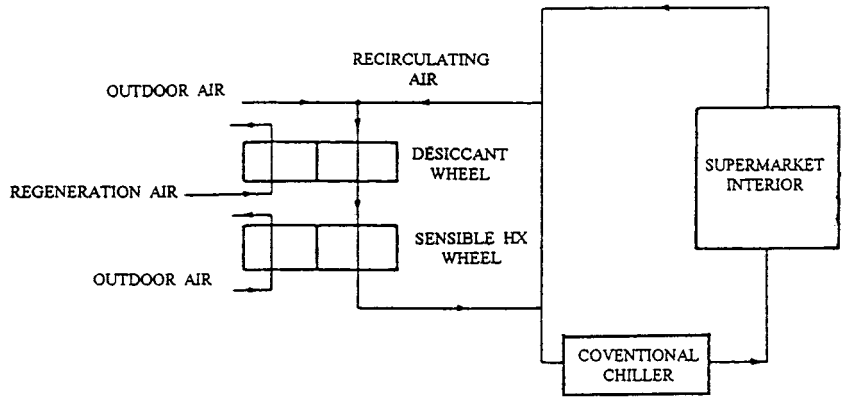

FIGURE 9.16.7 Hybrid air-conditioning system for supermarkets.

Ventilation Mode

In the *adsorption path* the process air stream drawn from the outdoors is passed through the dry section of the desiccant wheel where it is dehumidified and heated by the liberated heat of sorption. It then passes through the sensible heat exchanger wheel and exits as dry but slightly warm air. The hot and dry air leaving the dehumidifier enters the heat exchanger, where it is sensibly cooled down to near room temperature. It is then passed through the evaporative cooler, where it is further cooled and slightly humidified as it enters the conditioned space.

In the *desorption path*, air is drawn from the conditioned space; it is humidified (and thus cooled) in the evaporative cooler. The air stream enters the sensible heat exchanger, where it is preheated, and it is then heated to the desired regeneration temperature by a suitable heat source (natural gas, waste heat, or solar energy), passed through the desiccant wheel (regenerating the desiccant material), and discharged out of doors.

Performance. In order to achieve high performance, the maximum moisture content of the desiccant should be high and the isotherm should have the optimum shape (1 M). In addition, Zheng et al. (1993) showed that the optimum performance is very sensitive to the rotational speed of the desiccant wheel. Glav (1966) introduced stage regeneration. He showed that performance is improved when the reactivation segment of the wheel is at a temperature which increases in the direction of rotation. Collier (Collier et al., 1986) showed that well-designed open-cycle desiccant cooling systems can have a thermal COP of 1.3. This, however, would require the use of high-effectiveness sensible heat exchangers, which would be large and expensive. Smaller and more affordable heat exchangers should yield system COPs in the order of unity. An extensive review of the state-of-the-art assessment of desiccant cooling is given by Pesaran et al. (1992).

Conclusions

Desiccant-based air-conditioning offers significant advantages over conventional systems. Desiccant systems are already successfully used in some supermarkets. It is expected that these systems will gradually attain wider market penetration due to environmental requirements and potential energy savings.

The advantages of desiccant air-conditioning are summarized below:

No CFC refrigerants are used.
Indoor air quality is improved.
Large latent heat loads and dry air requirements are conveniently handled.
Individual control of temperature and humidity is possible.

The energy source may be natural gas and/or waste heat.
Less circulated air is required.
Summer electric peak is reduced.

Defining Terms

Absorb, absorption: When a chemical change takes place during sorption.
Adsorb, adsorption: When no chemical change occurs during sorption.
Dehumidification: Process of removing water vapor from air.
Desiccant: A subset of sorbents that has a particular affinity to water.
Desorb, desorption: Process of removing the sorbed material from the sorbent.
Isotherm: Sorbed material vs. relative humidity at a constant temperature.
Reactivation: Process of removing the sorbed material from the sorbent.
Recirculation: Indoor air only is continuously processed.
Regeneration: Process of removing the sorbed material from the sorbent.
Sorbent: A material that attracts and holds other gases or liquids.
Sorption: Binding of one substance to another.
Staged regeneration: When the temperature of the regeneration segment of the desiccant wheel is not uniform.
Ventilation mode: 100% of outdoor air is processed.

Electronic packaging is the art and science of connecting circuitry to reliably perform some desired function in some application environment. Packaging also provides ease of handling and protection for assembly operations. This chapter defines chip, or die-level, and assembly-level packaging, with an emphasis on recent technologies. The relative advantages of each technology will be discussed in relation to performance, cost, reliability, and manufacturability. Extensive details on electronic packaging can be found in the references.[1–6]

10A.1.1 Packaging the Die

A semiconductor device, also known as a *die* or *chip*, is fragile and must be packaged for protection and for interfacing with the outside world. The chip package provides an electrical interconnection to the assembly, module, or display and protects the chip in the manufacturing and application environments. A number of different materials can be used in the die package, including ceramics, plastics, and metals. Single-chip, three-dimensional, and multichip module (MCM) packages are some of the packaging formats. Interconnection is the process and technique of making electrical connections between the bond pads of the chip and a leadframe, substrate, or even another chip.

Plastic Die Package

Plastic packages are very popular in commercial applications because of their low cost and small size compared to ceramic packages. The cost of plastic packages is typically one half to one tenth the cost of comparable ceramic or metal packages. More than 98% of all integrated circuits were packaged in plastic in 1992. In a plastic package, the chip is encapsulated by a polymer, usually referred to as the *encapsulant*. An encapsulant is generally an electrically insulating material formulation that protects an electronic device and die-leadframe assembly from the adverse effects of handling, storage, and operation.

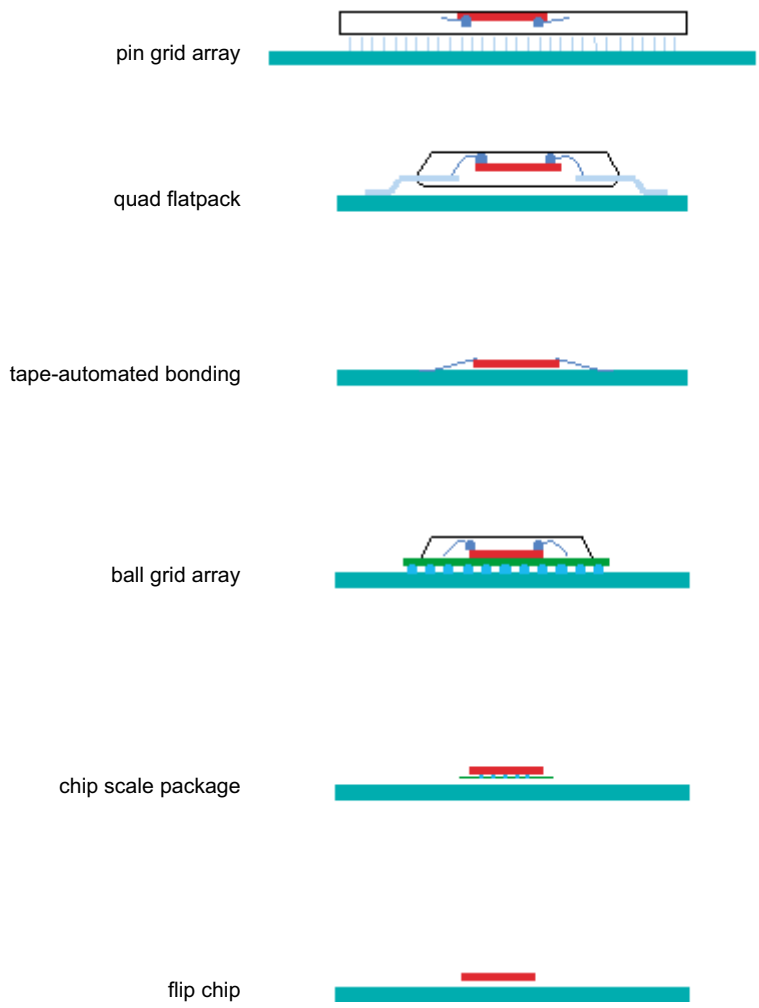

FIGURE 10A.1.1 Shrinking size of packaging.

Figure 10A.1.1 depicts the evolution of packaging shrinkage through the last three decades. Packaging size is being pressed by the shrinking feature size (approximately 15% per year) of CMOS integrated circuits. Package lead styles have changed dramatically from the 1970s when the dual in-line package (DIP) and pin grid array dominated the semiconductor industry. Even today, the DIP retains a sizable share of the market in which low-cost, rugged packaging meets the application need. Generally, there are at least three major lead types, with numerous variations of each: the through-hole, the surface-mount (J- or gull-lead), and the solder ball. The through-hole and leaded surface-mount packages usually have a leadframe to which the die is mounted. The plastic solder ball packages typically employ organic substrates that redistribute the die inputs-outputs (I/O) to an array or perimeter pattern of solder balls. (Substrate technologies are addressed in Section 10A.1.2.)

In the late 1980s, 1.27-mm pitch, surface-mount technology became prominent. As device complexity increased, the I/O count also increased. To keep electrical performance and package sizes reasonable, the lead pitch decreased, and fine-pitch leaded devices (lead pitch of less than or equal to 0.65 mm) were introduced.

Array packaging was first introduced in the mid-1970s with ceramic pin grid array packages. Surface-mount array packages evolved to plastic ball grid array (PBGA) and chip-scale packages (CSP). Solder

TABLE 10A.1.1 Typical Coplanarity Requirements for SMT Components[7]

Component	Pitch (mm)	Coplanarity Requirement (mm)
Leaded SMT	—	0.10
PBGA	1.27 –1.5	0.20
	1.0	0.15
	<1.0	0.08
CBGA	—	0.15
CSP	—	0.08

From Hwang, J.S., BGA and CSP solder spheres, *Surface Mount Technology,* April, p. 18, 1999. © 1999 by IHS Publishing Group (www.smtmag.com). With permission.

spheres — usually composed of 63% tin and 37% lead, 62/36/2 (% silver), or high-temperature 10/90 — form the connection between the package and the board.

The chip-scale package is typically defined as being not more than 20% larger than the die. The CSP interposer buffers the final assembly from die-shrink redesign. The interposer can be organic substrate, tape-automated bonded (TAB), or ceramic substrate. The interposer can also act as a stress buffer between the low thermal expansion of the semiconductor die and the higher expansion of the substrate. Tessera (San Jose, CA) adds a patented elastomer between the die and the interposer to further buffer the solder balls. While the majority of CSP used today have solder-ball interconnects, there are non-solder-ball variations that meet the CSP definition, such as the small-outline, no-lead (SON) and bottom-leaded plastic packages (BLP).

The coplanarity of surface-mount parts is an important mechanical parameter in assembly. Non-planar parts can lead to poor assembly yields (voids, electrical opens) and unreliable connections (misregistration). Table 10A.1.1 outlines typical coplanarity requirements.

Encapsulation techniques include molding, potting, glob-topping, and conformal coating, but the majority of encapsulated packages use the molding process. The molding compound is a proprietary multicomponent mixture of an encapsulating resin with various types of additives. The principal active and passive (inert) components in a molding compound include curing agents or hardeners, accelerators, inert fillers, coupling agents, flame retardants, stress-relief additives, coloring agents, and mold-release agents. Molding compounds have moved steadily toward all-epoxy systems.

Thermosetting encapsulation compounds are based on epoxy resins. In electrical and electronic applications, three types of epoxy resins are commonly used: the diglycidyl ethers of bisphenol A (DGEBA) or bisphenol F (DGEBF), the phenolic and cresol novolacs, and the cycloaliphatic epoxides. Novolac-based epoxies are supplied as molding bricks (preforms) that are ready for use in transfer-molding machines to produce single-in-line packages, dual-in-line packages, plastic leaded chip carriers, quad flatpacks, various types of small-outline integrated circuits (SOIC), and ball grid array packages.

Pin grid array carriers, some ball grid array packages, and carriers with metal cans frequently use multicomponent liquid epoxies or preforms. Flip chips mounted on organic substrates also use liquid epoxy underfills to protect the die surface environmentally as well as to provide stress relief to the solder balls. Polyurethanes, polyamides, and polyesters are used to encase modules and hybrids intended for use under low-temperature and high-humidity conditions. Modified polyimide encapsulants have the advantages of thermal and moisture stability, low coefficient of thermal expansion, and high material purity. Thermoplastics are rarely used because they generally require processing conditions of unacceptably high temperature and pressure, are low-purity materials, and can induce high moisture-induced stresses.

Several molding techniques (Table 10A.1.2) are available for the manufacture of plastic cases. The most widely used manufacturing process is the transfer molding process, used for molding thermosetting polymers. These polymers are plastic or fluid at low temperatures but, when heated, react irreversibly to

TABLE 10A.1.2 Comparison of Molding Processes

Molding type	Advantages	Disadvantages
Transfer molding	Multiple cavities, high yield Relative material savings Short cycle time Low tool maintenance costs	High molding pressure High viscosity Restricted to the packaging of leadframes
Injection molding	Good surface finish Good dimensional control	Poor material availability
Reaction-injection molding	Energy efficiency Low mold pressure Good wetting of chip surface Adaptability to TAB	Few resin systems available for electronic packaging Requires good mixing

form a cross-linked network no longer capable of being melted. Other processes include the injection molding process and the reaction-injection molding process.

Hermetic (Metal and Ceramic) Packages

Hermetic packages have been used predominantly for military and government applications because of their perceived reliability advantage over plastic packages. They have also been employed in some high-power applications when heat must be dissipated from the device. Metal packages are typically used for small integrated circuits with a low lead count and in applications that require electromagnetic shielding.

Both metal and ceramic packages can be made nearly impervious to moisture when hermetically sealed. A package is classified as hermetic if it has a minimal leak rate (the rate at which gases can diffuse into or out of the package). Typical acceptable helium leak rates depend on the package size and helium pressure in the package. Some metal packages (e.g., Olin Metal quad flatpacks) are sealed using epoxies and, therefore, are not hermetic.

Several major semiconductor companies (Intel, Motorola, and AMD) have announced their exit from military markets, and the availability of these packages is shrinking dramatically. Plastic components are finding their way into many applications that had once been dominated by hermetic packages.

Interconnection Technologies at the First Level of Packaging

The major interconnection technologies at the first level of packaging are wirebonding, flip chip, and TAB. Wirebonding, the mainstay of the microelectronics industry, still accounts for more than 98% of all semiconductor interconnections. Invented more than 30 years ago, flip chip was once available only to large, vertically integrated companies. Now, contract sources of wafer bumping are available, making flip chip one of the fastest growing interconnect methods. Tape-automated bonding (TAB) techniques are mature, although they are utilized only in limited, specialized applications because of high tooling costs. Chip stacking or three-dimensional (3-D) interconnection is typically used in systems where size, weight, and speed are critical. Comparisons of these technologies are provided in Tables 10A.1.3 and 10A.1.4.

Wirebond Interconnects

Wirebond interconnects are formed by metallurgically bonding a small-diameter wire from the semiconductor device to the leadframe, substrate, or other semiconductor. The wirebond forms a low-resistance path for signal propagation. Typical wire materials include aluminum, gold, and copper. Gold is usually bonded by thermocompression, while aluminum is usually bonded ultrasonically.

Common materials for pads on bondable surfaces include aluminum, gold, silver, nickel, and copper. Aluminum and gold are the most frequently used bondpad materials. Silver has been used as a bondable plating material on leadframes and as a bondable thick-film metallization in alloy form with platinum

TABLE 10A.1.3 Comparison of Interconnect Technologies

Attribute	Wirebonding	TAB	Flip TAB	Flip Chip	High-Density Interconnects
Minimum (and typical) I/O pitch (μm)	100 (150)	50 (100)	50 (100)	125 (250)	25/1 (50/2)
Maximum I/O range	256–500	400–700	400–700	>800	>1000
Lead inductance (nH)	1–2	1	0.1	0.05–0.1	<0.05
Mutual inductance between leads (pH)	100	5	5	1	<1
Typical effective diameter (μm)	25	50	50	125	N/A
Typical length (mm)	1	1	0.25	0.1	N/A
Connection technique	Perimeter; array area is difficult but possible, using multi-height loops	Perimeter; array area is moderately difficult but possible, using multilayer tape	Perimeter; array area is moderately difficult	Perimeter and array area	Perimeter and array area
Packaging efficiency	Medium	Medium	Medium-high	High	High
Pretestability in fine pitch	Difficult with available instrumentation	Good	Good	Difficult with available instrumentation	Difficult with available instrumentation
Ability to rework	Difficult	Fair	Good	Good	Good
Loop control	Fair	Good	Good	Good	Good
Flexibility of the manufacturing process	Excellent	Fair (gang bonding); good (single-point bonding)	Fair (gang bonding); good (single-point bonding)	Good	Good
Dominant failure mechanisms	Fatigue, bond-pad corrosion	Lead fatigue, interdiffusion	Lead fatigue, interdiffusion	Fatigue, intermetallics	Electromigration, corrosion
Heat dissipation	Good (die bonded to substrate)	Good (die bonded to substrate)	Poor, but excellent if heat sink attached to back side	Poor, but excellent if heat sink attached to back side	Good (die bonded to substrate)
Die availability	Excellent	Fair	Fair	Poor	Excellent
Tool availability	Excellent	Fair	Fair	Fair	Fair
Technology maturity	Excellent	Good	Good	Good	Fair
Market share	98%	<2%	<1%	<1%	<1%
Cost	Low	Medium	Medium	High (potentially low)	High (potentially low)

TABLE A10.1.4 Relative Advantages of Interconnect Technologies

	Advantages	Disadvantages
Wirebond	Low resistance interconnects Low capital investment Mature technology Highly stable manufacturing process	Potential for cross-talk High lead inductance Use of costly, precious metal wire Low interconnect density Limited chip size
Flip chip	Self-alignment during die joining Automatic die placement and testing Low lead inductance Less need for precious metals Simultaneous bonding	Potential for solder fatigue Thermal dissipation concerns
TAB	Lightweight packaging Small size/high I/O-count Simultaneous bonding	High capital investment
HDI	Power and signal distribution High frequency performance High clock-rate performance High wiring densities High device-to-substrate area ratio	Process not fully mature High cost of deposited HDI
3-D	Increased package density Better board utilization Increased electrical performance Shorter interchip connections Lower system power	Potential for cross-talk Thermal dissipation concerns Poor yields Process not fully mature

or palladium.[8] Nickel has been widely used as a substitute for gold in power devices. In addition, nickel or chromium serve as barrier layers to avoid unwanted intermetallic compounds and to facilitate adhesion.

Thermocompression and thermosonic bonds are typically used to produce a ball bond on the first bond and a wedge bond on the second. Thermocompression is used on gold and in plastic packages to prevent wire sweep. Thermocompression bonds occur when two metal surfaces are brought into intimate contact through a controlled time, temperature, and pressure cycle. Typical bonding temperatures during thermocompression bonding range from 300 to 400°C. Heat is generated during the manufacturing process, either by a heated pedestal on which the assembly is placed for bonding or by a heated capillary feeding the wire. Typically, bonding time is in the neighborhood of 40 ms, which translates to a machine speed of approximately two wires per second.

Thermosonic bonding combines ultrasonic energy with the ball-bonding capillary technique of thermocompression bonding. The processes are similar, but in thermosonic bonding the capillary is not heated and substrate temperatures are maintained between 100 and 150°C. Ultrasonic bursts of energy make the bond. Typically, at the second bond, the capillary leaves a characteristic circular pattern called a *crescent bond*. The bonding time is usually about 20 ms, or a machine speed of ten wires per second, for ball bonding and three wires per second for wedge bonding.

Ultrasonic bonding is a low-temperature process in which the source of energy for the metal welding is a transducer vibrating the bonding tool parallel to the bonding pad in a frequency range from 20 to 60 kHz. Ultrasonic bonding uses aluminum wire in ceramic/metal packages. Ultrasonic processes are used for wedge-wedge bonds, for which a common centerline and careful alignment during manufacture are critical to avoid large stresses and irregular deformation. Normally, the first bond is made to the die and the second to the substrate. Referred to as *forward bonding*, this is the preferred bonding procedure because it is less susceptible to edge shorts between the die and the wire. Typical bonding time for

ultrasonic bonding is about 20 ms, which translates to a machine speed of four wires per second. A disadvantage of wedge bonding over ball bonding is the necessity of maintaining the directional first-to-second alignment by rotating and aligning the die and substrate with the direction of the wire. Rotation is difficult in large MCMs (>7 cm on the side), as most equipment was designed for much smaller integrated circuit (IC) bonding. Thus, while ultrasonic bonding has the advantage of small bond pitch, the overall speed of the process is less than that for thermosonic bonds, due to machine rotational movements.

Some quality/infant-mortality failure mechanisms associated with wirebonding include cratering of the die or chip-out due to excessive bond stress on the die. It is important to maintain adequate bonding load and temperature to allow dispersion of contaminants. Cleanliness, proper atmosphere during bonding, and surface finish are also important assembly factors. Long-term failure mechanisms include differential thermal fatigue, electrical leakage, and Kirkendall voids — voids formed by different interdiffusion rates of gold and aluminum. Purple plague is a brittle, gold-aluminum intermetallic formed at high temperatures.

Flip Chip Bonding

Flip chip bonding is an interconnection technique in which the die is connected facedown onto the substrate. Solder bumps on area-array metallized terminals are reflowed to matching footprints of pads on a substrate. Flip chip bonding grew at a rate of about 18% compound annual growth (CAG) between 1991 and 1997. With wafer bumping services readily available, growth from now to the year 2002 is projected at nearly 50% CAG. One of the first products with extensive use of flip chip packaging was a Sony camcorder that contained sixteen flip chip die on chip-scale interposers.[9]

The three major steps involved in manufacturing flip chip bonds are (1) die or wafer bumping, (2) alignment of the die and substrate, and (3) assembly. Flip chip technology has several advantages over wirebonding:

- Self-alignment during die joining, which allows for automatic die placement and testing
- Low lead inductances, due to shorter interconnection lengths than wirebonding
- Reduced need for precious attach metals
- Increased productivity, due to the ability to make large numbers of bonds simultaneously

Evaporating and plating are the major methods of bump formation. Evaporated bumps (125 μm diameter and 100 μm high) can be smaller and more uniform than plated bumps (125–175 μm diameter and 25–100 μm high).

The flip chip assembly of a microelectronic component package is a composite of multiple, thin layers of metals. On the die bond pads, the pad structure is called *ball-limiting metallurgy* (BLM), *pad-limiting metallurgy* (PLM), or *under-bump metallurgy* (UBM). On the substrate bond pads, the connection structure is called *top-surface metallurgy* (TSM). Figure 10A1.2 shows a typical flip chip bond structure.

The BLM structure and solder bump manufacturing, called the *bumping process*, can be implemented using a variety of methods, including metal masking, photolithography, electroplating and ultrasonic soldering, maskless bumping, and copper bumping. Critical properties of the BLM adhesive layer include good electrical contact with the metallization pad on the die, strong adhesion to the pad and to the passivation layer surrounding it, and selective etchability of the metal layer, enabling the use of photolithography techniques during fabrication. The BLM barrier layer must also have good solderability and the capability to prevent interdiffusion between the solder and the pad metallization. Finally, the BLM bonding layer must provide an inert surface during bonding and protect the barrier layer from oxidation during storage.

The barrier layer of the TSM structure is made of a metal that increases wettability and has a surface suitable for solder reflow. The bonding layer uses metals that have the ability to retain wetting properties and provide adequate shelf life prior to die attachment. The melting point is the most important material property when selecting solder materials. High-melting-point solders are selected for die-level

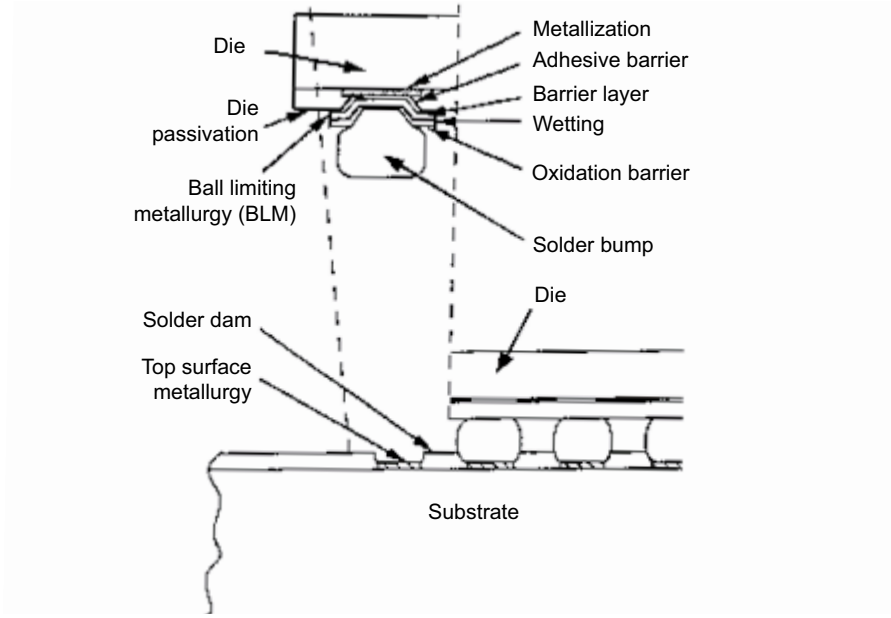

FIGURE 10A.1.2 Flip chip bond structure. (From Pecht, M. et al., *Quality Conformance and Qualification of Microelectronic Packages and Interconnects,* John Wiley & Sons, New York. With permission.)

interconnections to enable lower melting-point solders to be used for the board-level packaging. For example, 95Pb/5Sn solder (melting point around 315°C) is used with alumina ceramic substrates for die connections, while eutectic tin lead solder (melting point around 183°C) is used to attach dies to such organic substrates as Kapton film and glass/epoxy printed wiring boards.

Also important in solder selection is the cyclic strain hardening behavior of the solder, which describes the strain induced in the solder by a given stress condition. This material property strongly influences the thermal fatigue life of the solder. A slow interdiffusion rate that reduces intermetallic formation with the metal layers on the die and the substrate pads is required to enhance the thermal fatigue life of the solder. Intermetallics, though necessary to form a good bond, may reduce the thermal fatigue life if present in excessive quantities because of their brittle nature.

High corrosion resistance is required for solders used in non-hermetic packages to prevent corrosion-related failures. High oxidation resistance is also desirable, as the operational environment in non-hermetic packages accelerates solder oxidation, first on the surface and then in the bulk solder, which can eventually result in solder-die separation. High thermal conductivity is a benefit of metallic solders that allows the heat generated by the die to be dissipated to the substrate via solder bumps.

Tape-Automated Bonding (TAB)

Tape-automated bonding is particularly well suited for volume applications requiring small, lightweight, and high-I/O-count electronic packages. Furthermore, with hybrids and multichip modules, TAB has been used as a means to test and package very large-scale integration dies for a variety of products. (For TAB design guidelines and comparisons with other interconnect technologies, the interested reader is referred to Reference 2.)

The TAB assembly includes bumps, interface metallurgy, leads, lead plating, adhesive, polymeric tape, and encapsulant. In one-layer tape (all metal), the tape is made of metal foil with an etched lead pattern. In multiple-layer tape, the tape assembly consists of metal foil with an etched lead pattern and polymeric tape, with or without adhesive. A TAB assembly can be mounted onto the substrate face-up (conventional), facedown (flip-TAB), or in recessed pockets. Because of the geometry configuration, flip-TAB mounting offers options for either straight or formed leads.

TABLE 10A1.5 Dimensions of Tape-Automated Bonds[11–13]

Element of TAB	Dimensions
Bump	
Square	50–120 μm wide and 10–30 μm high
Truncated sphere	80- to 100-μm diameter and 25 μm high
Interface metallurgy	
Adhesion and barrier layers	0.08–1 μm
Bonding layer	0.1–0.3 μm
Lead	
Thickness	18–70 μm
Inner lead pitch	30–100 μm
Outer lead pitch	50–635 μm
Plating thickness	0.25–2 μm
Polymeric tape	
Width	8–70 mm
Thickness	25–127 μm
Polymeric adhesive thickness	12.7–25.4 μm
Die passivation thickness	1–1.5 μm

Common TAB dimensions are summarized in Table 10A.1.5. The bump configurations in TAB can be classified as bumped die, bumped leads (BTAB), transferred bumps (TTAB), or bumpless. The bumped-die approach requires bumping the die before bonding. One-layer tape typically consists of about 70-μm-thick etched copper foil. Two-layer tape consists of a polymeric film, approximately 50 μm thick, and a patterned metal layer of 20 to 40 μm. Three-layer tape consists of patterned metal, usually as sheets of electro-deposited or rolled copper (typically 35 μm thick), laminated with an adhesive to prepunched polymeric film (typically 125 μm thick). Two-metal-layer tapes with signal and ground planes and three-metal-layer tapes that provide signal, ground, and power planes are being used in some multichip modules.[10]

Ultrasonic bonding is typically used to create the inner-lead bond. The outer-lead bond can be ultrasonically bonded, adhesive bonded, or soldered to the board or substrate. The BTAB approach bonds an unbumped die to bumps on the tips of the inner leads. The TTAB approach bonds an unbumped die to bumps on a separate substrate, which are transferred to the inner leads. The bumpless TAB approach bonds the TAB inner leads directly to an unbumped die.

Tape-automated bonding is capable of accommodating dies with peripheral and area-array I/Os. In an area-array TAB (ATAB), a multilayer metal tape is usually used to provide interconnections between the die bumps and the substrate bonding pads. Area-array TAB increases the number of potential I/Os and improves integrated circuit design flexibility. The common inner lead pitch is 100 μm, with 50 μm wide lines and spacing.

The typical outer-lead pitch ranges from 200 to 625 μm. Tape widths can range from 8 to 70 mm to accommodate various die sizes and I/O counts. Multiple-conductor (multimetal) tapes have been developed to control impedance and reduce cross-talk.[10] An advantage of TAB is the ability to test the components at extremely fine pitches, prior to excision of the part from the tape. This practice prevents lead damage. TAB pitches of less than 50 μm are in production and perform electrically and thermally better than wirebonding.

Some disadvantages of TAB are tooling and nonrecurring costs. Each die design requires a new tape design. This reduces the flexibility to accommodate die shrinks.

Three-Dimensional Die Packaging

Three-dimensional (3-D) packaging and interconnection provide increased electrical performance and packaging density compared to traditional two-dimensional (2-D) approaches. Three-dimensional

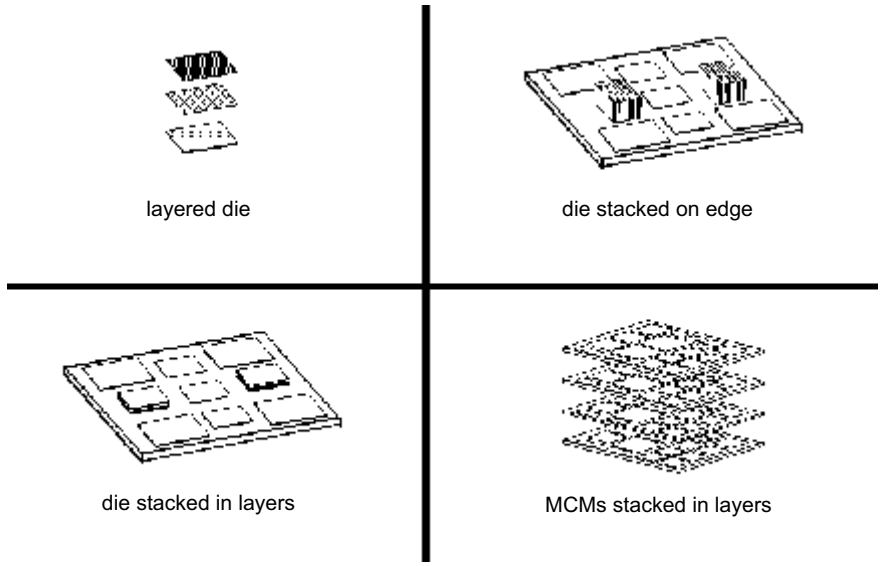

FIGURE 10A.1.3 Types of 3-D packaging. (From Pecht, M. et al., *Quality Conformance and Qualification of Microelectronic Packages and Interconnects,* John Wiley & Sons, New York. With permission.)

packaging and interconnection can increase density by a factor of more than 50 by stacking integrated circuits (ICs). Schematically illustrated in Figure 10A1.3 are four generic types of 3-D packaging: layered dies, dies stacked on edge, dies stacked in layers, and vertically stacked multichip modules.[3]

Cost-effective multiple IC packages have been in high volume production for several years. A polyimide tape interposer is used to mount mirrored memory die. One example of this is a Sharp (Osaka, Japan) device that integrates a static RAM with a flash memory. The result not only enhances access time but also reduces the area to about half of the size of conventional packaging.[14]

Three-dimensional packaging provides increased system performance over shorter interchip connections. Also, potentially lower system power is necessary for physically smaller and fewer drivers. To reduce the package thickness and bond length, the integrated circuits are often thinned. Three-dimensional techniques incorporate many of the manufacturing processes currently used in 2-D production, adapting standard semiconductor processing equipment. Most processing is accomplished simultaneously on multiple die.

The materials used in 3-D and their critical properties are the same as those used in advanced 2-D packaging and interconnection. Common materials found in both 2-D and 3-D structures include polyimides for dielectrics, copper or aluminum for conductors, solders for bonding, and a variety of substrates using alumina, silicon, and aluminum nitride. Common properties of these materials are discussed in the literature.[1,5] Much of the success of 3-D packaging will depend on adhesive technology. Thermosetting adhesives used to bond the dies together in a stack, including polyimides and epoxies, are selected for strength and stability. Thermoplastic adhesives used to bond stacked substrates are selected for compliance and reworkability. In some cases, a hierarchy of adhesives, based on melting or softening temperature, is needed to allow disassembly of the structure; this is unique to 3-D technology.

The manufacturing process for 3-D microelectronic devices depends on the format chosen for the final product. The package elements of layered die include the die themselves, the dielectric between the die, and interconnects. The elements of dies stacked on edge, layered dies, and vertically stacked modules include dies, attachments between dies or modules, wires and wirebonds, and interconnects between dies or modules. The package-to-substrate interconnects are usually solder bumps or pad arrays.

Table 10A1.6 compares the process attributes and interconnection techniques of some of the major 3-D package manufacturers. The manufacturing yield of 3-D packages depends on the number of directly

TABLE 10A.1.6 Comparison of Three-Dimensional Packaging Technology

	Supplier					
	Texas Instrument	**Irvine Sensor**	**Irvine Sensor**	**Thomson CSF**	**General Electric**	**Hughes**
Stack approach	Edge stack	Edge stack	Layered stack	Edge or layered stack	Stacked substrate	Stacked substrate

connected dies built into the device. For example, if the yield of a particular type of die is 90% and the completed 3-D module comprises three layers, the final yield of the module can be as low as 73%. In some format types, screening can be conducted prior to module assembly to remove defective dies from the 3-D structure or to "turn off" the defective die. In some cases, the fabrication process incorporates redundancy to minimize the number of costly screens.

In 3-D packaging, both single-level, horizontal cross-talk and cross-talk between different layers can be potential problems for very high-speed applications. Furthermore, the approach may require the use of heat spreaders when using multiple high-power devices in order to meet thermal operating specifications as well as thermal and thermomechanical stress design limits.

10A.1.2 Printed Wiring Board Technology

The printed wiring board is a substrate on which electronic components are mounted for electrical interconnection and mechanical support. The interconnection is provided by patterned metal tracks either on the surface or on the inner layers of the printed wiring board. Based on the raw materials used for manufacture, printed wiring boards can be either organic or ceramic boards. The most common organic board material consists of a woven glass fabric bound by a resin. Ceramic board materials typically include alumina, aluminum nitride, and beryllia. Often, in ceramic boards, materials and structures are added to create embedded capacitors and resistors, freeing precious top-layer real estate. While not widely in production, similar techniques can be used in the inner layers of organic boards.

Conventional Printed Circuit Board Technology

Conventional printed wiring board (PWB) technology can be categorized as single layer, double layer, or multilayer. Single-layer boards have conductors etched on one side of the board, usually without hole plating. Double-layer boards have conductors on both sides of the board, but no inner layers. Multilayer organic boards typically consist of stacks of partially or fully cured fabric-reinforced epoxy sheets and copper foil conductors.

While there are many ways to fabricate a multilayer printed wiring board, a typical flow chart of the fabrication process is shown in Figure 10A.1.4.[1] In conventional printed circuit board technology, the

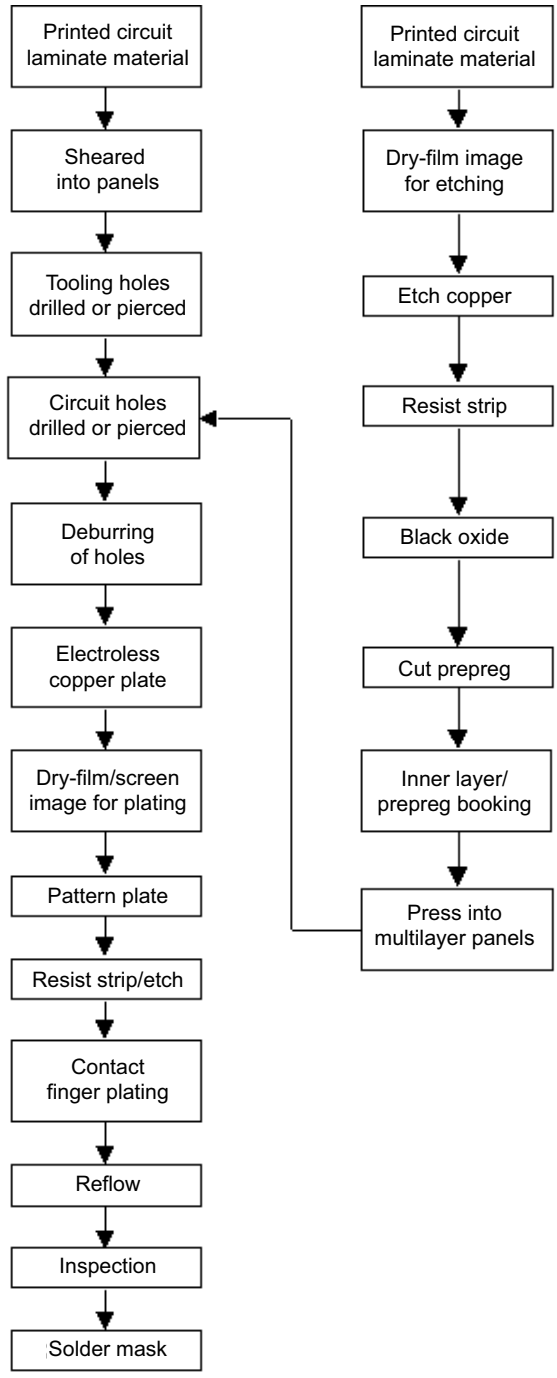

FIGURE 10A.1.4 Typical multilayer PWB fabrication process.

conductors are generally formed through both subtractive and additive processes. The partially cured laminate sheets, called *prepreg*, are cured and laminated with pressure and temperature.

The most common and least expensive resin system is FR-4 epoxy. This epoxy is a diglycidyl ether of tetrabromobisphenol A, with a glass transition temperature ranging from 135 to 180°C. Variations are

sometimes introduced in the resin to tailor desirable mechanical and electrical properties, including glass transition temperature, dielectric constant, coefficient of thermal expansion, moisture absorption, and thermal conductivity.

Holes in conventional PWBs are typically mechanically drilled. Those holes that allow conduction through all layers are called *plated through-holes* (PTH) for through-hole leads. For surface-mount devices, the holes are referred to as *plated through-vias* (PTV). Blind vias begin at a surface layer of the board and end at an internal layer. Buried vias are located in internal layers and do not include the external layers.

The explosion of commercial wireless (1–2 GHz) and high-performance processors (>1 GHz) is challenging the limits of FR-4. The edge rates of the signals and clock are actually more critical to application design than the clock frequency. The dissipation factor correlates with signal distortion and the dielectric constant with the signal delay. Thus, the relatively high dielectric constant of FR-4 (4.2) and high dissipation factor (0.030) make FR-4 use increasingly difficult for high-frequency (>150-MHz board frequencies) and fast-edge-rate (less than 1–2 ns) applications. While polytetrafluoroethylene (PTFE) materials have been used in military and high-end commercial applications for three decades because of their low dielectric constant of 2.4 to 2.6, these materials tend to be about 15 times costlier than FR-4. New materials such as polyphenylene oxide (PPO)/epoxy have reduced the dissipation factor significantly. Higher performance resins, such as polyfunctional FR-4 epoxy, bismaleimide triazine/epoxy (BT), cyanate esters (CE), and polyimide, are also used for a variety of special applications. Some key parameters and the relative costs of common materials are summarized in Table 10A.1.7.

Printed wiring boards can also be connected by flexible dielectric materials called flex print. The rigid portion of printed wiring boards can be either organic or ceramic, while flexible circuits use thinner, flexible organic base materials, including polyester and polyimide. Flex print provides an interconnection between boards that can be electrically superior to conventional connectors.

High-Density Interconnect Technology

Driven by increasing component I/O densities, board technology is migrating to the high-density interconnection (HDI). While there are numerous processes to form HDI layers, these can be classified into two general categories: microvia and thin-film. The microvia approach offers many advantages, including high frequency, high clock-rate performance, high wiring densities, and high ratios of active device area to substrate area. While the increased density comes at a higher cost, the per-function cost can actually be significantly lower. Thin-film HDI technology has been used in space applications and supercomputer applications.

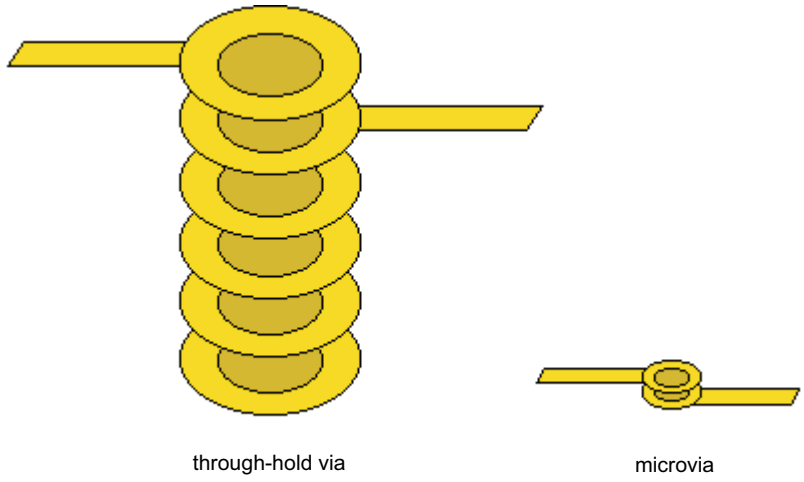

FIGURE 10A.1.5 Size advantage of microvia technology. (From IPC, *HDI and Microvia Technology,* Institute for Interconnecting and Packaging Electronic Circuits, Northbrook, IL, www.ipc.org/html/hdi.htm. With permission.)

Microvia HDI

Microvia HDI is becoming increasingly important with the advent of fine pitch array packaging. The Institute for Interconnecting and Packaging Electronic Circuits (IPC) defines a microvia as a blind or buried via of less than 150 μm, with a capture pad of less than 300 μm. Microvias can be used with conventional boards or chip-level packaging. In conventional boards, microvia technologies can be used selectively to redistribute difficult-to-route areas and enable components on both sides of the board. Ball grid arrays (BGAs) and CSPs with pitches of less than 1 mm typically require microvia redistribution layers. Figure 10A.1.5 shows the size advantage of microvias over conventional multilayer plated through-vias. Figure 10A.1.6 is a typical microvia stack-up; note that the microvia is actually included in the component solder pad. Current volume production yields exceed 99% in Japan and Taiwan. The microvias are generally formed by three basic approaches: plasma etch, photoimaging, and laser ablation. Laser ablation is a sequential technique, while plasma etch and photoimaging form vias simultaneously. Due to the high energy and difficulty of ablating glass fiber, the materials are typically not reinforced. Mechanical drilling can also be cost effective in material from 250 μm thick down to about 125 μm thick.[15]

Because there is no glass reinforcement, the dielectric constant of FR-4 epoxy is significantly lower than its reinforced counterpart. DYCOstrate®, developed by Dyconex of Zurich, Switzerland, is widely used in East Asia. An isotropic oxygen plasma is used to form vias that range from 75 to 150 μm in diameter. One advantage of this process is that the plasma removes all organic material, leaving the microvia clean.[17] The parallel processing and high yield make this process very cost effective.

A liquid- or dry-film photoimageable dielectric is generally an epoxy-acrylate material. Processing is similar to conventional soldermasking, followed by copper plating and patterning. Via diameters range from 50 to 250 μm.

Both CO_2 and ultraviolet (UV) lasers can be used to ablate the dielectric; UV can also burn through the copper layers. The CO_2 lasers are able to produce much smaller holes (10–25 μm) and are faster than the UV laser (25–200 μm). Laser vias can be formed in a variety of ways, including a two-pass process (first through copper, followed by a dielectric at a different frequency), a combination of conventional etching through the copper and laser ablation of the dielectric, and, finally, a deposited dielectric with laser via formation followed by an additive outer copper layer.[18] The remaining residue at the bottom of the ablated via can be removed with potassium permanganate or plasma etching for higher aspect ratio holes.

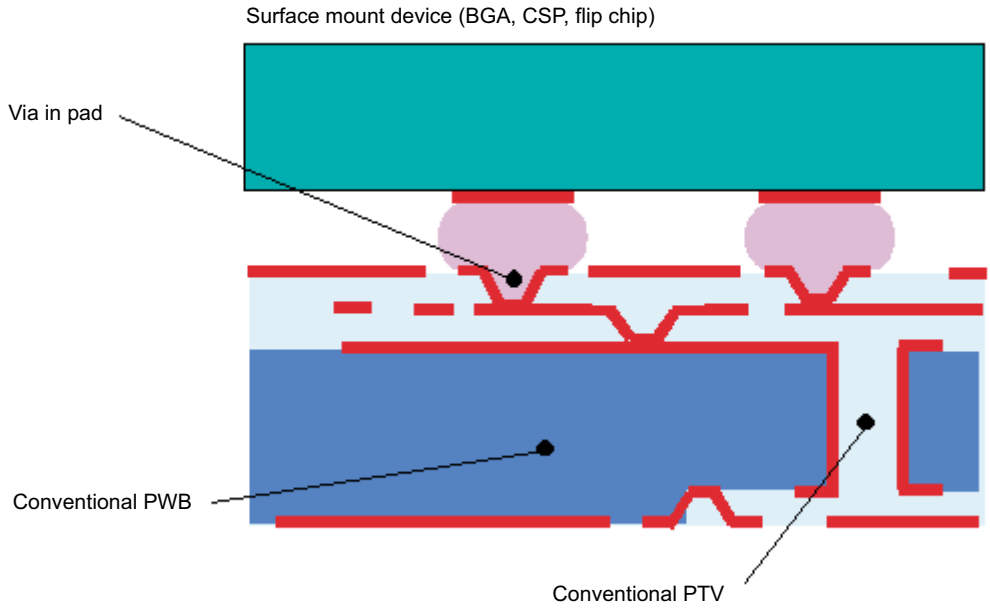

FIGURE 10A.1.6 Example of microvia technology. (From IPC, *HDI and Microvia Technology,* Institute for Interconnecting and Packaging Electronic Circuits, Northbrook, IL, www.ipc.org/html/hdi.htm. With permission.)

The reliability of the microvias is generally excellent, due to an aspect ratio of less than one. Other critical reliability factors are the hole diameter, plating thickness, hole cleanliness, and plating uniformity. In a sample of 15 different microvia test cases, only two test cases could not pass 2000 liquid-to-liquid thermal shock cycles (–55 to 125°C).[19] In another study of 18 U.S. and European fabricators, strong correlation was found between hole diameter and reliability. Holes of less than 150 μm were not reliable. Vias in solder pads were found to have no impact on solder-joint reliability.

Thin-Film HDI

All thin-film HDI approaches use deposited thin-film conductors with organic or inorganic interlayer dielectrics. The materials are sputtered with processes similar to semiconductor processing. Vias provide interconnection between conductor layers. Fully assembled modules using thin-film HDI are referred to as MCM-Ds.

Thin-film HDI can be classified into four generic types: overlay HDI, reach-through via HDI, beveled die-edge HDI, and conventional, chip-last, MCM-D, thin-film conductor and deposited dielectric HDI. A chip-last approach may employ wirebonding or other interconnects for die-to-substrate connectivity.

Table 10A.1.8 illustrates some of the many manufacturers and research institutions that make various types of HDI and MCM-D substrates. Typical design considerations, such as the number of metal layers, conductor line width, line spacing, via diameter, and via pitch, are listed in Table 10A.1.8 for each manufacturer. While many layers of dielectric and metal are possible, applications are often easily routed in two signal layers and a power-and-ground layer.

Ceramic Substrate Technology

Thick-film ceramic boards are formed by screen printing conductive, resistive, and dielectric paste onto a dielectric substrate and then firing. Typical thicknesses are in the range of 10 to 60 μm, depending on the materials. The classification "thin-film" refers to materials that are deposited in a sputtered vacuum process, similar to that used in semiconductor fabrication. Thin-film feature sizes are an order of

TABLE 10A.1.8 HDI and MCM-D Capabilities

Manufacturer	Maximum Number of Metal Layers	Minimum Line Width (μm)	Minimum Via Diameter (μm)	Minimum Line Spacing (μm)	Minimum Via Pitch (μm)

Polycon	8	5	5	10	10

magnitude less than the thick-film structures. These hybrid composites can have multiple conductor layers and can include both thick- and thin-film processes.

10A.1.3 Printed Circuit Assembly Processes

The printed circuit assembly processes consist of placing components on the printed wiring board, soldering the components, and post-solder processing steps such as cleaning and conformal coating. Classification of soldering processes is based on the method of applying the solder and the heating processes involved. Two processes in common use are wave soldering and reflow soldering. Wave soldering is used primarily for through-hole technology, while reflow soldering is used for surface-mount assembly.

Through-Hole Assembly

Through-hole components can be placed manually or with automated insertion equipment. High-speed equipment can place more than a thousand devices per minute, crimp the leads on the opposite side of the board, and dress the lead to an appropriate length. In wave soldering, the board is passed over a jet of molten solder. The hydrostatic pressure of the solder from the nozzle wets the underside of the PWB and pushes the solder slightly up the plated through-hole. Subsequent capillary action, resulting from the surface tension between the solder and the walls of the plated through-hole, forces the molten solder to rise through the hole and wet the upper lands of the through-hole, securing the part in place.

Before soldering, boards must be fluxed and preheated. Fluxing consists of applying a chemical compound with activators, solvents, and detergents to the solder-joint locations to chemically clean the surfaces to be joined. Preheating reduces thermal shock to the components and the PWB, activates the flux, and evaporates any flux solvents to prevent the formation of blowholes (voids) in the solder joint.

SMT Assembly

The reflow soldering process consists of remelting solder previously applied to a PWB joint site (pad) in the form of a preform or paste. No solder is added during reflow. The first step in the process is to apply solder paste and any necessary adhesives to the land patterns on the printed wiring board. Adhesives are needed only if the components cannot be held in place by the tackiness of the solder paste. After

component placement, the populated PWB is transported to the preheater to evaporate solvents in the solder paste. In this stage, the temperature of the board is raised to 100 to 150°C at a rate low enough to prevent solvent boiling and the formation of solder balls; 2°C/second has been accepted as an industry norm.[20]

The next stage in the reflow process is slow heating, which increases the temperature to the solder melting point and activates the flux in the solder paste. The activated flux removes oxides and contaminants from the surfaces of the metals to be joined. The next stage consists of melting the solder. During the melting stage, the temperature of the solder paste is raised to just above its melting point. When the solder melts, it replaces the liquid flux formed in the previous step. The temperature is held above the melting point while the solder coats the surfaces to be joined. The temperature must be regulated to allow the melted solder particles to coalesce and form a fillet around the component lead. Excessive temperatures increase the fluidity of the solder, causing it to move away from the desired joint location, while excessively long periods at the wetting temperature may lead to intermetallic formation and embrittlement. Fillet formation is the most critical part of the reflow process. The last stage involves cooling the solder joint, either by conducting the heat through the board layers or by natural or forced convection to the ambient air.

Reflow methods differ according to the method of heat transfer to the reflow site. Conductive, convective, and radiative heat transfers are variously used for this purpose. Conductive heat-transfer methods include the soldering iron, hot-bar reflow, and conductive-belt reflow. Radiative heat-transfer methodologies include infrared, laser, and optical fiber systems. Convective heat transfer is used in vapor-phase (or condensation) reflow systems. Each method has its own merits and limitations. The most common technique for mass reflow soldering is infrared heating/convection because it allows temperature control throughout the reflow soldering cycle. However, vapor-phase soldering is still considered the best way to limit the maximum temperature reached during reflow, as the temperature in the oven never rises above the temperature of the saturated vapor.

Connectors

Connectors can be classified based on the electronic elements being connected. Board-to-board connectors are used to connect two printed circuit boards; wire-to-board connectors are usually used to connect a source of power to a printed circuit board or to bus signals with high fidelity; and wire-to-wire connectors are generally used externally to the electronic equipment. In contemporary systems, connectors are a vital link in completing an electronic system. Connectors should be chosen carefully, taking into consideration current, voltage, impedance, EMI/EMR shielding, and allowable losses.

A connector is composed of four basic elements:[21] the contact interface, the contact finish, the contact spring, and the connector housing. The contact interfaces are of two kinds: separable and permanent. The separable connector allows for mating and unmating, while the permanent interface does not. The contact finish aids in establishing a contact interface and protecting the contact springs from corrosion. The contact spring is the electrically conducting element between the permanent connection to the subsystems and the separable interface that supplies the force necessary to maintain contact at the separable interface. The connector housing performs both mechanical and electrical functions by electrically insulating the individual contacts and supporting and locating them mechanically.

Board-to-board connectors are an important part of today's packaging. Commercial applications are making high-density connectors inexpensive. Mezzanine assemblies are gaining popularity, as processor modules become more complex in order to accommodate processor upgrades. One example is Intel's Pentium II® Mobile Module, which uses a 400-pin, 1.27-mm pitch connector.[22]

10A.1.4 Electronic Packaging Future

The future of electronic packaging promises an accelerating change. For several years now, industry roadmaps have assessed the capabilities, needs, direction, and future of electronic packaging. Hundreds

of companies, government agencies, consortia, and universities have contributed to roadmaps. There are a number of these long-range plans, including the National Electronics Manufacturing Initiative (NEMI),[14] the Japan Printed Circuit Association's *Report on the Technology Roadmap for Advanced System Integration and Packaging*,[23] and IPC's *The National Technology Roadmap for Electronic Interconnections*.[24] Many large companies and research universities involved in packaging, such as the University of Maryland's CALCE Electronic Products and Systems Center, also have roadmaps that complement and fill research holes.

The most recent findings are that cost is king in nearly all applications. Cost, a major driver in the advancement of technology, is also driving the trend toward electronics manufacturing service (EMS) suppliers or contract manufacturers. Cost and business pressures are fueling the 25% annual increase in EMS providers. The advantages of EMS include optimizing manufacturing cycle times, reducing working capital, and improving quality. The NEMI roadmap suggests that a downside of this EMS trend will be a slowing of research and development, as the EMS providers will push to keep the *status quo* rather than advance to less proven areas. The NEMI roadmap predicts that this will also lead to shorter product cycles and more conservative, evolutionary packaging approaches. If the new technology cannot achieve cost parity with existing technologies, then industry acceptance will be delayed. One example of this is flip chip packaging, competing with those technologies that are now widely used: CSP and BGA.[25]

The NEMI, IPC, and the Semiconductor Industry Association roadmaps all predict a movement from peripheral to array packaging; consequently, peripheral packages will not decrease below a 0.5-mm pitch. The growth of flip chip interconnection was seen as a growing trend in the industry by all roadmaps. The NEMI roadmap sees integral passives (resistors and capacitors) as an important part of the future in portable electronics, whereas the IPC sees the enabling technologies as immature.[26]

Some recent predictions from the NEMI roadmap are summarized in Tables 10A.1.9 and 10A.1.10. The cost of I/O and labor to assemble packages will continue to fall dramatically. Substrate lines, spaces, and device I/O pitch will also shrink to keep pace with silicon integration. Noncontact test infrastructure

TABLE 10A.1.9 NEMI Predictions for the Future[25]

	1999	2003
IC package costs per I/O (¢)	0.7–0.9	0.4–0.6
Board assembly conversion (¢)	0.7–0.9	0.5
Substrate lines and spaces (μm)	70	35
Process test pads (mm)	0.5	Non-contact
Flip chip pad pitch (μm)	180	130

TABLE 10A.1.10 Package Forecast by Lead Count Range

I/O	1998	2003
4–18	28,495	38,768
20–32	16,347	20,489
36–68	8442	18,502
72–100	2043	5160
104–144	1551	3222
148–208	922	2378
212–304	405	1070
308+	511	1710
Total	58,716	91,299

From Berry, S., The future of leadcounts, *HDI*, 2(4), 14–16, 1999. With permission.

will be required to provide efficient and cost effective assurance that assemblies are functional. A shift to higher pin-count packages is also expected, as shown in Table 10A.1.10. While the current percentage of packages with a pin count greater than 304 is less than 1%, the percentage in the year 2003 will nearly double.

Electronic packaging technology will continue to enable many compact and high-speed products of the 21st century. The need for innovations in cost, yields, and productivity will certainly challenge those engineers involved in the many facets of packaging. These improvements will eventually touch and, it is hoped, enhance the quality of life of all the world's people.

Introduction

Transportation is important for an industrial society because the movement of goods and people has significant impact on a country's economy. In the United States the transportation sector accounts for approximately 20% of the gross domestic product. The transportation sector also accounts for almost two thirds of the total U.S. petroleum consumption, with cars and light duty trucks accounting for more than 20% of the total U.S. energy use. The cost of imported petroleum in 1993 was $56 billion—almost 10% of all imports. The transportation sector is also the nation's largest single source of air pollution, with personal vehicles producing 26% of volatile organic compounds, 32% of nitrous oxides, and 62% of carbon monoxide. Thus, better ways to promote transportation efficiency is one of the most important facets of reducing fossil fuel consumption and improving environmental quality.

Transportation engineering is a highly interdisciplinary field dealing with the planning, design, construction, maintenance, and operation of various transportation modes. This section presents an overview of transportation engineering, emphasizing planning, design, operation, environmental impacts, legal,

system analysis, and emerging issues such as alternative fuels, electric vehicles, and intelligent highway systems. Emphasis is placed on those facets of transportation that impact the mechanical engineering profession, but the area also needs social, political, and management inputs to arrive at appropriate engineering solutions of specific problems.

10.1 Transportation Planning

M. D. Meyer

Transportation planning is the process of producing the information necessary to determine the most cost-effective strategy for improving the performance of the transportation system. Transportation planning can occur on different scales of analysis — at the national, multistate, state, metropolitan, subarea or corridor, and local levels. At each level the planning methodologies used, databases developed, and information produced are often heavily influenced by government regulations. No matter what modeling approaches are used in transportation planning, a fundamental concept that influences the way transportation demand is estimated is called **derived demand**. Derived demand means that a trip is taken to accomplish some activity at the destination, and that the trip itself is simply a means of reaching this activity. Transportation planning must therefore relate trip making to the types of activities that occur in a study area and also to the characteristics of the trip maker that will influence the way these trips are made. This end is reached by combining similar uses of land into a land use category that can then be used in transportation planning to estimate how many trips are attracted to each type of land use (e.g., the number of trips to schools, shopping centers, residential units, office complexes, etc.).

Basic Framework of Transportation Planning

The basic framework for transportation planning at any scale of application is shown in Figure 10.1.1. The steps shown in this framework are discussed in the sections that follow.

Inventory of Facilities

Knowing what a **transportation network** consists of and the condition and performance of these facilities is an important starting point for transportation planning. Transportation investment is usually aimed at upgrading the physical *condition* of a facility (e.g., repaving a road or building a new bridge) or at improving its *performance* (e.g., providing new person-carrying capacity by providing preferential treatment for high-occupancy vehicles or building a new road to serve existing demand).

Collect and Maintain Socioeconomic and Land Use Data

Given the concept of derived demand, a basic starting point for planning is characterizing the variables that will influence this demand. Current land use is readily attained through land use inventories. The methods of estimating future land use range from trends analysis to large-scale land use models that predict household and employment sites decades into the future. Socioeconomic characteristics often include the level of income, number of members in the household, number of autos in the household, number of children, age of the head of household, and highest level of education achieved.

Define Goals and Objectives

Goals are generalized statements that indicate the desired ultimate achievement of a transportation plan. *Objectives* are more specific statements that indicate the means by which these goals will be achieved. The identification of goals and objectives is critical in that they define the evaluation criteria that will be used later in the planning process to assess the relative impacts of alternative projects and strategies. These criteria are often called *measures of effectiveness*.

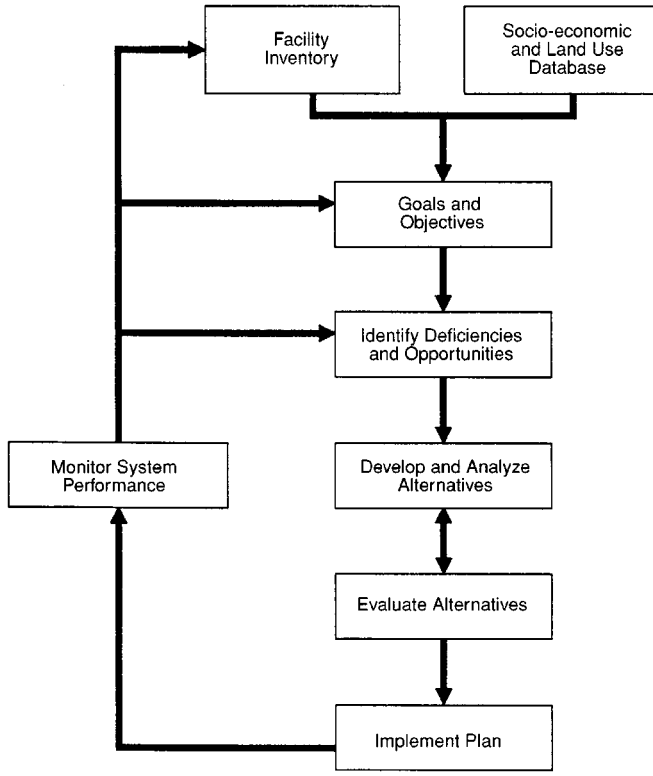

FIGURE 10.1.1 Basic elements of transportation planning.

Identify System Deficiencies or Opportunities

The methods used to identify transportation deficiencies and opportunities can vary widely. In some cases large-scale transportation network models are used to estimate future traffic volumes and then to compare them to the capacity of the road network to handle such volumes. This volume-to-capacity (V/C) ratio has served as the major means of identifying the location of system deficiencies. However, other *performance measures* can also be used in the transportation planning process that are much broader than the traditional V/C ratios, such as level of accessibility to economic activities, average travel times, and so on.

Develop and Analyze Alternatives

Various types of strategies can surface from the planning process: (1) those focused on improvements to highways — for example, adding new lanes, improving traffic control through signals or signing, or improving traffic flow through channelization; and (2) other strategies, such as reducing the demand for transportation through flexible working hours, increasing average vehicle occupancy through such measures as carpools or transit use, or raising the "price" of travel through the use of tolls. More recently, the application of advanced transportation technologies to the operation of a road system, known as *intelligent transportation systems*, has become an important strategy in many cities.

Evaluate Alternatives

Evaluation brings together all of the information gathered on individual alternatives and provides a framework to compare the relative worth of the alternatives. This evaluation process most often relies on the various measures of effectiveness that relate to the goals and objectives defined at the beginning of the planning process.

Implement Plan

The major products of the transportation planning process are the *transportation plan* and, at the state and metropolitan levels, the *transportation improvement program (TIP)*, which lists all of the transportation projects that will be implemented over the next few years in the region.

Monitor System Performance

Transportation planning continually examines the performance and condition of the transportation system to identify where improvements can be made. Some means of monitoring system performance is necessary to systematically identify areas where these improvements might occur. This system monitoring has traditionally been based on traffic volumes obtained from traffic counters placed at strategic locations in the network (e.g., increasing traffic volumes during a specific time period indicate congestion).

Transportation Modeling

The level of transportation analysis can vary according to the level of complexity and scale of application. In most cases, however, the modeling process consists of four major steps—trip generation, trip distribution, mode split, and trip assignment. Each study area (whether a nation, state, metropolitan area, or neighborhood) is divided into zones of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from, or attracted to, that zone. In most cases, transportation planners try to create a **zonal system** by defining zones that are related to other data collection activities (e.g., U.S. Census tracts). The transportation system is represented in models as a network of *links* and *nodes*. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as intersections. Given the complex nature of transportation systems, the typical transportation network consists of links representing only highly used facilities. The transportation modeling process can thus be represented as shown in Figure 10.1.2.

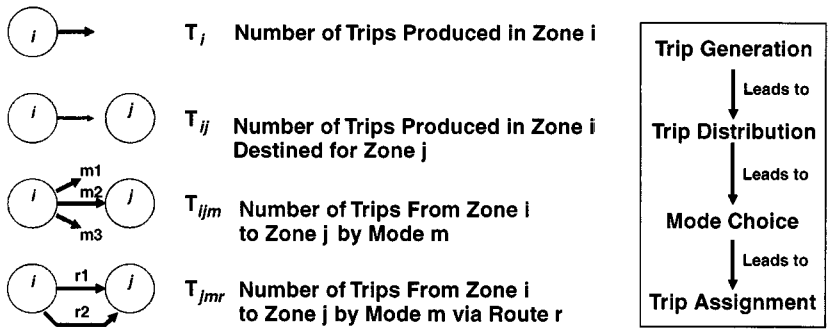

FIGURE 10.1.2 Transportation modeling framework.

Trip generation is the process of analytically deriving the number of trips that will be generated from a location or zone based on socioeconomic information of the travelers or, in the case of freight movement, zonal economic characteristics. The trip generation stage also includes predicting the number of trips that will be attracted to each zone in the study area:

- Number of trips produced in a zone = *f* (Socioeconomic characteristics, land use, transportation mode availability)
- Number of trips attracted to a zone = *f* (Attractiveness of zone)

There are two approaches for estimating trips generated. The first approach uses *trip rate models*. Based on existing data, trip rates can be calculated that relate trip-making to variables known to influence travel behavior. For an example, see Table 10.1.1.

TABLE 10.1.1 Cross-Classification Analysis

	Number of People in Households		
	1	**2**	**3+**
Low income	2.4	3.3	4.5
Medium income	3.5	3.8	4.8
High income	3.9	4.2	5.4

The other approach is to use *regression models*. Based on existing data, multiple regression equations are estimated relating trip generation to variables found to be significant in travel behavior. For example,

$$\text{Zone estimate:} \quad T_{iz} = 184.2 + 120.6\left(X1_i\right) + 34.5\left(X2_i\right)$$

$$\text{Household estimate:} \quad T_{ih} = 0.64 + 2.3\left(X1_{ih}\right) + 1.5\left(X2_{ih}\right)$$

$$\text{Zone attractions:} \quad T_j = 54.2 + 0.23(X3) + 0.43(X4)$$

where

T_{iz} = Total trips generated in zone i
T_{ih} = Total trips generated per household in zone i
T_j = Total trips attracted to zone j
$X1_i$ = Total number of workers in zone i
$X2_i$ = Total number of automobiles in zone i
$X1_{ih}$ = Number of employees per household in zone i
$X2_{ih}$ = Number of automobiles per household in zone i
$X3$ = Total number of office employees in zone j
$X4$ = Total number of retail employees in zone j

Trip distribution is the process of estimating the number of trips that originate in each zone in the study area and their corresponding destinations. The result of the trip distribution process is a matrix called a *trip table*, which shows the number of trips originating in each study zone and their corresponding destinations for the time period being examined. The most commonly used method for distributing trips in a zonal system is the gravity model, which is of the following form:

$$T_{ij} = P_i \frac{A_j \times F_{ij} \times K_{ij}}{\sum_j \left(A_j \times F_{ij} \times K_{ij}\right)} \tag{10.1.1}$$

where

T_{ij} = Number of trips originating in zone i and destined to zone j
P_i = Number of trips produced in zone i
A_j = Level of attractiveness of zone j (e.g., number of employees)
F_{ij} = Friction or impedance factor between zones i and j (a value usually a function of travel time)
K_{ij} = Socioeconomic adjustment factors for trips between zones i and j (a value that represents variables that influence trip making not accounted for by other variables)

Mode choice is the process of estimating the percentage of individuals who will use one mode of transportation over the others available for a given trip. The basic concept in making this estimation is that each mode of transportation has associated with it some empirically known characteristics that, when combined in a mathematical equation, can define that mode's *utility*. Variables such as travel time, travel cost, modal reliability, and so on are often incorporated into a mode's **utility function**, along with socioeconomic characteristics of the traveler. Freight models use a similar concept in estimating

commodity flows by mode. One of the most familiar forms of mode choice models is the logit model, which predicts mode shares based on the following equation:

$$P_{ik} = \frac{e^{U_k}}{\sum_{m=1}^{n} e^{U_m}} \tag{10.1.2}$$

where

P_{ik} = Probability of individual i choosisng mode k
U_k = Utility of mode k
U_m = Utility of mode m
n = Number of modes available for trip

The utility of each mode is often represented as a linear function of those variables found to influence an individual's choice of mode. For example, a utility function for the automobile mode might be of the form

$$U_a = 6.3 - 0.21(X_1) - 0.43(X_2) - 0.005(X_3) \tag{10.1.3}$$

where

U_a = Utility of automobile
X_1 = Access and egress time when automobile is chosen
X_2 = Line-haul time
X_3 = Travel cost

The utility functions of other modes available for a specific trip would be similarly specified. The probabilities would then be multiplied by the total number of trips to obtain the number of trips made by mode.

Trip assignment is the process of estimating the travel flows through a transportation network based on a trip table (which is produced in trip distribution). The basic concept found in all trip assignment models is that travelers choose routes that will minimize travel time—that is, they will choose the shortest path through the network. Link performance functions that relate travel time to number of vehicles on the link (see Figure 10.1.3) are used to iteratively update estimated link travel times so that minimum-path travel times reflect the effect of congestion. Recent research in trip assignment methods has introduced the concept of stochastic assignment, which means that some subset of trip routes will in fact have associated with them some characteristics that attract certain types of travelers, even if the travel time is longer.

Defining Terms

Derived demand: An assumption that travelers make a trip to accomplish some activity at the destination and that the trip itself is simply a means of reaching this activity.

Transportation network: A transportation system is represented in models as a network of *links* and *nodes*. Links represent line-haul facilities, such as roads or transit lines, and nodes represent points of connection, such as intersections. Given the complex nature of transportation systems, the typical transportation network consists of links representing only higher functionally classified facilities or those links that represent known highly traveled paths.

Utility function: A mathematical formulation that assigns a numerical value to the attractiveness of individual modes of transportation based primarily on that mode's characteristics.

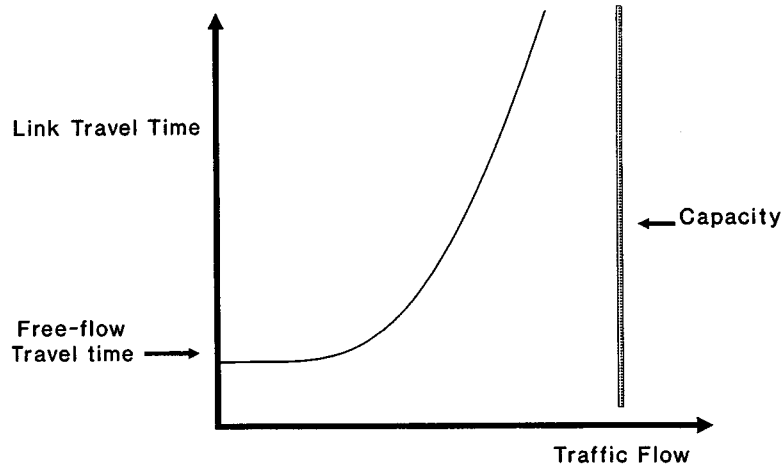

FIGURE 10.1.3 Link performance function.

Zonal system: Each study area (whether a nation, state, metropolitan area, or neighborhood) is divided into zones of homogeneous characteristics (e.g., similar household incomes) that can then be used as the basic foundation for estimating trips from or attracted to, that zone. In most cases transportation planners try to define zones that are related to other data collection activities (e.g., U.S. Census tracts).

10.2 Design of Transportation Facilities

John Leonard, II and Michael D. Meyer

The efficient movement of people and goods requires transportation systems and facilities that are designed to provide sufficient capacity for the demands they face in a safe manner. In addition, in most modern societies, the design of transportation facilities must explicitly minimize harm to the natural and human-made environment while providing for mitigation measures that relate to those impacts that are unavoidable. In many ways the critical challenge to today's designers of transportation projects is successfully designing a facility that minimally harms the environment.

The design of a transportation facility almost always takes place within the context of a much broader **project development process**. This process can vary in complexity with the type of project under design and with the scale of implementation. The importance of the project development process to the designer is that it

- Establishes the key characteristics of the project that must be considered in the design
- Indicates the time frame that will be followed for project design
- Establishes which agencies and groups will be involved in the process and when this involvement will likely occur
- Links the specific elements of the project design with other tasks that must be accomplished for the project to be constructed
- Satisfies legal requirements for a design process that is open for review and comment
- Indicates the specific products that must be produced by the designers to complete the project design process

In most cases the project development process consists of a well-defined set of tasks each of which must be accomplished before the next task can occur. These tasks include both technical activities and public involvement activities that are necessary for successful project development.

Components of the Project Development Process

Identify Project Need

A project need can be identified through a formal planning process or from a variety of other sources, including elected officials, agency managers, transportation system users, and citizens. Important in this early portion of project development is an indication of what type of improvement is likely to be initiated. For example, a project could relate to one or more of the following types of improvement strategies:

- *New construction.* A transportation facility constructed at a new location.
- *Major reconstruction.* Addition of new capacity or significant changes to the existing design of a facility, but usually occurring within the area where the current facility is located.
- *Rehabilitation/restoration.* Improvements to a facility usually as it is currently designed and focusing on improving the physical condition of the facility or making minor improvements to enhance safety.
- *Resurfacing.* Providing new pavement to a transportation facility that prolongs its useful life.
- *Spot improvements.* Correction of a problem or hazard at an isolated or specific location.

Establish Project Limits and Context

One of the very first steps in the design process is to define the boundaries or limits of the project. This implies establishing how far the project will extend beyond the area being targeted for improvement and the necessary steps to ensure smooth connections to the existing transportation system.

Establish Environmental Impact Requirements

The design of a project will very much be affected by environmental laws or regulations that require design compliance with environmental mandates. These environmental mandates could relate to such things as wetlands, historic properties, use of public park lands, water quality, navigable waterways, fish and wildlife, air quality, noise, and archaeological resources. One of the first steps in project development is to determine whether the likely project impacts are significant enough to require environmental study.

Develop Strategy for Interagency Coordination and Public Involvement

Depending on the complexity and potential impact of a project, the project designer could spend a great deal of time interacting with agencies having some role in or jurisdictional control over areas directly related to the project. These agencies could have jurisdiction by law (e.g., wetlands) or have special expertise that is important to project design (e.g., historic preservation). In addition to interagency coordination, transportation project development is often subject to requirements or public outreach and/or public hearings.

Initiate Project Design and Preliminary Engineering

Topographic data of the study area and forecasted vehicular volumes expected to use the facility in the design year are used as input into the preliminary design of the horizontal and vertical alignment of the facility, that is, the physical space the facility will occupy once finished. This preliminary engineering step also includes the preparation of initial right-of-way (ROW) plans, which indicate the amount of land that must be available to construct the facility.

Project Engineering

Once preliminary engineering has provided the basic engineering information for the project, the more detailed project design begins. This entails specific layouts of horizontal and vertical geometry, soils/subsurface examination and design, design of utility location, drainage design, more detailed ROW plans, and initial construction drawings. Concurrent with this design process, the environmental process continues with updated information on project changes that might cause additional environmental harm, the initiation of any permitting process that might be needed to construct the project (e.g., environmental agency permission to affect wetlands), and public hearings/meetings to keep the public involved with project development.

Final Engineering

The final engineering step is the culmination of the design process, which basically completes the previous design plans to the greatest level of detail. This step includes finalizing ROW plans, cost estimates, construction plans, utility relocation plans, and any agreements with other agencies or jurisdictions that might be necessary to complete the project. Environmental permits are received and final project review for environmental impacts is completed.

Basic Concepts of Project Design

Human Factors

Human factors have a great deal of influence on the design of transportation facilities in such areas as width of facility, length and location of access/egress points, braking distance, location of information/guidance aids such as signs, and geometric characteristics of the facility's alignment. The driver-vehicle-roadway interface is shown in Figure 10.2.1.

Vehicle or User Performance Factors

The dynamics of vehicle motion plan an important role in determining what is effective and safe design. The key vehicle characteristics that become important in design criteria include:

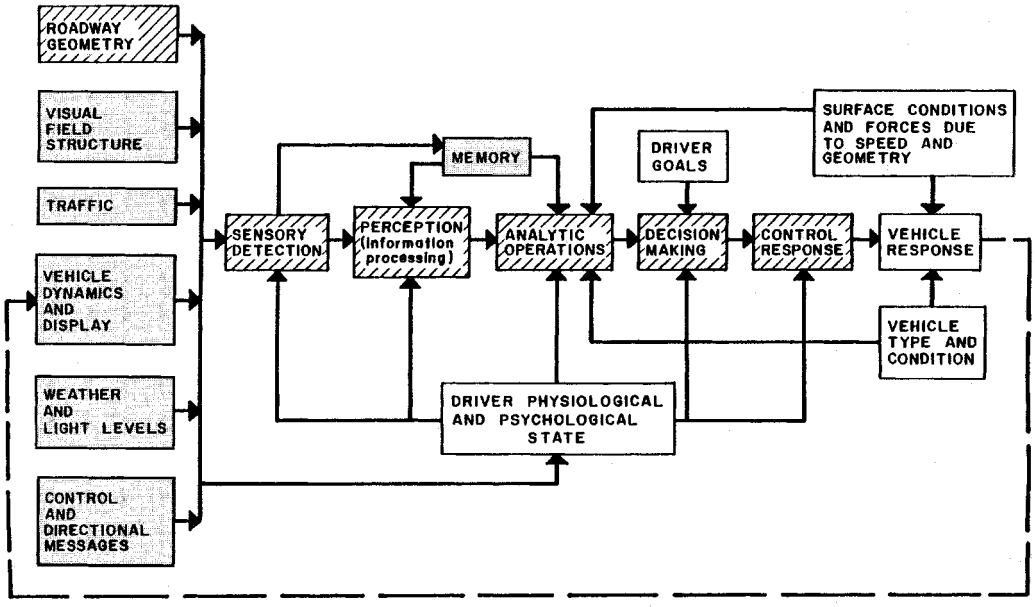

FIGURE 10.2.1 Driver-vehicle-roadway interface. Gray shaded boxes, information inputs; cross-hatched boxes, driver guidance and control process.

- *Vehicle size*. Influences vertical and horizontal clearances, turning radii, alignment width, and width of vehicle storage berths.
- *Vehicle weight*. Influences strength of material needed to support vehicle operations.
- *Vehicle or user performance*. Influences specifications for horizontal and vertical geometry, braking distances, and needed capacity to allow passing and successful maneuvering (e.g., assumed walking speed of pedestrians crossing a road).

Classification Schemes

The transportation system serves many functions, ranging from providing access to specific locations to providing high-speed, high-capacity movement over longer distances. Classification schemes are used to represent these various roles and influence the design criteria that are associated with the facilities in each classification category. A common **functional classification** scheme for highways is shown in Figure 10.2.2.

Capacity and Level of Service

Every design usually begins with some estimation of the demand for the transportation facility that will likely occur if the facility is built. The key design question then becomes, what facility capacity (e.g., number of road lanes, runways, transit lines, or vehicle departures) is necessary if a certain level of service is desired? The definition of **level of service (LOS)** thus becomes a critical element in establishing this important design factor (see Figure 10.2.3).

Design Standards

Design standards dictate minimum or maximum values of project characteristics that are associated with a particular facility type. Design standards usually result from extensive study of the relationship between various design characteristics and vehicle performance and the safe handling of the vehicles by human operators. Design standards often vary by the "design speed" of the facility (and thus the

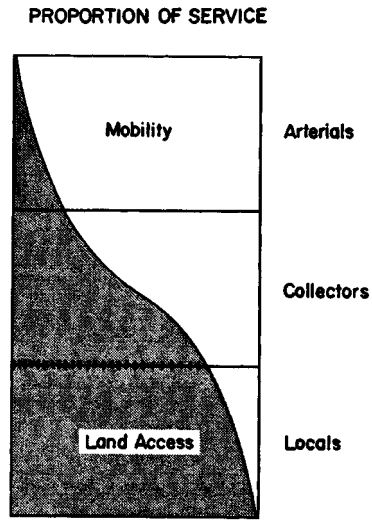

FIGURE 10.2.2 Relationship of functionally classified systems in service traffic mobility and land access. (*Source*: AASHTO, 1990, Figure I-5.)

importance of the-facility classification) and by the "design vehicle." Design standards are often the basis for developing typical cross sections (see Figure 10.2.4 and 10.2.5).

Intermodal Transportation Terminals or Transfer Facilities

Terminals or transfer facilities are locations where users of the transportation system change from one mode of travel to another. The effective design of such facilities is a critical element of successful transportation system performance, given the potential bottlenecks they represent if not designed appropriately. The design of terminals and transfer facilities must pay special attention to the needs of the users of the facility, in that they serve to establish the effective capacity of the facility. For example:

1. Internal pedestrian movement facilities and areas (stairs, ramps, escalators, elevators, corridors, etc.)
2. Line-haul transit access area (entry control, fare collection, loading, and unloading)
3. Components that facilitate movements between access modes and the station (ramps or electric doors)
4. Communications (public address systems and signage)
5. Special provisions for disabled patrons (elevators and ramps)

The criteria that could relate to the design of such a facility include threshold values for pedestrian level of service, delay at access points, connectivity from one area of the facility to another, and low-cost maintenance. For the vehicle side of such terminals, special consideration must be given to the performance of the design vehicle (e.g., turning radii of buses or semitrailer trucks) and the vehicle storage requirements (e.g., the number, size, and orientation of loading/unloading berths).

Advanced Technology Projects

One of the characteristics of transportation system development in recent years has been the increased application of advanced (usually electronic) technologies to improve system performance. The following steps apply to designing advanced technology projects.

FREEWAYS

Level of Service	Maximum Density (pc/mi/ln)	Minimum Speed (mph)	Max Service Flow Rate (pcphpl)	Maximum *v/c* Ratio
		Free-Flow Speed = 70 mph		
A	10.0	70.0	700	0.318/0.304
B	16.0	70.0	1120	0.509/0.487
C	24.0	68.5	1644	0.747/0.715
D	32.0	63.0	2015	0.916/0.876
E	36.7/39.7	60.0/58.0	2200/2300	1.000
F	var	var	var	var
		Free-Flow Speed = 65 mph		
A	10.0	65.0	650	0.295/0.283
B	16.0	65.0	1040	0.473/0.452
C	24.0	64.5	1548	0.704/0.673
D	32.0	61.0	1952	0.887/0.849
E	39.3/43.4	56.0/53.0	2200/2300	1.000
F	var	var	var	var
		Free-Flow Speed = 60 mph		
A	10.0	60.0	600	0.272/0.261
B	16.0	60.0	960	0.436/0.417
C	24.0	60.0	1440	0.655/0.626
D	32.0	57.0	1824	0.829/0.793
E	41.5/46.0	53.0/50.0	2200/2300	1.000
F	var	var	var	var
		Free-Flow Speed = 55 mph		
A	10.0	55.0	550	0.250/0.239
B	16.0	55.0	880	0.400/0.383
C	24.0	55.0	1320	0.600/0.574
D	32.0	54.8	1760	0.800/0.765
E	44.0/47.9	50.0/48.0	2200/2300	1.000
F	var	var	var	var

Note: In table entries with split values, the first value is for four-lane freeways, and the second is for six- and eight-lane freeways.

(D)

FIGURE 10.2.3 (continued) Example level of service characteristics.

Defining Terms

Design standard: Physical characteristics of a proposed facility that are professionally accepted and often based on safety considerations.

Functional classification: Classifying a transportation facility based on the function it serves in the transportation system. Such classification becomes important in that design standards are often directly related to the functional classification of a facility.

Level of service: An assessment of the performance of a transportation facility based on measurable physical characteristics (e.g., vehicular speed, average delay, density, flow rate). Level of service is usually subjectively defined as ranging from A (good performance) to F (bad or heavily congested performance).

Project development process: The steps that are followed to take a project from initial concept to final engineering. This process includes not only the detailed engineering associated with a project design but also the interaction with the general public and with agencies having jurisdiction over some aspect of project design.

10.3 Operations and Environmental Impacts

Paul W. Shuldiner and Kenneth B. Black

Highways are intended to provide for the safe and efficient movement of vehicles. These objectives are secured through careful geometric design of the layout and physical features of roads and streets and through appropriate operational procedures and devices designed to guide, advise, and regulate vehicle operators in their use of these facilities. Proper design of operational procedures and devices is based on a thorough understanding of the complex interactions among driver, vehicle, and roadway characteristics. Provided here is an overview of the fundamentals upon which such an understanding can be built.

Fundamental Equations

Flow, q, is given by the following formula:

$$q = \frac{n \times 3600}{T} \text{ vehicles per hour} \tag{10.3.1}$$

where n = number of vehicles passing a point in T seconds. **Density**, k, is given by

$$k = \frac{n}{L} \times 5280 \text{ vehicles per mile} \tag{10.3.2}$$

where n = number of vehicles occupying a length of road and L is in feet, or by

$$k = \frac{n}{L} \times 1000 \text{ vehicles per kilometer} \tag{10.3.3}$$

where n = number of vehicles occupying a length of road and L is in meters.

Average **speed**, $\bar{u}$, is given by

$$\bar{u}_t = \frac{1}{n}\sum_{i=1}^{n} u_i \tag{10.3.4}$$

where u_i = speed of the ith vehicle, termed the *time mean speed*, and by

$$\bar{u}_s = ns \Big/ \sum_{i=1}^{n} t_i \tag{10.3.5}$$

where t_i = time for the ith vehicle to traverse distance s, termed the *space mean speed*. The values $\bar{u}_s$ and $\bar{u}_t$ usually differ very slightly from one another unless there are wide variations among the speeds of individual vehicles.

Flow, Speed, and Density Relationships

There exists a dimensional identity between flow, density, and speed such that

$$q = k \times \bar{u}_s \tag{10.3.6}$$

For simplicity, it is often assumed that average speed, u, decreases linearly as density, k, increases. Given this assumption and the dimensional identity expressed in Equation (10.3.6), it follows that flow, density, and speed are related as shown in Figure 10.3.1. It may be seen from Figure 10.3.1 that:

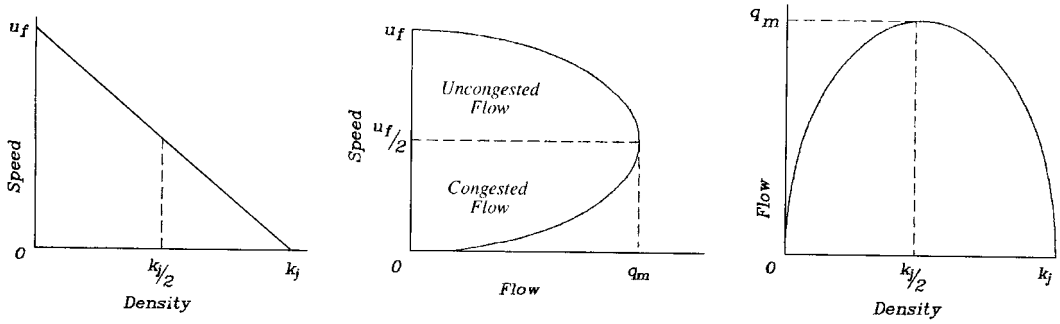

FIGURE 10.3.1 Relationships between flow, density, and speed.

1. When density on the highway is zero, there are no vehicles on the highway and the flow is zero.
2. As density rises to its maximum, flow goes to zero as vehicles line up—essentially bumper to bumper.
3. As density increases, flow also increases—up to the point where $k = kj/2$—and then decreases as density increases.
4. As flow increases from zero to a maximum (the capacity of the roadway), speed also decreases. Once the flow approaches capacity, any impediment to the steady movement of traffic will reduce both flow and speed abruptly, with a concomitant rapid increase in density.

Traffic Measurements

Measurements of traffic operating conditions are useful in the design of streets and highways and of the devices and measures necessary to promote safe and efficient operation of these facilities. Several of the more common types of traffic measurements and their applications are summarized as follows:

Measurement Type	Typical Measurement Device	Common Applications
Volume, roadway	Pneumatic road tubes and counters	Design of new facilities or capacity additions
	Magnetic induction loops	Traffic control
Volumes, intersection movements	Pneumatic tubes and counters	Traffic control
	Manual recording	Intersection design
Speed	Radar	Traffic control
	Pneumatic road tubes	Level of service
	Magnetic induction loops	Congestion management
Travel time and delay	"Floating cars" in traffic stream	Level of service
	License plate matching using laptop computers, pencil and paper, video camcorders	Congestion management
Accident records	Standardized police reports	Traffic control
	Condition and collision diagrams	Geometric improvements

Level of Service (LOS)

The **level of service** is a measure of how freely a given traffic system is operating. It is affected primarily by traffic **volume**, but other factors such as proportion of heavy vehicles, roadway geometrics, and

incidents also affect the level of service. LOS is designated by letters A through F. LOS A is characterized as *free flow* and is applied to conditions of very low traffic volume in which there is little or no restriction to traffic flow. LOS F is characterized as *forced flow* with congested, stop-and-go movement. LOS C involves some restriction to free movement of traffic and is the level of service commonly used as a design criterion.

Highway Capacity

The **capacity** of a highway depends on many geometric and traffic characteristics, the most important of which are number of lanes, width of lanes, lateral clearance to obstructions, percentage of the traffic stream made up of trucks and buses, and percent grade of the roadway. Ideally, lane widths should be at least 12 feet. Obstruction should be a minimum of 6 feet from the edge of pavement. Vertical grades of 3% or more that are one-half mile long or longer will reduce the capacity of a highway, especially where commercial vehicles are present. For freeways, maximum lane capacity under ideal conditions is generally assumed to be 2000 vehicles per hour. Ideal conditions, however, are seldom achieved.

A more useful number is the service flow. This is the ideal flow with several adjustment factors applied:

$$q_s = q^* N f_w f_{hv} \tag{10.3.7}$$

where

q_s = Service flow in vehicles per hour
q^* = Ideal flow in passenger cars per lane per hour
N = Number of freeway lanes
f_w = Adjustment factor for effect of lane widths and close lateral obstructions
f_{hv} = Adjustment factor for effect of heavy vehicles

See TRB (1985) for appropriate values of f_w and f_{hv}.

Intersection Capacity

The 1985 *Highway Capacity Manual* provides a quick method for estimating the capacity of a signalized intersection. This method is based on critical movement analysis and is known as the *planning procedure*. To apply this procedure, the sum of a through lane of traffic is added to the opposing left-turn traffic, and the highest resulting sum for both the north-south and east-west directions is considered the critical volume for an intersection. These volumes are compared with threshold values to establish the intersection capacity. These thresholds are presented in TRB (1985).

The analysis of capacity of unsignalized intersections is done by studying the degree to which motorists will accept gaps in traffic when they pull away from a stop or yield sign. The critical gap is the gap, in seconds, that 50% of the drivers will accept. The potential capacity minus the used capacity of a lane is the reserve capacity. It is this capacity that is the basis of establishing the level of service of the unsignalized intersection.

Traffic Control Devices

Traffic signs, signals, and pavement markings **(traffic control devices)** are used to regulate, warn, and guide traffic in the interest of promoting safe and efficient operation. The effectiveness of such devices is greatly enhanced through the uniformity of their design, including shape, color, and message, and through their use and placement on the roadway. Uniformity is ensured by adherence to the standards promulgated in the *Manual of Uniform Traffic Control Devices* (U.S. DOT and FHA, 1988) or the equivalent manual adopted by each state highway agency.

Stop Sign Warrants

Since stop signs are an inconvenience to motorists, they should only be used where one or more of the following conditions warrants.

1. At an intersection of a less important road with a main road where application of the normal right-of-way rule is unduly hazardous
2. Where a street enters a through highway or street
3. At an unsignalized intersection in a signalized area
4. At other intersections where a combination of high speed, restricted view, and serious accident record indicates a need for control by a stop sign

Consideration should be given to other less restrictive measures before these warrants are applied.

Traffic Signal Warrants

Traffic control signals should not be installed unless at least one of several signal warrants is met. Eleven signal warrants are used to account for such factors as traffic volume, accidents, and pedestrian volumes. The description of these warrants is presented in U.S. DOT and FHA (1988). In addition to a review of these warrants, an engineering study should be conducted to show that the installation of such a signal would improve the overall safety and operation of the intersection.

Air Quality Effects

Air quality effects of vehicles are a function of the number, type, and condition of vehicles on the highway and of the speed and efficiency with which these vehicles operate. Carbon monoxide, hydrocarbons, and oxides of nitrogen are the primary pollutants emitted by vehicular traffic. The level of emission of each pollutant is complicated and difficult to predict. In general, the emission of carbon monoxide and hydrocarbons is minimized at speeds between 35 and 45 miles per hour, whereas the emission of oxides of nitrogen increases over this speed range. Therefore, there is no ideal speed at which the level of emission of all three pollutants will be minimized. Nevertheless, smoothly flowing traffic will tend to produce less pollution, and therefore, whatever can be done to reduce delay and congestion—especially when combined with a reduction in total vehicle miles traveled—will result in an improvement in air quality.

Defining Terms

Capacity: A measure of a facility's ability to accommodate the movement of vehicles.

Density (k): Number of vehicles occupying a given length of roadway at an instant in time; usually expressed as veh/mi or veh/km.

Level of service (LOS): The quality of movement experienced by motorists in a traffic stream; usually expressed in terms of the freedom of movement of motorists, ranging from little or no restriction (LOS A) to essentially bumper-to-bumper congestion (LOS F).

Speed (u): Average speed of vehicles in a traffic stream; usually expressed as miles per hour (mph) or kilometers per hour (kph).

Traffic control devices: Signs, signals, and pavement markings placed on streets or highways to guide, inform, or regulate the movement of vehicles on those facilities.

Volume (q): Time rate of flow of vehicles; usually expressed as veh/h.

10.4 Transportation Systems

Paul Schonfeld

The various forms of transportation that have been developed over time are called **modes**. The classification of modes may be very broad (e.g., highway transportation or air transportation) or more restrictive (e.g., chartered helicopter service). The major distinctions among transportation modes that help to classify them include:

1. Medium (e.g., air, space, surface, underground, water, underwater)
2. Users (e.g., passengers vs. cargo, general-purpose vs. special trips or commodities, common vs. private carrier)
3. Service type (scheduled vs. **demand responsive**, fixed vs. variable route, nonstop vs. express or local, mass vs. personal)
4. Right-of-way type (exclusive, semi-exclusive, shared)
5. Technology:
   a. Propulsion (e.g., electric motors, diesel engines, gas turbines, linear induction motors, powered cables)
   b. Energy sources (e.g., petroleum fuels, natural gas, electric batteries, electric power from conducting cables)
   c. Support (e.g., aerodynamic lift, flotation on water, steel wheels on two steel rails, monorails, air cushions, magnetic levitation, suspension from cables)
   d. Local control (e.g., lateral control by steering wheels, wheel flanges on railroad vehicles, rudders, longitudinal control by humans or automatic devices)
   e. Network guidance and control systems (with various degrees of automation and optimization)

A mode may be defined by its combination of such features. The number of conceivable combinations greatly exceeds the number of modes that have been actually tried, which, in turn, exceeds the number of successful modes. Success may be limited to relatively narrow markets and applications (e.g., for helicopters or aerial cablecars) or may be quite general. Thus, automobiles are successful in a very broad range of applications and have become the basis for distinct transportation modes such as taxis, carpools, or ambulances.

The relative success of various transportation modes depends on available technology and socioeconomic conditions at any particular time, as well as on geographic factors. As technology or socioeconomic conditions change, new transportation modes appear, develop, and may later decline as more effective competitors appear. For many centuries water transportation was considerably cheaper than overland transportation. Access to waterways was quite influential in the location of economic activities and cities. Access to good transportation is still very important to industries and communities. Technological developments have so drastically improved the relative effectiveness of air transportation that within a short period (approximately 1950 to 1965) aircraft almost totally replaced ships for transporting passengers across oceans. It is also notable that as economic prosperity grows, personal transportation tends to shift from the walking mode to bicycles, motorcycles, and then automobiles. Geography can significantly affect the relative attractiveness of transportation modes. Thus, natural waterways are highly valuable where they exist. Hilly terrain decreases the economic competitiveness of artificial waterways or conventional railroads while favoring highway modes. In very mountainous terrain even highways may become uncompetitive compared to alternatives such as helicopters, pipelines, and aerial cablecars.

The relative shares of U.S. intercity passenger and freight traffic are shown in Table 10.4.1. The table shows the relative growth since 1929 of airlines, private automobiles, and trucks and the relative decline of railroad traffic.

TABLE 10.4.1 Volume of U.S. Intercity Freight and Passenger Traffic

Millions of Revenue Freight Ton-Miles and Percentage of Total

Year	Railroads	%	Trucks	%	Great Lakes	%	Rivers and Canals	%	Oil Pipelines	%	Air	%	Total
1929	454,800	74.9	19,689	3.2	97,322	16.0	8,661	1.4	26,900	4.4	3	0.0	607,375

Transportation System Components

The major components of transportation systems are:

1. Links
2. Terminals
3. Vehicles
4. Control systems

Certain "continuous-flow" transportation systems such as pipelines, conveyor belts, and escalators have no discrete vehicles and, in effect, combine the vehicles with the link.

Transportation systems may be developed into extensive networks. The networks may have a hierarchical structure. Thus, highway networks may include freeways, arterials, collector streets, local streets, and driveways. Links and networks may be shared by several transportation modes (e.g., cars, buses, trucks, taxis, bicycles, and pedestrians on local streets). Exclusive lanes may be provided for particular modes (e.g., pedestrian or bicycles) or groups of modes (e.g., buses and carpools).

Transportation terminals provide interfaces among modes or among vehicles of the same mode. They may range from marked bus stops or truck loading zones on local streets to huge airports or ports.

Evaluation Measures

Transportation systems are evaluated in terms of their effects on their suppliers, users, and environment. Both their costs and benefits may be classified into supplier, user, and external components. Private transportation companies normally seek to maximize their profits (i.e., total revenues minus total supplier costs). Publicly owned transportation agencies should normally maximize net benefits to their jurisdictions, possibly subject to financial constraints.

From the supplier's perspective, the major indicators of performance include measures of **capacity** (maximum throughput), **speed, utilization rate** (i.e., fraction of time in use), **load factor** (i.e., fraction of maximum payload actually used), energy efficiency (e.g., Btu per ton-mile or per passenger mile), and labor productivity (e.g., worker hours per passenger mile or per ton-mile). Measures of environmental impact (e.g., noise decibels or parts of pollutant per million) are also increasingly relevant. To users, price and service quality measure, including travel time, wait time, access time, reliability, safety, comfort (ride quality, roominess), simplicity of use, and privacy are relevant in selecting modes, routes, travel times, and suppliers.

Air Transportation

Air transportation is relatively recent, having become practical for transporting mail and passengers in the early 1920s. Until the 1970s its growth was paced primarily by technological developments in propulsion, aerodynamics, materials, structures, and control systems. These developments have improved its speed, load capacity, energy efficiency, labor productivity, reliability, and safety, to the point where it now dominates long-distance mass transportation of passengers overland and practically monopolizes it over oceans. Airliners have put ocean passenger liners out of business because they are much faster and also, remarkably, more fuel and labor efficient. However, despite this fast growth, the cargo share of air transportation is still small.

For cargoes that are perishable, high in value, or urgently needed, air transportation is preferred over long distances. For other cargo types, ships, trucks, and railroads provide more economical alternatives. In the 1990s, the nearest competitors to air cargo are containerships over oceans and trucks over land. For passengers, air transportation competes with private cars, trains, and intercity buses over land, with practically no competitors over oceans. The growth of air transportation has been restricted to some extent by the availability of adequate airports, by environmental concerns (especially noise), and by the fear of flying of some passengers.

There are approximately 10,000 commercial jet airliners in the world, of which the largest (as of 1997) are Boeing B-747 types, of approximately 800,000 lb gross takeoff weight, with a capacity of 550 passengers. The economical cruising speed of these and smaller "conventional" (i.e., **subsonic**) airliners has stayed at around 560 mph since the late 1950s. A few supersonic transports (SSTs) capable of cruising at approximately 1300 mph were built in the 1970s (the Anglo-French Concorde and the Soviet Tu-144) but, due to high capital and fuel costs, were not economically successful. About eight Concorde SSTs are still operating, with government subsidies.

The distance that an aircraft can fly depends on its payload, according to the following equation:

$$R = \frac{V}{c'}\left(\frac{L}{D}\right)\ln\left(W_{TO}/W_L\right) \tag{10.4.1}$$

where

R = range (mi)
c' = specific fuel consumption (lb fuel/lb thrust × h)
(L/D) = lift-to-drag ratio (dimensionless)
W_{TO} = aircraft takeoff weight (lb) = $W_L + W_F$
W_L = aircraft landing weight (lb) = $W_E + W_R + P$
W_E = aircraft empty weight (lb)
W_R = reserve fuel weight (lb)
W_F = consumed fuel weight (lb)
P = payload (lb)

This equation assumes that the difference between the takeoff weight and landing weight is the fuel consumed. For example, suppose that for a Boeing B-747 the maximum payload carried (based on internal fuselage volume and structural limits) is 260,000 lb, maximum W_{TO} is 800,000 lb, W_R = 15,000 lb, W_E = 370,000, L/D = 17, V = 580 mph, and c' = 0.65 lb/lb thrust × h. The resulting weight ratio [W_{TO}/W_L = 800/(370 + 15 + 260)] is 1.24 and the range R is 3267 mi. Payloads below 260,000 lb allow greater ranges.

Most airline companies fly scheduled routes, although charter services are common. U.S. airlines are largely free to fly whatever routes (i.e., origin–destination pairs) they prefer in the United States. In most of the rest of the world, authority to serve particular routes is regulated to negotiated by international agreements. The major components of airline costs are direct operating costs (e.g., aircraft depreciation or rentals, aircrews, fuel, and aircraft maintenance) and indirect operating costs (e.g., reservations, advertising and other marketing costs, in-flight service, ground processing of passengers and bags, and administration).

The efficiency and competitiveness of airline service is heavily dependent on efficient operational planning. Airline scheduling is a complex problem in which demand at various times and places, route authority, aircraft availability and maintenance schedules, crew availability and flying restrictions, availability of airport gates and other facilities, and various other factors must all be considered. Airline management problems are discussed in (Wells, 1984).

Airports range from small unmarked grass strips to major facilities requiring many thousands of acres and billions of dollars. Strictly speaking, an airport consists of an airfield (or "airside") and terminal (or "landside"). Airports are designed to accommodate specified traffic loads carried by aircraft up to a "design aircraft," which is the most demanding aircraft to be accommodated. The design aircraft might determine such features as runway lengths, pavement strengths, or terminal gate dimensions at an airport. Detailed guidelines for most aspects of airport design (e.g., runway lengths and other airfield dimensions, pavement characteristics, drainage requirements, allowable noise and other environmental impacts, allowable obstruction heights, lighting, markings, and signing) are specified by the U.S. Federal Aviation Administration (FAA) in a series of circulars.

Airport master plans are prepared to guide airport growth, usually in stages, toward ultimate development. These master plans:

1. Specify the airport's requirements.
2. Indicate a site if a new airport is considered.
3. Provide detailed plans for airport layout, land use around the airport, terminal areas, and access facilities.
4. Provide financial plans, including economic and financial feasibility analysis.

Major new airports tend to be very expensive and very difficult to locate. Desirable airport sites must be reasonably close to the urban areas they serve yet far enough away to ensure affordable land and acceptable noise impacts. Many other factors—including airspace interference with other airports, obstructions (e.g., hills, buildings), topography, soil, winds, visibility, and utilities—must be reconciled. Hence, few major new airports are being built, and most airport engineering and planning work in the United States is devoted to improving existing airports. Governments sometimes develop multi-airport system plans for entire regions or countries.

National agencies (such as the FAA in the United States) are responsible for traffic control and airspace management. Experienced traffic controllers, computers, and specialized sensors and communication systems are required for this function. Increasingly sophisticated equipment has been developed to maintain safe operations even for crowded airspace and poor visibility conditions. For the future we can expect increasing automation in air traffic control, relying on precise aircraft location with global positioning satellite (GPS) systems and fully automated landings. Improvements in the precision and reliability of control systems are increasing (slowly) the capacity of individual runways as well as the required separation among parallel runways, allowing capacity increases in restricted airport sites.

Railroad Tranportation

The main advantages of railroad technology are low frictional resistance and automatic lateral guidance. The low friction reduces energy and power requirements but limits braking and hill-climbing abilities. The lateral guidance provided by wheel flanges allows railroad vehicles to be grouped into very long trains, yielding economies of scale and, with adequate control systems, high capacities per track. The potential energy efficiency and labor productivity of railroads is considerably higher than for highway modes, but is not necessarily realized, due to regulations, managerial decisions, demand characteristics, or terrain.

The main competition of railroads include automobiles, aircraft, and buses for passenger transportation, and trucks, ships, and pipelines for freight transportation. To take advantage of their scale economies, railroad operators usually seek to combine many shipments into large trains. Service frequency is thus necessarily reduced. Moreover, to concentrate many shipments, rail cars are frequently re-sorted into different trains, rather than moving directly from origin to destination, which results in long periods spent waiting in classification yards, long delivery times, and poor vehicle utilization. An alternative operational concept relying on direct nonstop "unit trains" is feasible only when demand is sufficiently large between an origin–destination pair.

Substantial traffic is required to cover the relatively high fixed costs of railroad track. Moreover, U.S. railroads, which are privately owned, must pay property taxes on their tracks, unlike their highway competitors. By 1920 highway developments had rendered low-traffic railroad branch lines noncompetitive in the United States. Abandonment of such lines has greatly reduced the U.S. railroad network, even though the process was retarded by political regulation.

The alignment of railroad track is based on a compromise between initial costs and operating costs. The latter are reduced by a more straight and level alignment, which requires more expensive earthwork, bridges, or tunnels. Hay (1982) provides design guidelines for railroads.

In general, trains are especially sensitive to gradients. Thus, compared to highways, railroad tracks are more likely to go around rather than over terrain obstacles, which increases the **circuity factors** for railroad transportation.

The resistance for railroad vehicles may be computed using the Davis equation (Hay, 1982):

$$r = 1.3 + 29/w + bV + CAV^2/wn + 20G + 0.8D \tag{10.4.2}$$

where

- G = gradient (%)
- D = degree of curvature
- r = unit resistance (lb of force per ton of vehicle weight)
- w = weight (tons per axle of car or locomotive)
- n = number of axles
- b = coefficient of flange friction, swaying, and concussion (0.045 for freight cars and motor cars in trains, 0.03 for locomotives and passenger cars, and 0.09 for single-rail cars)
- C = drag coefficient of air [0.0025 for locomotives (0.0017 for streamlined locomotives) and single- or head-end-rail cars, 0.0005 for freight cars, and 0.00034 for trailing passenger cars, including rapid transit]
- A = cross-sectional area of locomotives and cars (usually 105 to 120 ft^2 for locomotives, 85 to 90 ft^2 for freight cars, 110-120 ft^2 for multiple-unit and passenger cars, and 70 to 110 ft^2 for single- or head-end-rail cars)
- V = speed (mph)

The coefficients shown for this equation reflect relatively old railroad technology and can be significantly reduced for modern equipment (Hay, 1982). The equation provides the unit resistance in pounds of force per ton of vehicle weight. The total resistance of a railroad vehicle (in lb) is

$$R_v = rwn \tag{10.4.3}$$

The total resistance of a train R is the sum of resistances for individual cars and locomotives. The rated horsepower (hp) required for a train is:

$$\text{hp} = \frac{RV}{375\eta} \tag{10.4.4}$$

where η = transmission efficiency (typically about 0.83 for a diesel electric locomotive).

The hourly fuel consumption for a train may be computed by multiplying hp by a specific fuel consumption rate (approximately 0.32 lb/hp × h for a diesel electric locomotive).

Diesel electric locomotives with powers up to 5000 hp haul most trains in the United States. Electric locomotion is widespread in other countries, especially those with low petroleum reserves. It is especially competitive on high-traffic routes (needed to amortize electrification costs) and for high-speed passenger trains. Steam engines have almost disappeared.

The main types of freight rail cars are box cars, flat cars (often used to carry truck trailers or intermodal containers), open-top gondola cars, and tank cars. Passenger trains may include restaurant cars and sleeping cars. Rail cars have tended toward increasing specialization for different commodities carried, a trend that reduces opportunities for back hauls. Recently, many “double-stack” container cars have been built to carry two tiers of containers. Such cars require a vertical clearance of nearly 20 ft, as well as reduced superelevation (banking) on horizontal curves. In the United States standard freight rail cars with gross weights up to 315,000 lb are used.

High-speed passenger trains have been developed intensively in Japan, France, Great Britain, Italy, Germany, and Sweden. The most advanced (in 1995) appear to be the latest French TGV versions, with cruising speeds of 186 mph and double-deck cars. At such high speeds, trains can climb long, steep grades (e.g., 3.5%) without slowing down much. Construction costs in hilly terrain can thus be significantly reduced. Even higher speeds are being tested in experimental railroad and magnetic levitation (MAGLEV) trains.

Highway Transportation

Highways provide very flexible and ubiquitous transportation for people and freight. A great variety of transportation modes, including automobiles, buses, trucks, motorcycles, bicycles, pedestrians, animal-drawn vehicles, taxis, and carpools, can share the same roads. From unpaved roads to multilane freeways, roads can vary enormously in their cost and performance. Some highway vehicles may even travel off the roads in some circumstances. The vehicles also range widely in cost and performance, and at their lower range (e.g., bicycles) are affordable for private use even in poor societies.

Flexibility, ubiquity, and affordability account for the great success of highway modes. Personal vehicles from bicycles to private automobiles offer their users great freedom and access to many economic and social opportunities. Trucks increase the freedom and opportunities available to farmers and small businesses. Motor vehicles are so desirable and affordable that in the United States the number of registered cars and trucks approximates the number of people of driving age. Other developed countries are approaching the same state despite strenuous efforts to discourage motor vehicle use.

The use of motor vehicles brings significant problems and costs. These include:

1. Road capacity and congestion. Motor vehicles require considerable road space, which is scarce in urban areas and costly elsewhere. Shortage of road capacity results in severe congestion and delays.
2. Parking availability and cost.
3. Fuel consumption. Motor vehicles consume vast amounts of petroleum fuels. Most countries have to import such fuels and are vulnerable to price increases and supply interruptions.
4. Safety. The numbers of people killed and injured and the property damages in motor vehicle accidents are very significant.
5. Air quality. Motor vehicles are major contributors to air pollution.
6. Regional development patterns. Many planners consider the low-density “sprawl” resulting from motor vehicle dominance to be inefficient and inferior to the more concentrated development produced by mass transportation and railroads.

In the United States trucks have steadily increased their share of the freight transportation market, mostly at the expense of railroads, as shown in Table 10.4.1. They can usually provide more flexible, direct, and responsive service than railroads, but at higher unit cost. They are intermediate between rail and air transportation in both cost and service quality. With one driver required per truck, the labor productivity is much lower than for railroads, and there are strong economic incentives to maximize the load capacity for each driver. Hence, the tendency has been to increase the number, dimensions, and weights allowed for trailers in truck-trailer combinations, which requires increased vertical clearances (e.g., bridge overpasses), geometric standards for roads, and pavement costs.

The main reference for highway design is the AASHTO manual [AASHTO, 1990]. For capacity, the main reference is the Transportation Research Board *Highway Capacity Manual* (TRB, 1985). Extensive software packages have been developed for planning, capacity analysis, geometric design, and traffic control.

Water Transportation

Water transportation may be classified into (1) marine transportation across seas and (2) inland waterway transportation; their characteristics differ very significantly. Inland waterways consist mostly of rivers, which may be substantially altered to aid transportation. Lakes and artificial canals may also be part of inland waterways. Rivers in their natural states are often too shallow, too fast, or too variable in their flows. All these problems may be alleviated by impounding water behind dams at various intervals. (This also helps generate electric power.) Boats can climb or descend across dams by using **locks** or other elevating systems (Hochstein, 1981). In the U.S. inland waterway network there are well over 100 major lock structures, with chambers up to 1200 ft long and 110 ft wide. Such chambers allow up to 18 large barges (35×195 ft) to be raised or lowered simultaneously.

In typical inland waterway operations, large diesel-powered "towboats" (which actually push barges) handle a rigidly tied group of barges (a "tow"). Tows with up to 48 barges (35×195 ft, or about 1300 tons per barge) are operated on the lower Mississippi, where there are no locks or dams. On other rivers, where locks are encountered at frequent intervals, tow sizes are adjusted to fit through locks. The locks constitute significant bottlenecks in the network, restricting capacity and causing significant delays.

Table 10.4.1 indicates that the waterway share of U.S. freight transportation has increased substantially in recent years. This is largely attributable to extensive improvements to the inland waterway system undertaken by the responsible agency, the U.S. Army Corps of Engineers.

The main advantage of both inland waterway and marine transportation is low cost. The main disadvantage is relatively low speed. Provided that sufficiently deep water is available, ships and barges can be built in much larger sizes than ground vehicles. Ship costs increase less than proportionally with ship size, for ship construction, crew, and fuel. Energy efficiency is very good at low speeds [e.g., 10–20 knots (nautical mi/h)]. However, at higher speeds the wave resistance of a conventional ship increases with the fourth power of speed (V^4). Hence, the fuel consumption increases with V^4 and the power required increases with V^5. Therefore, conventional-displacement ships almost never exceed 30 knots in commercial operation. Higher practical speed may be obtained by lifting ships out of the water on hyrdrofoils or air cushions. However, such unconventional marine vehicles have relatively high costs and limited markets at this time, ships have increased in size and specialization. Crude oil tankers of up to 550,000 tons (of payload) have been built. Tankers carrying fluids are less restricted in size than other ships because they can pump their cargo from deep water offshore without entering harbors. Bulk carriers (e.g., for coal, minerals, or grains) have also been built in sizes exceeding 300,000 tons. They may also be loaded through conveyor belts built over long pier structures to reach deep water. General cargo ships and containerships are practically always handled at shoreline berths and require much storage space nearby.

The use of intermodal containers has revolutionized the transportation of many cargoes. Such containers greatly reduce the time and cost required to load and unload ships. Up to 4500 standard 20-ft containers ($20 \times 8 \times 8$ ft) can be carried at a speed of about 24 knots on recently built containerships.

Port facilities for ships should provide shelter from waves and sufficiently deep water, including approach channels to the ports. In addition, ports should provide adequate terminal facilities, including loading and unloading equipment, storage capacity, and suitable connections to other transportation networks. Ports often compete strenuously with other ports and strive to have facilities that are at least equal to those of competitors. Since ports generate substantial employment and economic activities, they often receive financial and other support from governments.

Geography limits the availability of inland waterways and the directness of ship paths across oceans. Major expensive canals (e.g., Suez, Panama, Kiel) have been built to provide shortcuts in shipping routes. These canals may be so valuable that ship dimensions are sometimes compromised (i.e., reduced) to fit through these canals. In some parts of the world (e.g., Baltic Sea, North Sea, most U.S. coasts) the waters are too shallow for the largest ships in existence. Less efficient, smaller ships must be used there.

The dredging of deeper access channels and ports can increase the allowable ship size, if the costs and environmental impacts are considered acceptable.

Public Transportation

Public transportation is the term for ground passenger transportation modes available to the general public. It connotes public availability rather than ownership. "Conventional" public transportation modes have fixed routes *and* fixed schedules and include most bus and rail transit services. "Unconventional" modes (also labeled "paratransit") include taxis, carpools and van pools, rented cars, dial-a-ride services, and subscription services.

The main purposes of public transportation services, especially conventional mass transportation services in developed countries, are to provide mobility for persons without automobiles (e.g., children, poor, nondrivers); to improve the efficiency of transportation in urban areas; to reduce congestion effects, pollution, accidents, and other negative impacts of automobiles; and to foster preferred urban development patterns (e.g., strong downtowns and concentrated rather than sprawled development).

Conventional services (i.e., bus and rail transit networks) are quite sensitive to demand density. Higher densities support higher service frequencies and higher network densities, which decrease user wait times and access times, respectively. Compared to automobile users, bus or rail transit users must spend extra time in access to and from stations and in waiting at stations (including transfer stations). Direct routes are much less likely to be available, and one or more transfers (with possible reliability problems) may be required. Thus, mass transit services tend to be slower than automobiles unless exclusive rights-of-way (e.g., bus lanes, rail tunnels) can favor them. Such exclusive rights-of-way can be quite expensive if placed on elevated structures or in tunnels. Even when unhindered by traffic, average speeds may be limited by frequent stops and allowable acceleration limits for standing passengers. Prices usually favor mass transit, especially if parking for automobiles is scarce and expensive.

The capacity of a transit route can be expressed as:

$$C = FLP \tag{10.4.5}$$

where

C = one-way capacity (passengers/hour) past a certain point
F = service frequently (e.g., trains/hour)
L = train length (cars/train)
P = passenger capacity of cars (spaces/car)

For rail transit lines where high capacity is needed in peak periods, C can reach 100,000 passengers/hour (i.e., 40 trains/hour × 10 cars/train × 250 passenger spaces/car). There are few places in the world where such capacities are required. For a bus line the train length L would usually be 1.0. If no on-line stops are allowed, an exclusive bus lane also has a large capacity (e.g., 1000 buses/hour × 90 passenger spaces/bus), but such demand levels for bus lanes have not been observed.

The average wait time of passengers on a rail or bus line depends on the headways, which is the interval between successive buses or trains. This can be approximated by:

$$\overline{W} = \overline{H}/2 + \text{var}(H)/2\overline{H} \tag{10.4.6}$$

where

$\overline{W}$ = average wait time (e.g., minutes)
$\overline{H}$ = average headway (e.g., minutes)
var(H) = variance of headway (e.g., minutes^2)

It should be noted that the headway is the inverse of the service frequency.

The number of vehicles N required to serve a route is:

$$N = RFL \tag{10.4.7}$$

where R = vehicle round trip time on route (e.g., hours).

The effectiveness of a public transportation system depends on many factors, including demand distribution and density, network configuration, routing and scheduling of vehicles, fleet management, personnel management, pricing policies, and service reliability. Demand and economic viability of services also depend on how good and uncongested the road system is for automobile users.

Engineers can choose from a great variety of options for propulsion, support, guidance and control, vehicle configurations, facility designs, construction methods, and operating concepts. New information and control technology can significantly improve public transportation systems. It will probably foster increased automation and a trend toward more personalized (i.e., taxilike) service rather than mass transportation.

Defining Terms

Capacity: The maximum flow rate that can be expected on a transportation facility. "Practical" capacity is sometimes limited by "acceptable:" delay levels, utilization rates, and load factors.

Circuity factor: Ratio of actual distance on network to shortest airline distance.

Delay: Increase in service time due to congestion or service interruptions.

Demand-responsive: A mode whose schedule or route is adjusted in the short term as demand varies, such as taxis, charter airlines, and "TRAMP" ships.

Load factor: Fraction of available space or weight-carrying capability that is used.

Lock: A structure with gates at both ends which is used to lift or lower ships or other vessels.

Modes: Distinct forms of transportation.

Subsonic: Flying below the speed of sound (Mach 1), which is approximately 700 mph at cruising altitudes of approximately 33,000 ft.

Utilization rate: Fraction of time that a vehicle, facility, or equipment unit is in productive use.

Further Information

The ITE Handbook (Homburger, 1992) and Morlok (1978) cover most transportation modes. Horonjeff and McKelvey (1994), Hay (1982). Wright and Paquette (1987), Brun (1981), and Vuchic (1981) are more specialized textbooks covering airports, railroads, highways, ports, and urban public transportation systems, respectively. Periodicals such as *Aviation Week & Space Technology, Railway Age, Motor Ship, and Mass Transit* cover recent developments in their subject areas.

10.5 Alternative Fuels for Motor Vehicles

Paul Norton

Overview

Motor vehicle fuels that provide an alternative to conventional gasoline or diesel include ethanol, methanol, natural gas, propane, electricity, and biodiesel. Legislation such as the Clean Air Act Amendments of 1990 (CAAA) and the Energy Policy Act of 1992 (EPACT) has increased interest in alternative fuels. This legislation promotes alternative fuels for their potential to decrease emissions from cars and trucks and lessen the dependence of the United States on imported petroleum.

Modifications must be made to conventional vehicles to use alternative fuels. Electric vehicles (EVs) are powered by one or more electric motors that are energized by batteries. This requires a complete replacement of the conventional engine, fuel system, and drive train. The changes required for the other alternative fuels are less dramatic. All the remaining alternative fuels are burned in internal combustion engines similar to those used for conventional gasoline or diesel fuel. However, the engine and fuel system must be modified to account for the properties of the alternative fuel. The components that are typically added or changed to transform a gasoline vehicle into a compressed natural gas vehicle are shown in Figure 10.5.1. A major challenge is finding space on the vehicles for enough gas cylinders to give the vehicle an acceptable range between refuelings. These cylinders store the natural gas at pressures of 3000 to 3600 psi and must be protected from road debris and corrosive substances such as battery acid.

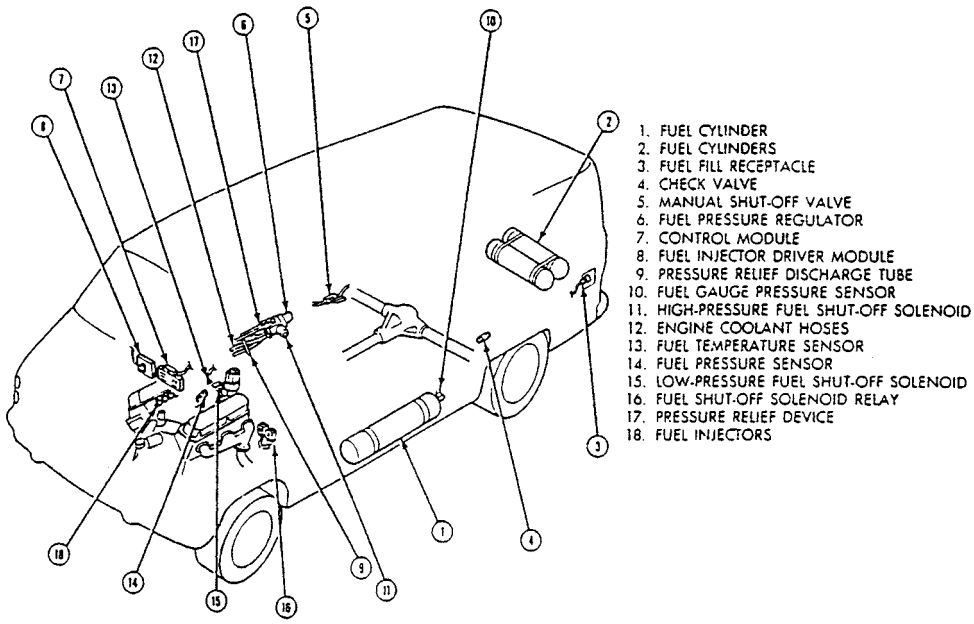

FIGURE 10.5.1 Typical Components of a compressed natural gas vehicle.

In light-duty "flexible-fueled" or "variable-fueled" vehicles, ethanol and methanol is blended with gasoline in the vehicle's fuel tank. The car can be fueled on any mix of the specified alcohol and gasoline up to 85% alcohol. Therefore an ethanol flexible-fueled vehicle (FFV) could be fueled on 85% ethanol (E85) at one refueling, and pure gasoline at the next. A sensor in the fuel line constantly measures the percentage of ethanol in the fuel and the engine control system adjusts the air/fuel ratio accordingly. The typical unique components in an FFV are shown in Figure 10.5.2. All components in the fuel system

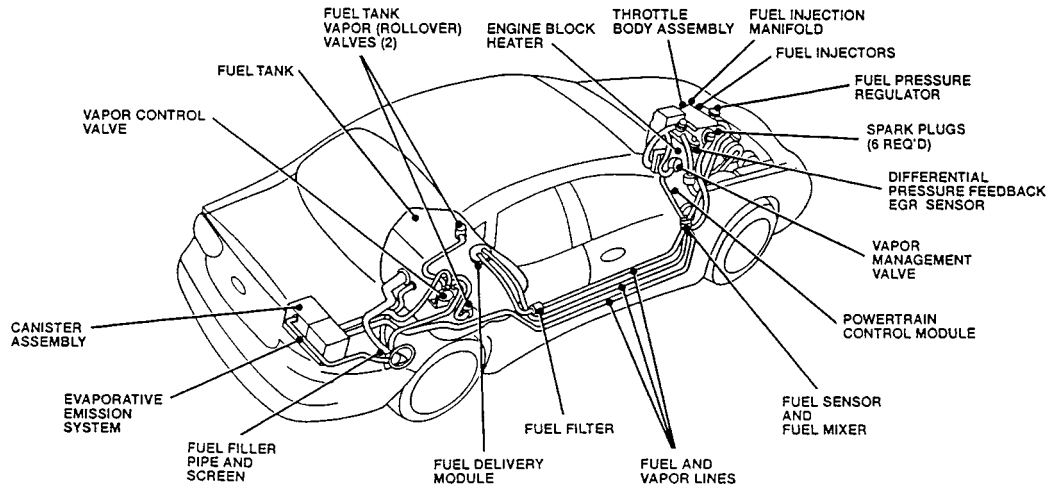

FIGURE 10.5.2 Components of a flexible fuel vehicle.

must be compatible with ethanol or methanol. The fuel injectors must have a higher flow capacity to account for the lower heating value of ethanol and methanol compared to gasoline.

Vehicles can be modified to run on an alternative fuel by the original manufacturer (OEM) or they can be modified by an aftermarket conversion shop. In general, alternative fuel vehicles produced by an OEM go through a much more rigorous development and testing process than an aftermarket conversion. The alternative fuel system for the OEM vehicle is designed for one specific model of vehicle or engine, whereas the aftermarket conversion is designed to fit on a wide variety of vehicles. Therefore the OEM system can be optimized for the one vehicle it was designed for, but the aftermarket conversion kit must be a compromise that will work with many different vehicles. Today's cars and trucks are highly developed and difficult to improve upon. Recent studies have found that compressed natural gas and propane aftermarket conversions had higher emissions in some regulated properties than they did on gasoline before the conversions (Motta et al., 1996). The same study points out that tests on OEM compressed natural gas cars showed substantially lower levels of all four regulated emissions than their gasoline powered counterparts.

Advantages and Disadvantages of Alternative Fuels

Each alternative fuel has unique physical properties that lead to advantages and disadvantages compared to conventional fuels and to each other. All the alternative fuels contain less energy per unit volume than gasoline or diesel fuel. This leads to the need to store more fuel on the vehicle to achieve the same operating range between refuelings as a gasoline car or diesel truck. In many cases, this disadvantage is balanced by lower fuel cost and/or lower emissions than a gasoline or diesel vehicle. A summary of some of the properties of the most popular alternative fuels is shown in Table 10.5.1. Some of the advantages and disadvantages of using these fuels are outlined in Table 10.5.2.

TABLE 10.5.1 Properties of Conventional and Alternative Fuels

Fuel	Cetane Number	Research Octane Number	Motor Octane Number	Density (lb/gal)	LHV[a] (Btu/gal)	LHV[a] Btu/lb)	DEE[b] Gallons	DEE[b] Pounds
Liquids at atm. Pressure

TABLE 10.5.2 Advantages and Disadvantages of Alternative Fuels

Fuel	Advantages	Disadvantages
Liquefied Petroleum Gas (LPG) Liquefied petroleum gas is the most widely used alternative fuel. In the U.S., LPG is mostly propane with small amounts of butane and ethane. In 1993, an estimated 350,000 vehicles powered by propane (mostly conversions) were plying the nation's highways.	• Most widely available alternative fuel with an estimated 11,000 refueling sites nationwide • LPG is nontoxic • Liquefies at relatively low pressures • One gallon of liquefied propane has about 70% energy content of gasoline • Can reduce carbon monoxide and ozone forming hydrocarbon emissions • Refueling stations are relatively inexpensive	• 45% of LPG in the U.S. is derived from oil • Proper detection and ventilation are required for indoor storage and maintenance of vehicles • Starting problems may occur at very low temperatures due to low vapor pressure • Perception of a safety problem
Compressed Natural Gas (CNG) Natural gas is composed primarily of methane. It is stored on the vehicle under 3000 to 4000 psi of pressure. There are currently an estimated 50,000 vehicles operating on compressed natural gas in U.S. fleets.	• High North American resource base • Natural gas reserves are more globally distributed than oil reserves • Can reduce all regulated emissions • Is especially effective in reducing particulate emissions from large trucks • Less expensive than gasoline • Eliminates evaporative emissions because the fuel system is sealed • Can be produced from renewable resources	• Requires bulky pressure cylinders and high pressure fuel lines • Fuel system costs as much as $5,000 more than gasoline for cars • Refueling infrastructure is expensive • Energy storage density is low, making it difficult to achieve adequate range • Composition of natural gas varies regionally
Methanol Methanol is an alcohol which can be produced from coal, wood, methane, or natural gas. It is often blended with gasoline; e.g., "M85" contains 85 percent methanol and 15 percent gasoline to overcome cold start and poor flame visibility problems.	• Can be produced domestically but near-term sources are likely to be imports • Can be produced from renewable resources, but is currently produced predominantly from natural gas • Can reduce ozone-forming hydrocarbon emissions and particulate emissions • Eliminates toxic benzene emissions • A liquid fuel at ambient temperatures	• May increase formaldehyde emissions • Corrosive and toxic • Requires the use of special methanol-compatible materials in fuel system • Poor flame visibility • Has a lower energy content than gasoline, therefore requires larger fuel tanks • Currently significantly more expensive than gasoline • Lack of refueling infrastructure • Difficult to start in cold temperatures
Ethanol Ethanol is an alcohol derived from biomass-corn and other agricultural products such as sugar cane. Ethanol is often blended with gasoline to avoid taxation as an alcoholic beverage.	• Is produced domestically from renewable resources • Can reduce carbon dioxide and ozone-forming hydrocarbon emissions • Eliminates toxic benzene emissions • A liquid fuel at ambient temperatures • May increase acetaldehyde emissions • Has higher energy content than methanol	• Currently significantly more expensive than gasoline • Has a lower energy content than gasoline; therefore requires larger fuel tanks • Lack of refueling infrastructure • Requires the use of special ethanol-compatible materials in fuel system • Ability to meet large-scale demand is questionable • May compete for land with food crops

TABLE 10.5.2 Advantages and Disadvantages of Alternative Fuels (continued)

Fuel	Advantages	Disadvantages
Reformulated Gasoline* (RFG) Reformulated gasoline is made by changing the composition of conventional gasoline to reduce emissions. It often contains an oxygenate such as methyl tertiary butyl ether (MTBE).	• Reduces air pollution • Can be used in all existing cars • Can use existing refueling infrastructure	• Slightly more expensive • Does not reduce oil imports significantly • May increase engine wear and maintenance costs
Liquefied Natural Gas (LNG) Natural gas can be stored on the vehicle as a cryogenic liquid at about –260F. LNG is used primarily for heavy-duty vehicles.	Same advantages as CNG plus: • Has higher storage density than CNG so a higher range can be achieved • Usually higher methane content than CNG • Does not require high pressure cylinders for storage	• Is a cryogenic liquid with special handling requirements • Requires vacuum-insulated storage tank • Refueling infrastructure is expensive • Lack of refueling infrastructure • Low cetane number for diesel engines
Electricity Electricity is stored in a battery bank in the vehicle. The vehicle is powered by one or more electric motors.	• No tailpipe emissions • Reduces noise pollution • Can use domestic fuel sources	• Not cost competitive • Limited range per charge • Limited recharging infrastructure • May increase sulfur emissions if power is generated by coal • Potential battery disposal problem
Biodiesel Biodiesel is a methyl ester that can be made from a variety of products. Most biodiesel used in the U.S. is made from soybeans. Biodiesel is usually blended with diesel. The most common blend is 20% biodiesel, 80% conventional diesel.	• Is made from a renewable resource • Is produced domestically • Can reduce carbon monoxide, hydrocarbon, and particulate matter emissions • Is used in existing diesel engines without modifications • Is nontoxic • Has energy content comparable to diesel	• Is several times more expensive than conventional diesel • May reduce reliability and durability of the engine • Can increase emissions of oxides of nitrogen • Needs to be blended with conventional diesel to reduce gelling effect at low temperatures • May not blend easily with conventional diesel under some conditions
Dimethyl Ether (DME) DME can be made from natural gas and is a liquid at relatively low pressures (similar to LPG). It appears to be a good candidate for heavy-duty trucks. Prototype engines are currently being produced.	• Can reduce emissions significantly • Has a high cetane number so it can be used in a diesel engine • Can be produced from domestic renewable sources	• No commercially available engines at this time • Limited fuel supply • No refueling infrastructure • Uncertain production cost

* Reformulated gasoline is considered a “clean fuel” in the Clean Air Act Amendments, but is not considered an alternative fuel in the Energy Policy Act of 1992.

10.6 Electric Vehicles

Frank Kreith

Electric vehicles have recently received nationwide attention because the California Air Resources Board (CARB) has developed a plan that will require 10% of all vehicles sold in California by the year 2003 to be zero emission vehicles (ZEV) and other states are considering similar mandates. The only type of vehicle currently available that can meet the ZEV regulation is an electric vehicle (EV) powered by a bank of batteries. Figure 10.6.1 is a schematic diagram of the major components of a typical battery powered electric vehicle. Such vehicles can be built from stock automobiles with relatively minor body modification, and several types are commercially available. At this time, lead-acid batteries are the only kind ready for deployment on a large scale, but some car manufacturers are promising nickel–metal hydride batteries for their 1998 electric cars.

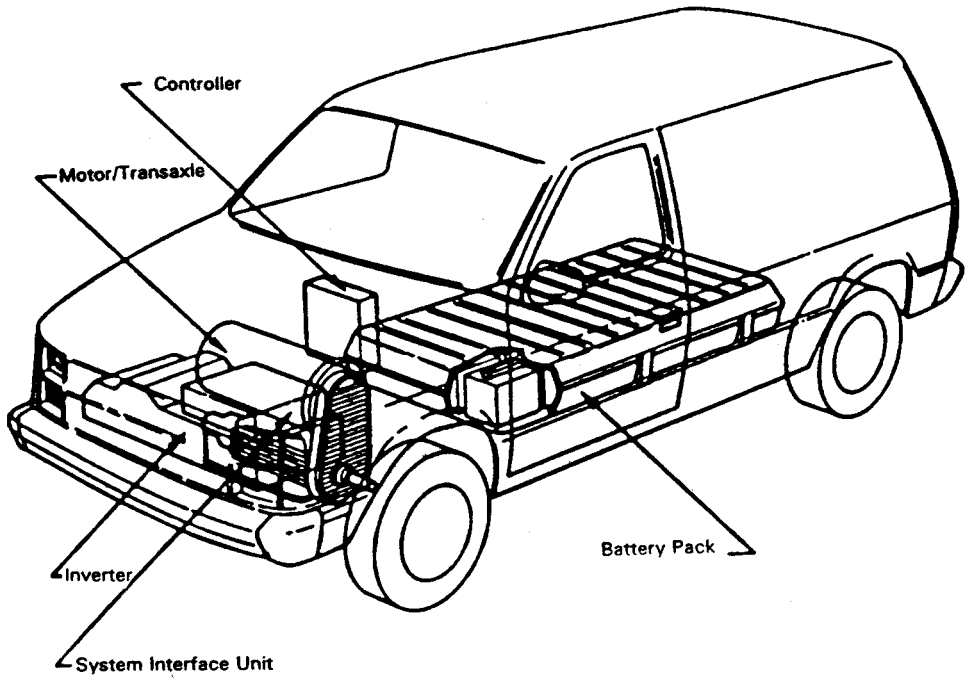

FIGURE 10.6.1 Major components of a battery powered electric vehicle. Source: Brown, P.J. 1990. Overview of the U.S. government's electric vehicle program, in *Electric Vehicles, A Decade of Transition* (Society of Automotive Engineers PT-40), p. 5.

The total cost of operating an electric vehicle consists of the purchase price and operating expenses. Electric vehicles are not yet in mass production and the cost of vehicles available in 1997 was more than twice that of equivalent gasoline powered vehicles. In addition to the cost of electric power required to charge the batteries, operating costs also include battery replacement. A typical battery pack for an electric vehicle costs between $2000 and $8000 and must be replaced after approximately 500 charge and discharge cycles for lead acid batteries and 1000 to 2000 cycles for nickel based batteries. Battery development is focusing on increasing charge cycles, reducing recharge time, and eliminating maintenance by using sealed units. Table 10.6.1 gives the performance characteristics of some batteries currently available. The main problem with deploying batteries in vehicles is their low power-to-weight ratio, called specific power, which is between 100 and 200 watts per kilogram with currently available technology. The driving range of currently available electric vehicles is between 50 and 100 miles

TABLE 10.6.1 Near-Term Battery System Performance Characteristics

Battery Type	1990 Energy Storage Density (Wh/kg)	1990 Specific Power (W/kg)	1990 Cycle Life	1995 Energy Storage Density (Wh/kg)	1995 Specific Power (W/kg)	1995 Cycle Life

Battery availability for near-term (1998) electric-vehicles, *Electric Vehicle R&D* (Society of Automotive Engineers, SP-880, September), 17, with additions from Taylor Moore. 1994. Producing the near-term EV battery, *EPRI J.*, April/May. 6-13 and Prof. A. Frank, U. of California.

between recharging, but that range is reduced by factors such as increased vehicle payload, high speeds, steep hills, cold temperatures, and the use of auxiliary systems such as air-conditioning.

From an efficiency perspective, electric vehicle power systems are approximately as efficient as internal combustion engines according to EPA. Overall vehicle energy conversion efficiency as shown in Table 10.6.2 is between 15 and 18% with current battery technology, compared to gasoline engine powered vehicles, which have an overall efficiency of about 16%. Although electric vehicles produce no tail pipe emission, air pollution is generated by the power plants that provide the electricity to charge the batteries, and environmental/health problems may also be associated with the manufacture and disposal of batteries. Table 10.6.3 compares emission from electric vehicles with those from fossil fueled vehicles. It can be seen that electric vehicles would reduce emissions of hydrocarbons and carbon monoxide, but would produce more emissions in other categories of pollutants such as carbon dioxide, nitrous oxides, and sulfur oxides. Actual vehicle emissions would vary from region to region due to variations in the local electric generation fuel mix.

TABLE 10.6.2 Vehicle Power System Efficiencies

Primary Energy Source	Power System Component Efficiency						
	Gasoline Engine	Electric Vehicle

Hybrid and Fuel Cell Vehicles

In view of the shortcomings of battery powered electric vehicles, efforts are currently underway to develop automotive hybrid and fuel cell powered vehicles.

A hybrid vehicle employs a small engine and a generator to supplement battery power to the electric motor drive, thereby increasing the vehicle's range and reducing the size of the engine and the battery pack. Although hybrid vehicles are technically not "zero emission," they do reduce emission appreciably and overcome some of the shortcomings of battery powered pure electric cars.

Hybrid vehicles may be either charge sustaining or charge depleting. A charge sustaining hybrid is one that maintains the electrical energy stored on board by charging the storage device with liquid fuel from the tank. Auxiliary off-board electrical energy from a stationary power plant may or may not be required. A charge depleting hybrid is one which does not charge the electrical energy storage device directly with on-board fuel. The electrical storage device is charged by electricity from a stationary power plant only. For both, supplementary charge can be obtained by converting the kinetic energy of the vehicle to electric power during braking and deceleration.

A hybrid vehicle configuration that drives the wheels of a vehicle only electrically is called a series arrangement. When the wheels can be powered both electrically and mechanically, it is called a parallel arrangement. The two arrangements are shown schematically in Figure 10.6.2. Both parallel and series configurations may be used for city and highway driving. The parallel system may require more on-off cycles of the gasoline engine for city driving but will be more efficient in general. Both series and parallel vehicle configurations can operate in a zero tailpipe emission mode when the batteries are charged. When the batteries are drained to a certain level, the engine can turn on to recharge them.

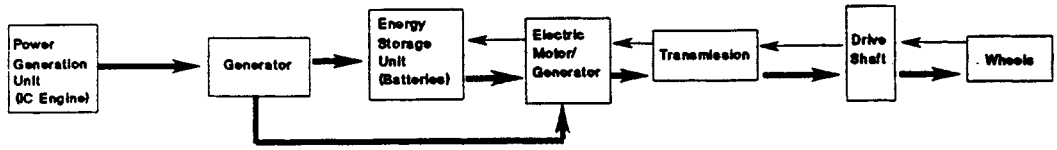

FIGURE 10.6.2A Series Hybrid Electric Vehicle.

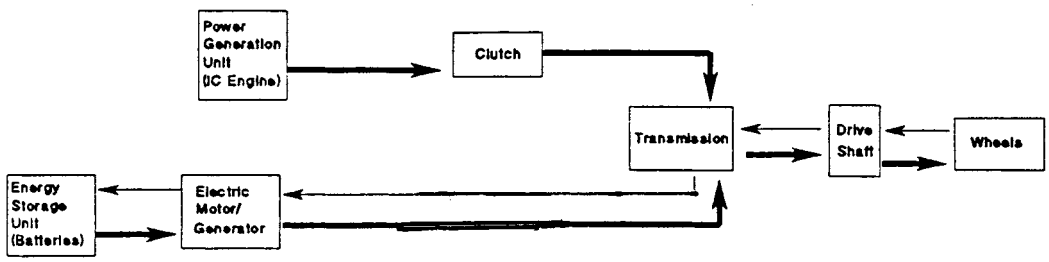

FIGURE 10.6.2B Parallel Hybrid Electric Vehicle.

Some advantages of the parallel configuration include:

- More power for a given motor size because both the engine and the motor can supply power simultaneously;
- Greater continuous operation efficiency because the engine is directly coupled to the drive shaft; and,
- Fewer components in the drive line and all of the components are available.

The benefits of a series configuration include:

- Since the engine drives a generator, it never idles and can operate at a speed that gives optimum performance;
- A smaller engine can be used, which reduces pollution and improves mileage; and,
- The configuration provides for a variety of options to arrange the engine and vehicle components.

The parallel configuration is best suited for longer trips and highway driving, while the series configuration is best suited for start-and-stop city driving.

A fuel cell converts the chemical energy of hydrogen and oxygen directly into electric power. In a fuel cell powered vehicle, hydrogen, stored under pressure in the vehicle or produced on board through a chemical process, is mixed with oxygen from the air to produce electricity in a fuel cell. The problem is creating hydrogen for a fuel cell. If it is done on-board by a reformer, the overall efficiency is very poor. If it is done off-board by a hydrogen generation plant, storing is a problem as is overall energy efficiency. However, if stored as a compressed gas, enough hydrogen to provide a 250 mile range can be stored in a 35 to 40 gallon canister. Other storage methods may be even more compact. A fuel cell electric vehicle would meet the zero emission requirements and a fuel cell powered 20 passenger bus is currently under test in Canada. Chapter 8 provides more technical background on fuel cells.

10.7 Intelligent Transportation Systems

James B. Reed and Janet B. Goehring

Introduction

Computers, communications systems, and automotive technologies provide the basis for intelligent transportation systems (ITS). These systems apply new technologies to address the many challenges of surface transportation—safety, productivity, environmental concerns, and mobility in the face of increasing congestion. ITS applications include, among others, on-board computer mapping devices to help drivers find unknown locations, robotic systems that automatically control braking and acceleration, "Mayday" beacons for stranded vehicles, sophisticated traffic control centers, and electronic toll collectors that do not require stopping. Most ITS initiatives emphasize highway and automobile improvements, though some focus on public transportation.

The goals of ITS are to improve transportation safety, reduce congestion, and develop new technologies. ITS can potentially reduced the national highway death toll of about 40,000 annually. According to the U.S. Department of Transportation (DOT) each year traffic accidents alone cause $70 billion in costs, not counting the loss of life or the consequences of long-term injuries. In addition, traffic congestion delays cause staggering losses in productivity of approximately $100 billion per year. An estimated 2 billion hours and 1 billion gallons of gasoline are wasted in America's collective traffic jams annually. ITS may cut travel times and fuel consumption by 10% or more, without constructing new roads. A Federal Highway Administration estimate predicts a yearly reduction in fatalities by at least 8 percent and 400,000 fewer injuries by 2011. Fewer accidents, in turn, decrease congestion since 60% of highway jamming is caused by accidents.

The **Intelligent Vehicle-Highway Systems Act of 1991**, part of the landmark Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA), authorized a program of research, development, and operational testing to establish ITS as a component of the nation's surface transportation system. The program is intended to enhance the capacity, efficiency, and safety of the federally supported highway system and the states' efforts to attain mandated air quality goals. Its goal is reducing societal, economic, and environmental costs associated with traffic congestion. In addition, the legislation promotes an ITS industry in the United States, as well as the development of a technological base that would improve industrial and economic competitiveness, facilitate technology transfer, and establish a U.S. presence in this emerging field of technology.

The Intelligent Transportation Society of America (ITS America), a partnership of constituencies formed in 1990 and later designated a federal advisory committee, assists in the coordination and acceleration of the development and deployment of advanced transportation technologies in the United States. ITS America, a nonprofit educational and scientific association, includes over 750 members from federal, state, and local government, private industry, universities, research institutions and automobile organizations. ITS joined with the U.S. Department of Transportation in working to develop the comprehensive National ITS Program Plan (March 1995).

Major Elements of ITS

ITS is categorized into seven basic groupings or bundles of services.

- Travel and transportation management
- Travel demand management
- Public transportation operations
- Electronic payment
- Advanced vehicle control and safety systems

- Emergency management
- Commercial vehicle operations

Table 10.7.1 summarized from the *1995 ITS National Program Plan*, lists the "bundles" and the associated user services.

TABLE 10.7.1 ITS Bundles and User Services

Bundle	User Services
Travel and transportation management	En route driver information, route guidance, traveler services information, traffic control, incident management, emissions testing and mitigation
Travel demand management	Demand management and operations, pre-trip travel information, ride matching
Public transportation operations	Public transportation management, en-route transit information, personalized public transit, public travel security
Electronic payment	Electronic payment services, "smart cards"
Commercial vehicle operations	Electronic clearance, automated roadside safety inspection, on-board safety monitoring, administrative processes, freight mobility, hazardous material incident response
Emergency management	Emergency notification, personal security, emergency vehicle management
Advanced vehicle control and safety systems	Collision avoidance, vision enhancement, safety readiness, pre-crash restraint deployment, automated highway systems

Intelligent Transportation Infrastructure

In order to assist the linking of ITS systems and technologies, the DOT developed with ITS America a national ITS framework referred to as "system architecture" (Figure 10.7.1).

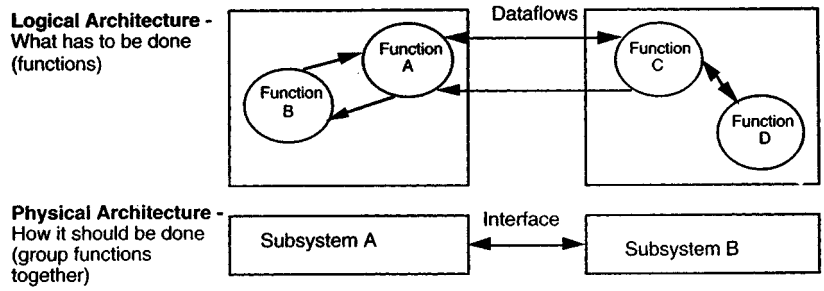

FIGURE 10.7.1 Schematic Diagram of ITS Architecture.

The architecture defines a series of *functions* that an ITS system would carry out, e.g., traffic surveillance or operating transit vehicles. These high-level functions are broken down into subfunctions. Higher level functions are depicted graphically as data flow diagrams or *DFDs*. Each of the lower level functions is given a precise definition, known as a process specification or P-spec for short.

One of the primary roles of the architecture is to assign functions to various components, or *subsystems*, of the overall ITS system. Traffic management or transit management are example of subsystems. However, the various subsystems cannot act independently of one another. Information must be exchanged between these subsystems if the overall ITS system is to act in a coordinated, integrated fashion. Therefore, the architecture also defines the connections or *interfaces* between these subsystems in terms of *data flows* as shown in Figure 10.7.1.

To enhance the deployment efforts of ITS projects and test the architecture, the DOT initiated the Intelligent Transportation Infrastructure (ITI) in 1996. Also called "Operation TimeSaver," the ITI

promises to reduce the travel time of Americans by 15% once the infrastructure is fully in place. The ITI seeks to link individual ITS components already in existence in major metropolitan areas and to put the national architecture into action. DOT established nine integrated components for the ITI focus: traffic signal control, freeway management, incident management, electronic fare payment, electronic toll collection, railroad grade crossings, emergency management services, and regional multimodal traveler information.

Traffic Signal Control

Traffic signal control systems react to changing traffic conditions to improve transportation system efficiency. State-of-the-art traffic controls, often using fuzzy logic control, have the capability to modify signal timings in response to traffic demand. The signal systems employ a variety of mechanisms to collect and process real time traffic conditions. When integrated into an ITI system, the control devices can give priority to emergency response vehicles or transit to facilitate the efficient flow of traffic.

To provide metropolitan-wide signal coordination, the systems in one region should be able to share traffic flow information electronically with the systems of neighboring jurisdictions. This information sharing ensures smooth traffic flow along major corridors.

Freeway Management

Real-time information about traffic and road conditions aids in the efficient management of the freeway system. Methods for gathering such information include video monitors, microwave radar, ultrasonic monitors, and citizen and police reports. The information is provided to travelers through infrastructure-based devices such as variable message signs and highway advisory radio broadcasts. The relevant information can also be used to support incident management activities and can help determine the severity and type of incident to direct the appropriate response team. The freeway management system can also be used to streamline the traffic logistics of a large special event, such as, for example, the fuzzy system control in Munich.

Transit Management

Transit management aids in the on-time performance of transit systems. Transit fleet management includes real-time transit information to travelers, monitoring the location of buses and other equipment, flexible rerouting of vehicles and automated maintenance monitoring. Other enhancements include displays of routes and schedules for passengers on the vehicle.

Incident Management

Rapid and efficient response to accidents and other incidents is a key factor in saving lives and easing travel delays. Incident management systems help fire and police to quickly identify and respond to incidents. Objectives of these systems include coordination of services across regional boundaries, improvement of response times, the use of in-vehicle navigation equipment to assist emergency vehicles in locating the scene of the accident, and the reduction of traffic congestion from the incidents.

Electronic Fare Payment

Electronic fare payment involves the use of a one payment system such as a “smart card” for transit fares, parking fees, and other travel related fees. The cards reduce the time needed for travelers to search for exact change or figure out fare amounts. The cards can work as credit/debit cards or stored value cards.

Electronic Toll Collection

Electronic toll collection reduces delays at toll plazas and the operating costs of toll agencies. The systems include payment cards or tags on the vehicle and a communications link between the vehicle and the toll crossing. As the vehicle passes the toll station the payment is automatically processed. The use of common toll readers and tags that promote interoperability further decreases the time and cost to travelers.

Railroad Grade Crossings

Intersections of a highway and railroad tracks pose a unique safety hazard, because trains that travel at high speeds may take more than one mile to stop. The ITI deployment objectives include automated warnings at rail crossings, advanced warning systems to travelers, and the coordination of rail movements with traffic signal control systems.

Emergency Management Services

Emergency management services assist emergency vehicles in responding in a more efficient manner to incidents. One ITI application includes an on-board vehicle mapping system. Also included are automated vehicle location devices to inform dispatchers of the exact location of the emergency vehicle. The timely and accurate information made available by these systems will also improve the response to hazardous materials incidents.

Regional Multimodal Traveler Information

Traveler information systems provide integrated road and transit information to travelers to assist them in making travel choices in a metropolitan area. This system promotes regional coordination in the collecting, processing, and presentation of traveler information. One method of making the information available is through a multimedia kiosk placed in transit stations, tourist centers, or other convenient locations. The information may also be provided to the public via a range of communications systems such as broadcast radio, television, or the Internet.

The ITS national architecture addresses the systems that make up ITI and arranges data to be shared. The architecture supports the deployment process and helps to create an integrated system infrastructure that promises to ease surface transportation.

Defining Terms

Intelligent transportation infrastructure: The systems related to traffic detection, monitoring, communications, and control that are required to support ITS products and services in metropolitan and rural areas.

Intermodal: Possessing the ability to transfer people and goods between transportation modes such as rail, air, water, and highway.

ITS system architecture: The written framework that describes how system components interact and work together to achieve system goals.

Fuzzy logic (see Section 19.15).

Real-time traffic information: Instantaneous video or other data on traffic status, i.e., congestion and collisions, that is conveyed from a central location to travelers and others who require such data.

11.1 Introduction

Nam P. Suh

Traditionally, the design field has been identified with particular end products, e.g., mechanical design, electrical design, ship design. In these fields, design work is largely based on specific techniques to foster certain product characteristics and principles. Examples include the principles of constant wall thickness, lightweight construction, and shortest load path. Also, the design field has been subdivided by an increasing reliance on specialized knowledge and the division of labor. Precision engineering and robotics are examples of subfields that are distinguished by the accuracy and reliability that the product must have. In the field of precision engineering, for instance, the dimensions of interest are nanometers, which are often encountered in the semiconductor industry. Each one of these fields also has its specific know-how and paradigms to support effective design have also sub-divided the design field.

There are three branches of design. The traditional school, which still dominates, believes that design requires experience and cannot be taught. The second group deals with optimization as a subset of design, using computer-based tools such as genetic algorithms, fuzzy logic, and the like. The third school of thought believes that there are axioms that govern good design decisions. A good designer needs to use all three methodologies.

11.2 Elements of the Design Process

Nam P. Suh

All design activities must do the following:

1. *Know* the "*customers' needs*."
2. *Define the essential problems* that must be solved to satisfy the needs.
3. *Conceptualize the solution through synthesis*, which involves the task of satisfying several different functional requirements using a set of inputs such as product design parameters within given constraints.
4. *Analyze* the proposed solution to establish its optimum conditions and parameter settings.
5. *Check the resulting design solution* to see if it meets the original customer needs.

Design proceeds from abstract and qualitative ideas to quantitative descriptions. It is an iterative process by nature: new information is generated with each step, and it is necessary to evaluate the results in terms of the preceding step. Thus, design involves a continuous interplay between *the requirements the designer wants to achieve* and *how the designer wants to achieve these requirements*.

Designers often find that a clear description of the design requirements is a difficult task. Therefore, some designers deliberately leave them implicit rather than explicit. Then they spend a great deal of time trying to improve and iterate the design, which is time consuming at best. To be efficient and generate the design that meets the perceived needs, the designer must specifically state the users' requirements before the synthesis of solution concepts can begin.

Solution alternatives are generated after the requirements are established. Many problems in mechanical engineering can be solved by applying practical knowledge of engineering, manufacturing, and economics. Other problems require far more imaginative ideas and inventions for their solution. The word "creativity" has been used to describe the human activity that results in ingenious or unpredictable or unforeseen results (e.g., new products, processes, and systems). In this context, creative solutions are discovered or derived by inspiration and/or perspiration, without ever defining specifically what one sets out to create. This creative "spark" or "revelation" may occur, since our brain is a huge information storage and processing device that can store data and synthesize solutions through the use of associative memory, pattern recognition, digestion and recombination of diverse facts, and permutations of events. Design will always benefit when "inspiration" or "creativity," and/or "imagination" plays a role, but this process must be augmented by amplifying human capability systematically through fundamental understanding of cognitive behavior and by the development of scientific foundations for design methods.

11.3 Concept of Domains

Nam P. Suh

Design is made up of four *domains*: the customer *domain*, the *functional domain*, the *physical domain*, and the *process domain* (see Figure 11.3.1). The domain on the left relative to the domain on the right represents "what the designer wants to achieve," whereas the domain on the right represents the design solution, or "how the designer proposes to satisfy the problem." Therefore, the design process can be defined as mapping from the "what" domain to the "how" domain. During product design, the mapping is from the functional domain to the physical domain. In manufacturing process design, the designer maps from the physical domain to the process domain.

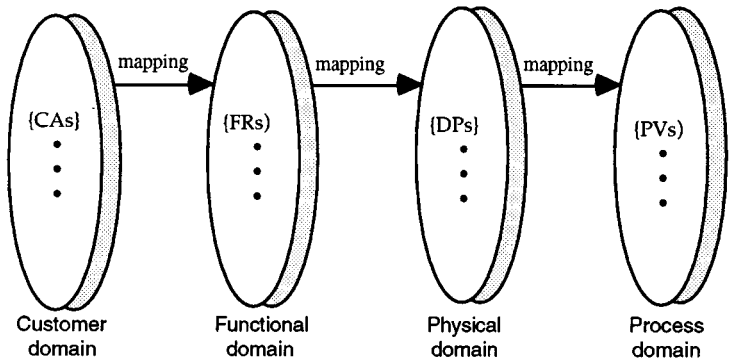

FIGURE 11.3.1 Four domains of the design world. {x} are characteristic vectors of each domain.

The customer domain is characterized by customer needs or the attributes the customer is looking for in a product, process, system, or material. In the functional domain, the designer formally specifies customer needs in terms of functional requirements (FRs). In order to satisfy these FRs, design parameters (DPs) are conceived in the physical domain. Finally, a means to produce the product specified in terms of DPs is developed in the process domain, which is characterized by process variables (PVs).

In mechanical engineering, design typically refers to product design and, often, hardware design. However, mechanical engineers also deal with other equally important designs such as software design, design of manufacturing processes and systems, and organizations. All designers go through the same thought process, although some believe that their design is unique and different from those of everyone else. In materials science, the design goal is to develop materials with certain properties (i.e., FRs). This is done through the design of microstructures (i.e., DPs) to satisfy these FRs, and through the development of material processing methods (i.e., PVs) to create the desired microstructures. To establish a business, the goals are {FRs}, and they are satisfied by structuring the organization in terms of its departments {DPs} and finding the human and financial resources {PVs} necessary to staff and operate the enterprise. Similarly, universities must define the mission of their institutions (i.e., FRs), design their organizations effectively to have an efficient educational and research enterprise (i.e., DPs), and must deal with human and financial resource issues (i.e., PVs). In the case of the U.S. government, the President of the United States must define the right set of {FRs}, design the appropriate government organization and programs {DPs}, and secure the resources necessary to get the job done {PVs}, subject to the constraints imposed by the Constitution and Congress. In all organizational designs the process domain represents the resources: human and financial.

Table 11.3 shows how seemingly different design tasks in many different fields can be described in terms of the four design domains. In the case of the product design, the customer domain consists of the customer requirements or attributes the customer is looking for in a product; the functional domain consists of functional requirements, often defined as engineering specifications and constraints; the

TABLE 11.3 Characteristics of the Four Domains of the Design World for Various Designs: Manufacturing, Materials, Software, Organizations, and Systems

Domains Character Vectors	Customer Domain {CAs}	Functional Domain {FRs}	Physical Domain {DPs}	Process Domain {PVs}
Manufacturing	Attributes which consumers desire	Functional requirements specified for the product	Physical variables which can satisfy the functional requirements	Process variables that can control design parameters (DPs)
Materials	Desired performance	Required properties	Microstructure	Processes
Software	Attributes desired in the software	Output	Input variables and algorithms	Subroutines
Organization	Customer satisfaction	Functions of the organization	Programs or offices	People and other resources that can support the programs
Systems	Attributes desired of the overall system	Functional requirements of the system	Machines or components, subcomponents	Resources (human, financial, materials, etc.)

physical domain is the domain in which the key design parameters {DPs} are chosen to satisfy the {FRs}; and the process domain specifies the manufacturing methods that can produce the {DPs}. It is indeed fortunate that all designs fit into these four domains, since in a given design task, mechanical design, software design, manufacturing issues, and organizational issues must often be considered simultaneously. Because of this logical structure of the design world, generalized design principles can be applied to all design applications, and the issues that arise in the four domains can be considered systematically and concurrently.

Customer needs are often difficult to define. Nevertheless the designer must make every effort to understand customer needs by working with customers to appreciate and establish their needs. Then these needs (or the attributes the customer is looking for in a product) must be translated into functional requirements (FRs). This must be done in a "solution neutral environment." This means that the FRs must be defined without bias to any existing or preconceived solutions. If the FRs are defined based on an existing design, then the designer will simply be specifying the FRs of that product and creative thinking cannot be done.

To aid the process of defining FRs, QFD (quality function deployment) has been used. In QFD customer needs and the possible functional requirements are correlated and important FRs are determined. Experience plays an important role in defining FRs, since qualitative judgment is often necessary for assessing customer needs and identifying the essential problems that must be solved.

11.4 The Axiomatic Approach to Design

Nam P. Suh

The creative process of mapping the FRs in the functional domain to DPs in the physical domain is not unique; the solution varies with a designer's knowledge base and creative capacity. As a consequence, solution alternatives may vary in their effectiveness to meet the customer's needs. The axiomatic approach to design is based on the premise that there are generalizable principles that form the basis for distinguishing between good and bad designs.

Suh (1990) identified two design axioms by *abstracting* common elements from a body of good designs, including products, processes, and systems. The first axiom is called the *Independence Axiom*. It states that the independence of *functional requirements* (FRs) must be always maintained, where FRs are *defined as the minimum set of independent functional requirements* that characterize the design goals. The second axiom is called the *Information Axiom*, which states that among those designs that satisfy the Independence Axiom the design that has the highest probability of success is the best design. During the mapping process (for example, mapping from FRs in the functional domain to DPs in the physical domain), the designer should make correct design decisions using the Independence Axiom. When several designs that satisfy the Independence Axiom are available, the Information Axiom can be used to select the best design.

Axioms are general principles or self-evident truths that cannot be derived or proven to be true; however they can be refuted by counterexamples or exceptions. Through axioms such as Newton's laws and the laws of thermodynamics, the concepts of force, energy, and entropy have been defined. One of the main reasons for pursuing an axiomatic approach to design is the generalizability of axioms, which leads to the derivation of corollaries and theorems. These theorems and corollaries can be used as design rules that precisely prescribe the bounds of their validity because they are based on axioms. The following corollaries are presented in Suh (1990).

Corollary 1: (Decoupling of Coupled Designs)
Decouple or separate parts or aspects of a solution if FRs are coupled or become interdependent in the designs proposed.

Corollary 2: (Minimization of (FRs)
Minimize the number of FRs and constraints.

Corollary 3: (Integration of Physical Parts)
Integrate design features in a single physical part if FRs can be independently satisfied in the proposed solution.

Corollary 4: (Use of Standardization)
Use standardized or interchangeable parts if the use of these parts is consistent with FRs and constraints.

Corollary 5: (Use of Symmetry)
Use symmetrical shapes and/or components if they are consistent with the FRs and constraints.

Corollary 6: (Largest Tolerance)
Specify the largest allowable tolerance in stating FRs.

Corollary 7: (Uncoupled Design with Less Information)
Seek an uncoupled design that requires less information than coupled designs in satisfying a set of FRs.

The ultimate goal of axiomatic design is to establish a science base for design and improve design activities by providing the designer with a theoretical foundation based on logical and rational thought processes and tools.

The First Axiom: The Independence Axiom

The Independence Axiom may be formally stated as:

Axiom 1: The Independence Axiom
Maintain the independence of the functional requirements.

As stated earlier, functional requirements, FRs, are defined as the minimum set of independent requirements that the design must satisfy. A set of functional requirements is the description of design goals. The Independence Axiom states that when there are two or more functional requirements, the design solution must be such that each of the functional requirements can be satisfied without affecting any of the other requirements. This means that the designer must choose the correct set of DPs so that functional dependence or coupling is not introduced. When there is only one FR, the Independence Axiom is always satisfied. In this case, the given design alternatives should be optimized and the second axiom, the Information Axiom, is used to select the best design.

To apply the Independence Axiom, the mapping process from the design goals to the design solutions can be expressed mathematically. The set of functional requirements that define the specific design goals constitutes a vector {FRs} in the functional domain. Similarly, the set of design parameters in the physical domain that describe the design solution also constitutes a vector {DPs}. The relationship between the two vectors can be written as

$$\{\text{FRs}\} = [A]\{\text{DPs}\} \tag{11.4.1}$$

where [A] is the design matrix that characterizes the nature of the mapping. Equation (11.4.1) may be written in terms of its elements as $FR_i = A_{ij}DP_j$. Equation (11.4.1) is a design equation that may be used for the design of a product or the microstructure of a material. For the design of processes, the design equation may be written as

$$\{\text{DPs}\} = [B]\{\text{PVs}\} \tag{11.4.2}$$

where [B] is the design matrix that characterizes the process design.

Designs that satisfy the Independence Axiom must have either a diagonal or triangular design matrix (see Figure 11.4.1). When the design matrix [A] is diagonal, each of the FRs can be satisfied independently by adjusting one DP. Such a design is called an *uncoupled design*. When the matrix is triangular, the independence of FRs can be guaranteed if and only if the DPs are changed in a proper sequence. Such a design is called a *decoupled* or *quasi-coupled design*. Although the design matrix is a second-order tensor (note: stress, strain, and moment of inertia are also second-order tensors), the usual coordinate transformation technique cannot be applied to Equations (11.4.1) or (11.4.2) to find the invariants such as the diagonal matrix, since [A] and [B] typically involve physical phenomena and geometric relationships that are not amenable to coordinate transformation.

In addition to the Independence Axiom, the mapping of the design goals (FRs or DPs) to design solutions (DPs or PVs, respectively) is often subject to constraints, Cs. Constraints establish the bounds on the acceptable design solutions and differ from FRs in that they do not have to be independent. Cost, for example, is often considered a constraint since it is affected by all design decisions, but the design is acceptable as long as the cost does not exceed a set limit.

Example 1: Shaping of Hydraulic Tubes

In many applications (e.g., aircraft industry), steel tubes must be bent to complex shapes without changing the circular cross-sectional shape of the tube. To design a machine and a process that can achieve the task, the functional requirements can be formally stated as

FR1 = Bend the steel tube to prescribed curvatures.
FR2 = Maintain the circular cross section of the bent tube.

$$\begin{Bmatrix} FR_1 \\ FR_2 \\ FR_3 \end{Bmatrix} = \begin{bmatrix} X & 0 & 0 \\ 0 & X & 0 \\ 0 & 0 & X \end{bmatrix} \begin{Bmatrix} DP_1 \\ DP_2 \\ DP_3 \end{Bmatrix}$$

a) Uncoupled design

$$\begin{Bmatrix} FR1 \\ FR2 \\ FR3 \end{Bmatrix} = \begin{bmatrix} X & 0 & 0 \\ X & X & 0 \\ X & X & X \end{bmatrix} \begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix}$$

b) Decoupled design

$$\begin{Bmatrix} FR1 \\ FR2 \\ FR3 \end{Bmatrix} = \begin{bmatrix} X & 0 & X \\ X & X & 0 \\ X & X & X \end{bmatrix} \begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix}$$

c) Coupled design

FIGURE 11.4.1 Examples of uncoupled, decoupled, and coupled designs.

One mechanical concept that can do the job is shown schematically in Figure 11.4.2 for a two-dimensional bending case. It consists of a set of matching rollers with semicircular grooves on their periphery. These "bending" rollers can counterrotate at different speeds and move relative to each other to control the bending process. The centers of these two bending rollers are fixed with respect to each other, and the contact point of the bending rollers can rotate about a fixed point. A second set of "feed" rollers, which counterrotate at the same speed, feed the straight tube feedstock into the bending rollers. As the tubes are bent around the rollers, the cross-sectional shape will tend to change to a noncircular shape. The deformation of the cross section is prevented by the semicircular cam profile machined on the periphery of the bending rollers. The DPs for this design are

DP1 = Differential rotation of the bending rollers to bend the tube
DP2 = The profile of the grooves on the periphery of the bending rollers

The kinematics of the roller motion needs to be determined. To bend the tube, one of the bending rollers must rotate faster than the other. In this case, the tube will be bent around the slower roller. The forward speed of the tube is determined by the average speed of the two bending rollers. The motion of these rollers can be controlled digitally using stepping motors.

The design shown in Figure 11.4.2 is an uncoupled design, since each of the proposed DPs only affects one FR. Is this the best design? The only way this question can be answered is to develop alternative designs that satisfy the FRs, constraints (Cs), and the Independence Axiom. Then the information content for each of the proposed designs must be computed so as to use the Information Axiom to select the best among the proposed designs.

Decomposition, Zigzagging, and Hierarchy

In the preceding example the design was completed when the two FRs in the functional domain were mapped to two DPs in the physical domain. However, in many designs both the FRs and DPs must be decomposed into hierarchies because the high level conceptual design ideas need further design details before they can be implemented. To create the hierarchies for the FRs and DPs, the designer must return to the functional domain from the physical domain. As shown in Figure 11.4.3, the design process requires the designer to alternate or zigzag between the functional domain and the physical domain.

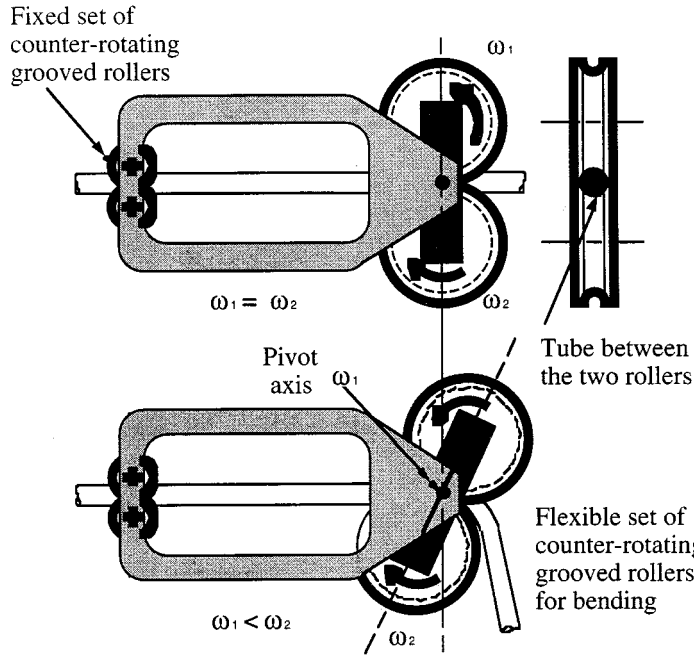

FIGURE 11.4.2 Concept for tube bending.

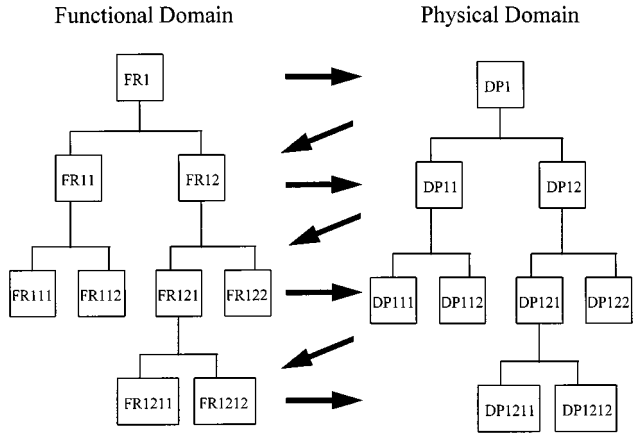

FIGURE 11.4.3 Hierarchical decomposition of FRs and DPs and zigzag mapping.

In many organizations, functional requirements or design specifications are decomposed without zigzagging by remaining only in the functional domain. This means that the designers are not working in a *solution-neutral environment*; they are specifying the requirements for an existing design. For example, assume that the design objective is to develop a vehicle that goes forward, stops, and turns. This vehicle has to satisfy these three FRs. These FRs cannot be decomposed until they are mapped to a set of DPs in the physical domain. This high-level mapping is often referred to as the *conceptual phase* of design. If, for instance, an electric motor is adopted as a means to move forward, then the FR "go forward" would be further decomposed in terms of this physical concept, and the evolving functional hierarchy will be different from that associated with the decision to use gas turbines. Therefore, to define the FRs in a solution-neutral environment, the designer needs to "zig" to the physical domain, and after proper DPs are chosen, the designer must then "zag" to the functional domain for further decomposition.

This process of mapping and zigzagging must continue until the design is completed, resulting in the creation of hierarachical trees for both FRs and DPs. This will be illustrated in the following example.

Example 2: Refrigerator Design

Historically, humankind has had the need to preserve food. Now consumers want an electrical appliance that can preserve food for an extended time. The typical solution is to freeze food for long-term preservation or to keep some food at a cold temperature without freezing for short-term preservation. These needs can be formally stated in terms of two functional requirements:

FR1 = Freeze food for long-term preservation.
FR2 = Maintain food at cold temperature for short-term preservation.

To satisfy these two FRs, a refrigerator with two compartments is designed. The two DPs for this refrigerator may be stated as

DP1 = Freezer section
DP2 = Chiller (i.e., refrigerator) section

To satisfy FR1 and FR2, the freezer section should only affect the food to be frozen and the chiller (i.e., refrigerator) section should only affect the food to be chilled without freezing. In this case, the design matrix will be diagonal. However, the conventional freezer/refrigerator design uses one compressor and one fan which turns on when the freezer section temperature is higher than the set temperature, and the chiller section is cooled by controlling the opening of the vent (see Figure 11.4.4). Therefore, the temperature in the chiller section cannot be controlled independently from that of the freezer section.

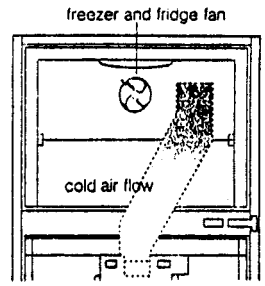
Fan ----------> Freezing Room
Fan + Damper -----> Refrigerating Room

Thermo Sensor in F-Room Only

The Damper produces large pressure loss

a



b

FIGURE 11.4.4 Conventional refrigerator/freezer cooling system.

Having chosen DP1, FR1 can now be decomposed as

FR11 = Control temperature of the freezer section in the range of –18°C.
FR12 = Maintain the uniform temperature throughout the freezer section at the preset temperature.
FR13 = Control humidity to relative humidity of 50%.

FR2 may be decomposed in the context of DP2 as

FR21 = Control the temperature of the chilled section in the range of 2 to 3°C.
FR22 = Maintain a uniform temperature throughout the chilled section at a preset temperature to within 1°C.

To satisfy the second level FRs, i.e., FR11, FR12, FR21, etc., the designer has to conceive a design and identify the DPs for this level of decomposition. Just as FR1 and FR2 were independent from each other through the choice of proper DP1 and DP2, the FRs at this second level must also be independent from one another.

Suppose that the requirements of the freezer section will be satisfied by pumping chilled air into the freezer section, circulating the chilled air uniformly throughout the freezer section, and monitoring the returning air for temperature and moisture in such a way that the temperature is controlled independently from the moisture content of the air. Then the second level DPs may be chosen as

DP11 = Turn the compressor on or off when the air temperature is higher or lower than the set temperature, respectively.
DP12 = Blow the air into the freezer section and circulate it uniformly throughout the freezer section at all times.
DP13 = Condense the moisture in the returned air when its dew point is exceeded.

The design equation is written as

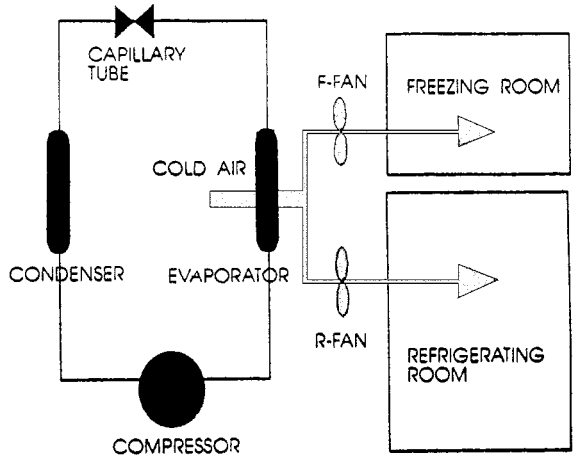
$$\begin{vmatrix} FR12 \\ FR11 \\ FR13 \end{vmatrix} = \begin{vmatrix} x & 0 & 0 \\ x & x & 0 \\ x & 0 & x \end{vmatrix} \begin{vmatrix} DP12 \\ DP11 \\ DP13 \end{vmatrix} \tag{11.4.3}$$

Equation (11.4.3) indicates that the design is a decoupled design.

The chilled section, where the food has to be kept in the range of 2 to 3°C, can now be designed. Here, again, a compressor may be used to control the air temperature within a preset range, and chilled air may be circulated to maintain a uniform temperature throughout the chilled section. This solution would result in a decoupled design as well. One of the design questions to be answered here is whether one compressor and one fan can be used to satisfy both {FR11, FR12, FR13} and {FR21, FR22}. Such a solution would minimize the information content without compromising functional independence (see Corollary 3). Most commercial refrigerators use only one compressor and one fan to achieve these goals (see Figure 11.4.4); however, many of these are coupled designs.

One can propose various specific design alternatives and evaluate the options in terms of the Independence Axiom. If a design allows the satisfaction of these FRs independently, then the design is acceptable for the set of specified FRs. If a solution that satisfies the Independence Axiom cannot be devised, then the designer must compromise the FRs by either eliminating some of the FRs or increasing the tolerance for temperature control, moisture control, etc.

One company has improved the preservation of food in their chilled section by providing one additional fan so as to be able to control the temperature of the chilled section more effectively (see Figure 11.4.5). This can be done since the evaporator was sufficiently cold to cool the air being pumped into the chiller section, even during periods when the compressor was not running. To maintain a uniform temperature distribution, extra vents were provided to insure good circulation of air. In this design, DP21 refers to



TWO COOLING FAN TYPE

FIGURE 11.4.5 New refrigerator/freezer cooling system.

the fan for the chiller section, and DP22 represents the vents. The design matrix for the {FR21, FR22}–{DP21, DP22} relationship is diagonal as shown in the design equation:

$$\begin{vmatrix} FR21 \\ FR22 \end{vmatrix} = \begin{vmatrix} X & 0 \\ 0 & X \end{vmatrix} \begin{vmatrix} DP21 \\ DP22 \end{vmatrix} \tag{11.4.4}$$

The company has compared the performance of the uncoupled design with that of competing coupled designs. For instance, the new design provides much more uniform temperature in the chiller section (Figure 11.4.6a) and much less temporal fluctuation than the existing coupled designs (Figure 11.4.6b). They also found that the uncoupled design saves electricity because air can be defrosted due to the air flow into the chiller section when the compressor is not operating. They also found that this new design enables the use of a quick refrigeration mode in the chilled section by turning on the fan of the chiller section as soon as food is put into the chiller section. To cool 100 g of water from 25 to 10°C it took only 37 vs. 58 min in a conventional refrigerator (Figure 11.4.7).

According to Corollary 3 (Integration of Physical Parts), the innovative idea of using two fans and uniformly positioned ducts may or may not be the best solution if the FRs can be satisfied independently using only one fan. If there is an alternative design that can satisfy the Independence Axiom, the Information Axiom and the detailed calculation of the information content must be used to determine the better of the two designs. As discussed in "The Second Axiom: The Information Axiom" (below), the best design is the one that has the minimum information content since it has the highest probability of success.

In the preceding example, the design matrices were formulated in terms of Xs and Os to model the nature of the relationship between each FR and each DP. In some cases, this simple, conceptual notation is sufficient to complete and implement the design. However, in many cases further steps should be taken to optimize the design. This means that the FR-DP relationships must be modeled more precisely after the conceptual design is represented in terms of Xs and Os.

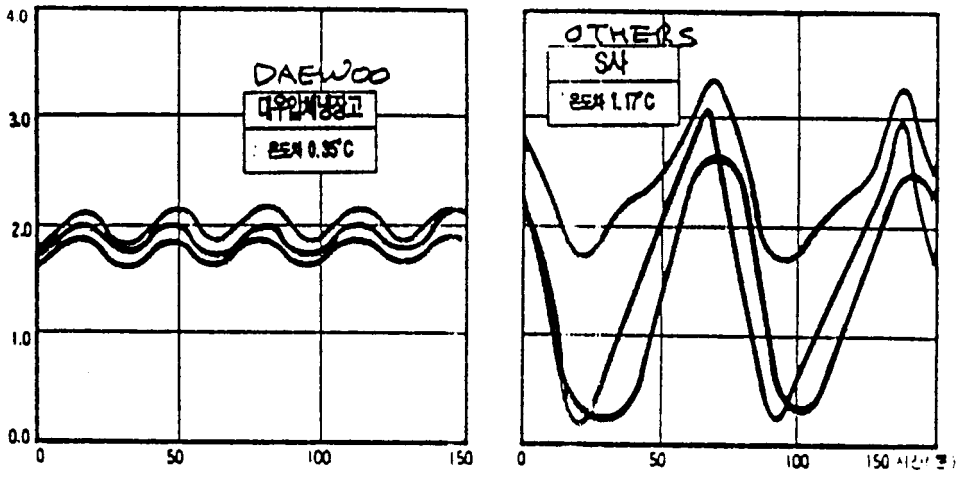
Concurrent Design and Manufacturing Considerations

The previous section, Decomposition, Zigzagging, and Hierarchy, demonstrates use of the Independence Axiom during mapping from the physical domain to the process domain, i.e., product design. In order to implement the chosen DPs, the designer has to map from the physical domain to the process domain (i.e., process design) by choosing the process variables, PVs. This process design mapping must also satisfy the Independence Axiom, although sometimes the solution may simply involve the use of existing processes. When existing processes must be used to minimize capital investment in new equipment, the corresponding PVs must also be used to complete the mapping from the physical domain to the process domain. Therefore, the PVs act as constraints in choosing DPs. Since early design decisions may determine 70 to 80% of manufacturing productivity in many enterprises, the product design and process design (or selection) should be performed at the same time in order to develop designs that can be manufactured without incurring cost overruns and schedule slippage. This is sometimes called *concurrent design*.

The Second Axiom: The Information Axiom

When there is only one FR, the Independence Axiom is always satisfied, and the only task left is to optimize the given design. Various optimization techniques have been advanced to deal with optimization problems involving one objective function. However, when there are two or more FRs, some of these optimization techniques do not work. In these cases, we must first develop a design that is either uncoupled or decoupled. If the design is uncoupled, it can be seen that each FR can be satisfied and the optimum points can be found. If the design is decoupled, the optimization technique must follow a set sequence.

For a given set of FRs, it is most likely that every designer will come up with different designs, all of which are acceptable in terms of the Independence Axiom. However, one of these designs is likely to be the superior alternative. The Information Axiom provides a quantitative means for establishing the merits of a given design, and this value is used to select the best solution. Specifically, the Information Axiom may be stated as



a

■ +2°C fixed temperature refrigeration

FIGURE 11.4.7 Quick refrigeration performance.

Axiom 2: The Information Axiom
Minimize the information content.

Information is defined in terms of the information content **I** that is related, in its simplest form, to the probability of satisfying a given set of FRs. If the probability of success is p, the information content **I** associated with the probability is defined as

$$\mathbf{I} = -\log_2 p \tag{11.4.5}$$

Equation (11.4.5) defines information content in the units of binary digits or bits. In the general case of an uncoupled design with *n* FRs, **I** may be expressed as

$$I = -\sum_{i=1}^{n} \log_2 p_i = \sum_{i=1}^{n} I_i \tag{11.4.6}$$

where p_i is the probability of DP_i satisfying FR_i. Since there are *n* FRs, the total information content is the sum of all the individual measures. When all probabilities p_i are equal to one, the information content is zero. Conversely, the information content is infinite when one or more probabilities are equal to zero.

A design is called *complex* when its probability of success is low. The quantitative measure for complexity is the information content: complex systems require more information to make the system function (see Equation 11.4.5). Thus, a large system that is comprised of many subsystems and components is not necessarily complex. Even a small system can be complex if its probability of success is low.

Example 3: Cutting a Rod to a Length

Suppose we need to cut rod A to the length 1 +/– 0.000001 m and rod B to the length 1 +/– 0.1 m. Which task is more complicated?

The answer depends on the cutting equipment available for the job! However, most engineers with some practical experience would say that the one that has to be cut within 1 μm would be more difficult, because the probability of success associated with the smaller tolerance is lower than that associated

with the larger tolerance. Therefore, the job with the lower probability of success is more *complex* than the one with higher probability. The Information Axiom links the notion of complexity with the specified tolerances for the FRs: the tighter the tolerance, the more difficult it may be to choose a design solution or a system that can satisfy the FRs.

In practice, the probability of success is a function of the intersection of the tolerances defined by the designer to satisfy the FRs and the ability of the chosen system to produce the part within the specified tolerances. This value can be computed by specifying the *design range* (*dr*) for an FR and by determining the *system range* (*sr*) that the proposed design can provide to satisfy the FR. Figure 11.4.8 illustrates these two ranges graphically. The vertical axis (the ordinate) is for the probability density function and the horizontal axis (the abscissa) is for either FR or DP, depending on the mapping domains involved. When the mapping is between the functional and the physical domains (as in product design), the abscissa is for FR, whereas for mapping between the physical and the process domains (e.g., process design), the abscissa is for DP.

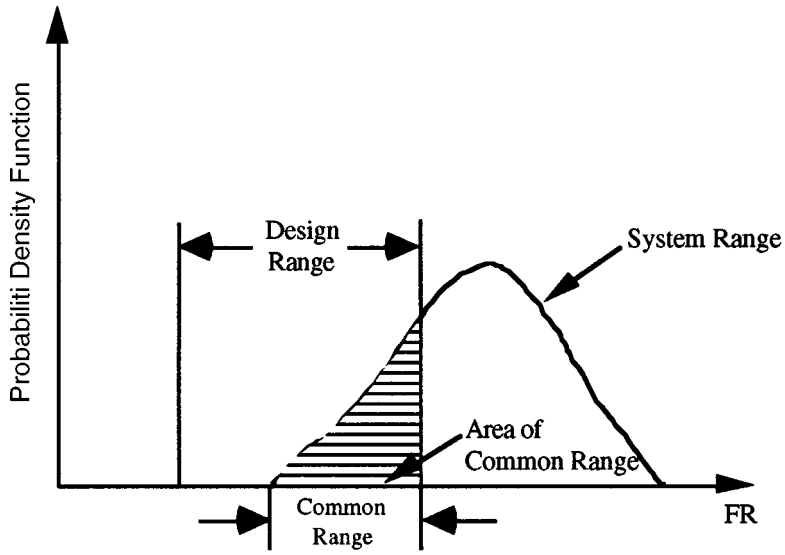

FIGURE 11.4.8 Design range, system range, and common range in a plot of the probability density function (pdf) of a functional requirement.

In Figure 11.4.8 the system range is plotted as a probability density function vs. the specified FR. The intersection of the design range and the system range is called the *common range* (*cr*), and this is the only region where the design requirements are satisfied. Consequently, the area under the common range divided by the area under the system range is equal to the design's probability of success. Then the information content may be expressed as

$$\mathbf{I} = \log_2\left(A_{sr}/A_{cr}\right) \tag{11.4.7}$$

where A_{sr} denotes the area under the system range and A_{cr} is the area within the common range. Furthermore, since A_{sr} =1.0 and there are *n* FRs to satisfy in most cases, the information content may be expressed as

$$I = -\sum_{i=1}^{n} \log_2\left(1/A_{cr}\right)_i \tag{11.4.8}$$

11.5 Algorithmic Approaches to Design

Leonard D. Albano

In addition to the axiomatic approach to design (see Section 11.4), there are many methods that are based on an algorithmic approach to design. In algorithmic design, the design process is identified or prescribed so that it leads the designer to a solution that satisfies the design goals. Algorithmic methods can be divided into several categories: pattern recognition, associative memory, analogy, experientially based prescription, extrapolation, interpolation, selection based on probability, etc. This section briefly discusses three common algorithmic methods for design: systematic design, the Taguchi method, and design for assembly (DFA).

Systematic Design

Systematic design methods prescribe how design should be done and provide standardized solutions for fulfilling certain functional requirements. Examples of systematic design methods include Pahl and Beitz (1988), Hubka and Eder (1988), and the German Standards Institute (VDI). This section describes the approach advanced by Pahl and Beitz.

The method of Pahl and Beitz (1988) divides the design process into a number of steps and prescribes methods for dealing with each step. Design starts with an appreciation of customers needs, which are then clarified in terms of an overall function. By definition, the overall function of an engineering system is to convert matter (e.g., energy, materials, signals). Energy, for example, can be converted from chemical energy to mechanical and thermal energy; materials can be shaped, finished, and coated to provide particular geometries and surface finishes; and signal conversion is often used to control the conversion of energy and materials. The overall function is an abstract formulation of customers needs and is defined in terms of inputs and outputs to a system.

Next, the overall function is decomposed into a hierarchy of generic subfunctions (i.e., energy, material, and signal conversions) that the product must perform in order to meet the overall function. The combination of subfunctions is termed a *function structure*. Use of the function structure facilitates the design task by breaking down the overall, complex function into smaller problems that can be divided among a number of experts. Construction of the function structure starts with the logical analysis of the functions that must appear in the solution if the overall function is to be satisfied. For example, a device for producing small, thermoplastic parts should include the following subfunctions: feed plastic pellets, melt plastic pellets, shape molten plastic into desired part geometry, cool part, dispense part, and control material flow. This function structure may be expanded during later steps of the design process as the designer gains additional insight.

Once a simple function structure is established, the designer searches for suitable solution principles to satisfy each of the subfunctions. Solution principles consist of some underlying physical principle or principles to effect the required conversion and some geometric form. Shear and torsion, for example, are physical principles for transferring mechanical energy, and the screw drive is a geometric form that embodies these effects. Published design catalogs, such as the VDI guidelines (VDI), provide a data base of standardized solution principles which facilitates the solution process. A design concept is obtained by integrating the solution principles for each subfunction.

The quality of the proposed design concept increases with the number of solution principles that are considered for each subfunction. Therefore, multiple solution principles should be identified for each subfunction, and these solution principles can be combined in various permutations to produce a rich solution field. Formulating the required subfunctions and the proposed principles in matrices provides a convenient scheme for organizing the results (see Figure 11.5.1). Each row of the matrix refers to a subfunction and the columns of the matrix contain combinations of solution principles.

The reduction of the solution field to a few promising proposals for further development involves a number of ad hoc strategies. One strategy relies on the experience of the designer to identify those

Sub-functions		Solution Concepts					
		1	2	...	j	...	m
1	F_1	S_{11}	S_{12}		S_{1j}		S_{1m}
2	F_2	S_{21}	S_{22}		S_{2j}		S_{2m}
:	:	:	:		:		:
i	F_i	S_{i1}	S_{i2}		S_{ij}		S_{im}
:	:	:	:		:		:
n	F_n	S_{n1}	S_{n2}		S_{nj}		S_{nm}

FIGURE 11.5.1 Matrix approach for developing solution concepts based on mapping different principles S_{xy} to each subfunction F_x.

combinations of solution principles that are not compatible with customers needs or with one another. A second strategy is to use value analysis to evaluate and compare the solution variants generated by the matrix combination. The general procedure for value analysis involves identifying evaluation criteria and assigning relative weights to each criterion. Each solution variant is then assigned a value by combining its weighted value for each criterion. The solution variants are then compared on the basis of their total weighted value, and the best solution is selected.

The selected solution concept is then developed in terms of its layout and detail specifications. Much of the design development relies on design rules and knowledge readily available in handbooks and design guidelines. In addition to the development of production drawings and specifications, detail design often involves optimization of the solution principles and their geometric forms. The reader is referred to Pahl and Beitz (1988) for additional information.

The Taguchi Method
