The Taguchi method (1987, 1993) provides a mathematical basis for analyzing product robustness and is intended as a guide for improving design quality. According to Taguchi, higher quality products satisfy customers needs with less variation and are manufactured at lower cost. This definition of quality is based on a cost model that emphasizes the costs associated with product variability. Costs due to variation include those incurred during manufacturing (such as the cost of materials, machine adjustments, and scraps) and those assumed by the customer (e.g., the cost to repair and/or replace the deficient product). The significance of the Taguchi cost model is the fact that it forces the designer to focus on *offline quality control* as a means to improve product quality.

Offline quality control (QC) is a strategy for reducing variability and improving quality during product design and process planning. It is an attempt to take advantage of the fact that most of the cost is committed during the early stages of product development, while only a very small percentage of the cost is actually expended. In contrast, the concept of *online quality control* has been used historically to advance quality products during manufacturing operations. However, during this stage of the product life cycle, much of the cost has been expended and committed. Statistical process control is an example of online quality control.

The practice of offline QC divides the design process into three stages: system design, parameter design, and tolerance design. System design refers to the conceptual phase of design when customers needs are formulated into a design problem and solutions are generated and evaluated. Once a solution is established and defined in terms of its characteristic attributes or parameters, parameter design is used to establish appropriate parameter settings so as to reduce the design's sensitivity to uncontrollable sources of variation. Taguchi refers to these conditions as *noise factors*. Environmental factors (e.g., people and ambient temperature) and time-dependent phenomena (such as tool wear and material

shrinkage) are examples of noise factors. As a last step, tolerance design is used to enhance or fine-tune the quality improvements realized during parameter design. However, tolerance design often involves a trade-off between the improved quality and the increased production costs incurred by tightening tolerances.

Parameter and tolerance design rely on experimental and mathematical techniques to determine the best design, subject to various noise factors. Various strategies may be used to conduct the experiments. Consider a system that involves five design parameters and three levels of settings — high, medium, and low — for each parameter. The simplest strategy is to investigate all possible combinations of parameters and level settings, which would require $3^5 = 243$ sets of experiments. Instead, orthogonal arrays are an efficient and economical alternative to complete enumeration.

Figure 11.5.2 shows a portion of the L18 orthogonal array that enables a reduction in the work scope from 243 to 18 sets of experiments. The column headings A, B, C. D, and E correspond to each of the five design parameters or controllable factors, and the column entries refer to the three level settings 1, 2, and 3. Each row of the array defines an experiment as a unique combination of parameter settings. Any two columns have nine combinations of level settings — (1,1), (1,2), (1,3), (2,1), (2,2), (2,3), (3,1), (3,2), and (3,3) — and each combination appears with the same frequency. This balance is indicative of the array's orthogonality in a statistical sense because the influence of each control factor can be evaluated independently. The basic array can be extended to include the influence of noise factors and their level settings.

Experiment	Parameter Level Setting				
	A	B	C	D	E
1	1	1	1	1	1
2	2	2	2	2	2
3	3	3	3	3	3
4	1	1	2	2	3
5	2	2	3	3	1
6	3	3	1	1	2
7	1	2	1	3	2
8	2	3	2	1	3
9	3	1	3	2	1
10	1	3	3	2	2
11	2	1	1	3	3
12	3	2	2	1	1
13	1	2	3	1	3
14	2	3	1	2	1
15	3	1	2	3	2
16	1	3	2	3	1
17	2	1	3	1	2
18	3	2	1	2	3

FIGURE 11.5.2 Portion of L18 orthogonal array to investigate all combinations of five parameters with three level settings.

Analysis of variation techniques provide a mathematical basis for organizing and interpreting the experimental results. For each performance requirement, signal-to-noise (S/N) ratio is used to express how sensitive each design parameter is to uncontrollable noise (which is indicative of *design robustness*). A robust design has a high S/N ratio and performs well despite the influence of noise. Many equations are available for calculating S/N ratios, and the selection of the appropriate equation is a function of the type of cause–effect relationship under study. Examples include *higher-is-better, lower-is-better,* and *nominal-is-best*. The reader is referred to Taguchi (1987, 1993) for further information.

Design for Assembly

Design for assembly (DFA) supports the analysis and design of products for ease of assembly. Based on a collection of empirical time-study data, if–then rules, and design checklists, DFA methods and tools help the designer to focus on the relationship between the geometric features of a design and its

components and the effort and resources necessary to assemble these components into the desired product. Philips International, Hitachi, Xerox, Ford, and General Electric have been industry leaders in the adoption and dissemination of DFA. In this section the most widely known method, advanced by Boothroyd and Dewhurst (1985), is considered. The method gives the total assembly time and design efficiency, and these measures are then used to guide redesign.

The method of Boothroyd and Dewhurst (1985) starts with the description of a product's assembly sequence in terms of components, component features, and the basic assembly tasks of handling and insertion (which includes fastening). For each component involved in the assembly sequence, a catalog of generic part features is used to classify the component with respect to its difficulty for handling and insertion. These classifications are then used to determine the time required for each assembly task, and the task times are added to give the total operation time for the component. Therefore, the total assembly time (TM) for the design is the sum of the operation times for each component.

Design efficiency is the ratio of an estimated, ideal assembly time to TM. The ideal assembly time is based on a theoretical minimum number of parts (NM). The estimation of NM relies on a checklist for identifying redundant components or components that may be combined to reduce parts count. For manual assembly, the ideal assembly time is specified as 3 sec per part, and design efficiency EM is given by the equation

$$\mathrm{EM} = 3 \times \mathrm{NM}/\mathrm{TM} \tag{11.5.1}$$

The resulting values for assembly time and design efficiency provide the designer with a basis for redesign. Suggested strategies for redesign include reduction in parts count, use of symmetry to facilitate handling, and use of alternative fastening mechanisms to facilitate insertion (e.g., snap-fit elements are faster to insert than parts requiring screw tightening). The reader is referred to Boothroyd and Dewhurst (1985) for further information.

11.6 Strategies for Product Design

Michael Pecht

Requirements

The design team must have a clear appreciation of user requirements and constraints before a design can begin. Requirements are established within the context of product effectiveness attributes and include limits on parameters such as speed, miles per gallon, computations per second, and accuracy, as well as constraints on size, weight, reliability, and cost. Often, contractual requirements and company policy can dictate a product type, such as the use of an in-house technology or product, or the exclusion of a technology or product.

Requirements must be addressed holistically in the design of a product and must not be limited to those that affect the product's immediate performance. For example, the supportability of the product is a critical product requirement for many products in terms of the ease of maintenance and accessibility to the products, spares, support equipment, the time and required personnel to repair the product, and the ease of discovering or detecting where a problem occurs. A poor definition of requirements could lead to a design where, for example, the air conditioning compressor has to be removed to replace a spark plug, or where special tools are required to replace the oil in a car. Note also that the design team should be aware of the impact of administrative policies on the reliability of products as reflected in the product's scenario for use. For example, outdated standards can contribute to failures that are not the result of either faulty design or human error.

The Life Cycle Usage Environment

The life cycle usage environment or scenario for use of a product goes hand-in-hand with the product requirements. The life cycle usage information describes the storage, handling, and operating stress profiles and thus contains the necessary "load" input information for effective assessment and development of design guidelines, screens, and tests. The stress profile of a product is based on the application profile and the internal stress conditions of the product. Because the performance of a product over time is often highly dependent on the magnitude of the stress cycle, the rate of change of the stress, and even the time and spatial variation of stress, the interaction between the application profile and internal conditions must be specified. Specific information about the product environment includes absolute temperature, temperature ranges, temperature cycles, temperature gradients, vibrational loads and transfer functions, chemically aggressive or inert environments, and electromagnetic conditions. The life cycle usage environment can be divided into three parts: the application and life profile conditions, the external conditions in which the product must be stored, handled, and operated, and the internal product-generated stress conditions.

The application and life profile conditions include the application length, the number of applications in the expected life of the product, the product life expectancy, the product utilization or nonutilization (storage, testing, transportation) profile, the deployment operations, and the maintenance concept or plan. This information is used to group usage platforms (i.e., whether the product will be installed in a car, boat, satellite, underground), develop duty cycles (i.e., on–off cycles, storage cycles, transportation cycles, modes of operation, and repair cycles), determine design criteria, develop screens and test guidelines, and develop support requirements to sustain attainment of reliability and maintainability objectives. The external operational conditions include the anticipated environment(s) and the associated stresses that the product will be required to survive. The stresses include temperature, vibrations, shock loads, humidity or moisture, chemical contamination, sand, dust and mold, electromagnetic disturbances, radiation, etc.

The internal operational conditions are associated with product-generated stresses, such as power consumption and dissipation, internal radiation, and release or outgassing of potential contaminants. If

the product is connected to other products or subsystems in a system, stresses associated with the interfaces (i.e., external power consumption, voltage transients, electronic noise, or dissipation) must also be included.

Characterization of Materials, Products, and the Manufacturing Processes

Design is intrinsically linked to the materials, products, interfaces, and manufacturing processes used to establish and maintain functional and structural integrity. It is unrealistic and potentially dangerous to assume defect-free and perfect-tolerance materials, products, and structures. Materials often have naturally occurring defects and manufacturing processes can induce additional defects to the materials, products, and structures. The design team must also recognize that the production lots or vendor sources for products that comprise the design are subject to change. Even greater variability in products characteristics is likely to occur during the fielded life of a product as compared to its design or production life cycle phases.

Design decisions involve the selection of products, materials, and controllable process techniques, using tooling and processes appropriate to the scheduled production quantity. Often, the goal is to maximize product and configuration standardization; increase package modularity for ease in fabrication, assembly, and modifications; increase flexibility of design adaptation to alternate uses; and utilize alternate fabrication processes.

Design Guidelines and Techniques

Generally, new products replace existing products. The replaced product can be used for comparisons (i.e., a baseline comparison product). Lessons learned from the baseline product can be used to establish new product parameters, to identify areas of focus in the new product design, and to avoid the mistakes of the past.

Once the products, materials, processes, and stress conditions have been characterized, design begins. In using design guidelines, there may not be a unique path to follow. Multiple branches may exist depending upon the input design constraints. The design team should explore enough of the branches to gain confidence that the final design is the best for the prescribed input information. The design team should also use guidelines for the complete design and not those limited to specific aspects of an existing design. This statement does not imply that guidelines cannot be used to address only a specific aspect of an existing design, but the design team may have to trace through the implications that a given guideline suggests.

Design guidelines that are based on physics of failure models can also be used to develop tests, screens, and derating factors. Tests can be designed from the physics of failure models to measure specific quantities and to detect the presence of unexpected flaws, manufacturing, or maintenance problems. Screens can be designed to precipitate failures in the weak population while not cutting into the design life of the normal population. Derating or safety factors can be determined to lower the stresses for the dominant failure mechanisms.

Preferred Products

In many cases, a product or a structure much like the required one has already been designed and tested. This is called a “preferred product or structure” in the sense that variabilities in manufacturing, assembly, and field operation that can cause problems have been identified and corrected. Many design teams maintain a list of preferred products and structures with acceptable performance, cost, availability, and reliability.

Redundancy

Redundancy permits a product to operate even though certain components and interconnections have failed. Redundant configurations can be classified as either active or standby. Elements in active redundancy operate simultaneously in performing the same function. Elements in standby redundancy are

designed so that an inactive one will be switched into service when an active element fails. The reliability of the associated function is increased with the number of standby elements (optimistically assuming that the sensing and switching products of the redundant configuration are working perfectly, and failed redundant components are replaced before their companion component fails).

A design team may often find that redundancy is a way to improve product reliability if time is of prime importance, if the products requiring redundancy are already designed and the products are known to be of poor reliability.

On the other hand, in weighing its advantages, the design team may find that redundancy will

- Prove too expensive, if the products and redundant sensors and switching products are costly
- Exceed the limitations on size and weight, particularly in avionics, missiles, and satellites
- Exceed the power limitations, particularly in active redundancy
- Attenuate the input signal, requiring additional amplifiers (which increase complexity)
- Require sensing and switching circuitry so complex as to offset the reliability advantage of redundancy

Protective Architectures

It is generally desirable to include means in a design for preventing a product, structure, or interconnection from failing catastrophically, and instead allow it to fail safely.

Fuses and circuit breakers are examples used in electronic products to sense excessive current drain and disconnect power from a failed circuit. Fuses within circuits safeguard products against voltage transients or excessive power dissipation and protect power supplies from shorted parts. Thermostats may be used to sense critical temperature, limiting conditions and shutting down the product or a component of the system until the temperature returns to normal. In some products, self-checking circuitry can also be incorporated to sense abnormal conditions and operate adjusting means to restore normal conditions or activate switching means to compensate for the malfunction.

Protective architectures can be used to sense failure and protect against possible secondary effects. In other cases, means can be provided for preventing a failed product or structure from completely disabling the product. For example, a fuse or circuit breaker can disconnect a failed product from a product in such a way that it is possible to permit partial operation of the product after the failure, in preference to total product failure. By the same reasoning, degraded performance of a product after failure of a product is often preferable to complete stoppage. An example is the shutting down of a failed circuit whose design function is to provide precise trimming adjustment within a deadband of another control product. Acceptable performance may thus be permitted, perhaps under emergency conditions, with the deadband control product alone.

Sometimes the physical removal of a part from a product can harm or cause failure of another part of the product by affecting load, drive, bias, or control. In some cases, self-healing techniques can be employed to self-check and self-adjust to effect changes automatically to permit continued operation after a failure.

The ultimate design, in addition to its ability to act after a failure, would be capable of sensing and adjusting for drifts to avert failures.

In the use of protective techniques, the basic procedure is to take some form of action after an initial failure or malfunction, to provide perhaps reduced performance, and to prevent additional or secondary failures. Such techniques can be considered as enhancing product reliability, although they also affect availability and product effectiveness. No less a consideration is the impact of maintenance, repair, and product replacement. If a fuse protecting a circuit is replaced, what is the impact when the product is reenergized? What protective architectures are appropriate for postrepair operations? What maintenance guidance must be documented and followed when fail-safe protective architectures have or have not been included?

Stress Margins

Products and structures should be designed to operate satisfactorily at the extremes of the parameter ranges, and allowable ranges must be included in the procurement or reprocurement specifications. To guard against out-of-tolerance failures, the design team must consider the combined effects of tolerances on products, subsequent changes due to the range of expected environmental conditions, drifts due to aging over the period of time specified in the reliability requirement, and tolerances in products used in future repair or maintenance functions.

Methods of dealing with product and structural parameter variations include statistical analysis and worst-case analysis. In statistical design analysis, a functional relationship is established between the output characteristics of the structure and the parameters of one or more of its products. In worst-case analysis, the effect that a product has on product output is evaluated on the basis of end-of-life performance values or out-of-specification replacement products.

Derating

The principle of derating is that there are no distinct stress boundaries for voltage, current, temperature, power dissipation, etc. above which immediate failure can occur and below which the product will operate indefinitely. Instead, the life of some products increases in a continuous manner as the stress level is decreased below the rated value. Practically, however, there are minimum stress levels below which increased derating will lower reliability, and the complexity required to step up performance will offset any gain in reliability.

Size and Weight Control

Methods to reduce product volume include:

- Eliminating unused space
- Selecting an exterior shape to require least possible volume when integrated with the intended installation structure
- Eliminating separable interconnections, using optimally shaped components and subassemblies
- Minimizing interconnection requirements
- Eliminating support components such as heat sinks, blowers, and special coolant flow passages
- Eliminating redundant components
- Using components and package elements to perform multiple functions

Methods to lower product weight include using high-strength lightweight materials, eliminating duplicate structures, and providing only that degree of strength required to reach a desired safety factor.

Potential Failure Sites and Failure Mechanisms

The design team must evaluate the potential failure mechanisms, failure stresses, failure sites, and failure modes, given a product architecture, the comprising products and materials, and the manufacturing processes. One approach to evaluation consists of the assessment of a list of candidate or "potential" failure mechanisms. The load conditions that cause the failure mechanisms to occur are then determined in light of the life cycle usage environment identified earlier. Table 11.6.1 presents various failure mechanisms and the associated load conditions.

Once the failure mechanisms and associated stresses have been identified, then failure sites are specified and a detailed reliability assessment is conducted for each location suspected to be a potential area of failure. Table 11.6.2 presents an example case of various failure sites, mechanisms, and load structures for a microelectronic product.

Failures can be categorized by their impact on end product performance. A critical failure is an event that reduces the performance of the end product to unacceptable levels. A noncritical failure, also called a fault, does not reduce performance to unacceptable levels. Failures can also be classified by the time

TABLE 11.6.1 The Load Conditions which Cause Failure Mechanisms

Failure Mechanism	Containment	Δ T (Temperature Cycle Magnitude)	RH (Relative Humidity)	T (Steady-State Temperature)	Vibration/Shock	Maintenance and Handling	Voltage
Brittle fracture		X		X	X	X	
Ductile fracture				X	X		
Yield		X		X	X		
Buckling		X		X	X	X	
Large elastic deformation		X			X		
Interfacial deadhesion	X	X	X	X	X		
Fatigue crack initiation	X	X	X	X	X		
Wear					X		
Creep		X		X	X		
Corrosion	X		X	X		X	
Dendritic growth	X		X			X	X
Fatigue crack propagation		X			X	X	
Diffusion				X			X

TABLE 11.6.2 Example: Failure Sites, Operational Loads, and Failure Mechanisms for a Microelectronic Product

Site	Containment	Δ T (Temperature Cycle Magnitude)	RH (Relative Humidity)	T (Steady-State Temperature)	Vibration/Shock	Voltage	Maintenance and Handling
Die		A, L, G	I		A, L, G		
Die attach		A, F, L, G			A, L, G, C		
Flip-chip solder joints	I, K	L, G	I	B, C, I, N	L, G	M	
Tape automated bonds	I, J, K	L, G	I, J	A, B, I, J, M	L, G	M, J	
Wire	I	G, L	I		G, L, E		
Leads	I, J	L	I, J	I	D, L, H	L, J	D, G
Substrate		L, G			A, B, L, G		
Substrate attach		F, L, G			C, L, G		

Note: A — brittle fracture; B — ductile fracture; C — yield; D — buckling; E — large elastic deformation; F — interfacial deadhesion; G — fatigue crack initiation; H — wear; I — corrosion; J — dendritic growth; K — interdiffusion; L — fatigue crack propagation; M — diffusion.

frame and manner in which the event occurs. The categories are catastrophic, intermittent, out-of-tolerance, and maladjustment.

1. **Catastrophic failures.** A catastrophic failure occurs when a product becomes completely inoperative or exhibits a gross change in characteristics. Examples are an open or shorted resistor or capacitor, a leaky valve, a stuck relay, or a broken switch.
2. **Intermittent failures.** Intermittent failures are nonperiodic failures that can occur within products, interconnects, or product interfaces including software. Examples include switch bouncing and poor transmission of signals. The design team must not only safeguard against the effects of intermittent failures, but also avoid creating possible modes of such failures (e.g., conditions permitting product-to-product or structural breakdowns).
3. **Out-of-tolerance failures.** Out-of-tolerance failures result from degradation, deterioration, drift, and wearout. Examples are the drifting of resistor and capacitor values and the wearing out of relays and solenoid valves and precision gears. The changes can arise as a result of time, temperature or temperature cycles, humidity, altitude, etc. When these changes, considered collectively, reach the point where product performance is below acceptable limits, we say that the product has failed.
4. **Maladjustment failures.** Maladjustment failures are often due to human error. Failures arise from improper adjustment of products, as well as abuse of adjusting products due to lack of understanding of the adjustments and the capabilities of the products. Such failures are hard to evaluate and difficult to avoid but must be considered if the reliability of the product is to be sustained.

Designing for the Application Environment

The design of modern products requires that the team be acquainted with the environmental factors affecting product performance over time. The environment is seldom forgiving and when a weak point exists, performance suffers. Design teams must understand the environment and its potential effects and then must select designs or materials that counteract these effects or provide methods to alter or control the environment within acceptable limits.

In addition, a product can create or perturb an environment. For example, many epoxies out-gas during cure, releasing corrosive or degrading volatiles or particulates into the product. Teflon may release fluorine and polyvinylchloride (PVC) may release chlorine. Certain solid rocket fuels are degraded into a jelly-like mass when exposed to aldehydes or ammonia, either of which can come from a phenolic nozzle cone. Common environmental considerations follow.

Temperature Control

Temperature is a powerful agent for electrical, chemical, and physical deterioration for two basic reasons:

- The physical properties of almost all known materials are modified by changes in temperature, temperature gradients, and temperature extremes.
- The rate of most chemical reactions is influenced by the temperature of the reactants.

Nevertheless, the effects of steady-state temperature and spatial and temporal temperature gradients must be clearly understood before a thermal control method is determined. A good practice is to develop a table of potential failure sites and failure mechanisms and the effects of temperature in its many forms.

Poor heat removal of dissipated I^2R losses, hysteresis, or eddy current losses can result in physical damage or accelerated chemical reaction rates. The latter occurrence, affecting certain types of materials, can cause general degradation and catastrophic or intermittent failures. But the fault is not always with the design; air intakes or outlets could be blocked because of faulty installation, or maintenance personnel might fail to clear or replace air filters.

Thermal management schemes for electronic equipment are selected, once the heat flux and the maximum temperature difference available for heat transfer have been identified. A complete thermal

management strategy involves selecting an appropriate heat removal scheme for each level of packaging. For low heat fluxes, passive thermal management techniques can be used. Such techniques do not require the expenditure of external energy for the heat removal. Interest in such techniques is currently very strong, due to their design simplicity, low cost, and high reliability.

Examples of passive cooling techniques include conduction cooling using high thermal conductivity substrates and/or heat sinks and natural convection air cooling. Conduction cooling can be employed when the heat source is not directly exposed to the coolant. This method is desirable in dense electronic packages, where radiation and convection are not effective cooling means. Natural convection cooling relies on the buoyancy-induced flows generated due to heating. For a maximum temperature rise of 85°C above the environment, heat fluxes of up to about 0.1 W/cm^2 can be removed by natural convection air cooling under nominal sea-level environmental conditions.

For higher heat fluxes, a combination of passive and active techniques can sometimes be used. This may include, for example, a high thermal conductivity substrate at the board level, along with forced air cooling at the box level. For this range of heat fluxes, the use of cold plate technology, thermoelectrics, and flow-through cooling are also possible; other common techniques are the use of heat pipe or thermosyphon (see Chapter 4).

Besides the out-gassing of corrosive volatiles when subjected to heat, almost all known materials will expand or contract when their temperature is changed. This expansion and contraction causes problems with fit between product interface and interconnections. Local stress concentrations due to nonuniform temperature are especially damaging, because they can be so high. A familiar example is a hot water-glass that shatters when immersed in cold water. Metal structures, when subjected to cyclic heating and cooling, may ultimately collapse due to the induced stresses and fatigue caused by flexing. The thermocouple effect between the junction of two dissimilar metals causes an electric current that may induce electrolytic corrosion.

Plastics, natural fibers, leather, and both natural and synthetic rubber are all particularly sensitive to temperature extremes as evidenced by their brittleness at low temperatures and high degradation rates at high temperatures.

Shock and Vibration Control

Shock and vibration can harmfully flex leads and interconnects, dislodge parts or foreign particles into bearings, pumps, and electronics, cause acoustical and electrical noise, and lead to structural instabilities. Protective measures against shock and vibration stresses are generally determined by an analysis of the deflections and mechanical stresses produced by these environmental factors. This generally involves the determination of natural frequencies and evaluation of the mechanical stresses within components and materials produced by the shock and vibration environment. If the mechanical stresses so produced are below the acceptable safe working stress of the materials involved, no direct protection methods are required. If, on the other hand, the stresses exceed the safe levels, corrective measures such as stiffening, reduction of inertia and bending moment effects, and incorporation of further support members are indicated. If such approaches do not reduce the stresses below the acceptable safe levels, further reduction is usually possible by the use of shock-absorbing mounts.

Products are sometimes specially mounted to counter the destructive effects of shock and vibration. Shock mounts often serve this purpose, but effective means for attenuating shock and vibration simultaneously are complex. Isolation of a product against the effects of vibration requires that the natural frequency of the product be substantially lower than the undesired frequency of vibration.

Three basic kinds of isolators are available:

- Elastomers made of natural or synthetic rubber, used in a shear mode or in a diaphragm to dampen the induced shock or vibration.
- Metallic isolators, such as springs, metal meshes, or wire rope. Springs lack good damping qualities, but meshes and rope provide smooth friction damping.

- Viscous dampers (similar to the type used on automobiles) which are velocity-sensitive, tend to become ineffective under high-frequency vibration. Resilient mounts must be used with caution, since they can amplify the intensity of shock and vibration if improperly placed. The ideal goal is to design a product to be resistant to shock and vibrations, rather than to provide complete isolation.

Another vibration protective technique is potting or encapsulation of small parts and assemblies. The potting material should be compliant enough to dampen vibrations. Some materials polymerize exothermically, and the self-generated heat may cause cracking of the casting or damage to heat-sensitive products. Another problem is shrinkage of the potting material. In some cases, molds are made oversized to compensate for shrinkage.

One factor that is not often considered is that the vibration of two adjacent components, or separately insulated subsystems, can cause a collision if maximum excursions and sympathetically induced vibrations are not accounted for in design. Another failure mode, fatigue (the tendency for a material to break under cyclic stress loads considerably below its tensile strength), includes high cycle fatigue, acoustic fatigue, and fatigue under combined stresses such as temperature extremes, temperature fluctuations, and corrosion.

In addition to using proper materials and configuration, it may still be necessary to control the amount of shock and vibration experienced by the product. Damping products are used to reduce peak oscillations and special stabilizers can be employed when unstable configurations are involved. Typical examples of dampeners are viscous hysteresis, friction, and air damping. Vibration isolators commonly are identified by their construction and material used for the resilient elements (rubber, coil spring, woven metal mesh, etc.). Shock isolators differ from vibration isolators in that shock requires a stiffer spring and a higher natural frequency for the resilient element. Some of the types of isolation mounting products are underneath, over-and-under, and inclined isolators. In some cases, however, even though an item is properly insulated and isolated against shock and vibration damage, repetitive forces may loosen the fastening products. If the fastening products loosen enough to permit additional movement, the product will be subjected to increased forces and may fail. Many specialized self-locking fasteners are commercially available.

Chemical Action Control

The earth's environment contains numerous deteriorators including oxygen, carbon dioxide, nitrogen, snow, ice, sand, dust, salt water spray, organic matter, and chemicals in general. Product specifications often state limits on temperature, humidity, altitude, salt spray, fungus, sunshine, rain, sand, and dust.

A material or structure can chemically change in a number of ways. Among them are interactions with other materials (i.e., metal migration, diffusion) and modifications in the material itself (recrystallization, stress relaxation, phase changes, or changes induced by irradiation). In addition to the deterioration problems associated with the external environments to which products are subjected, adhesives, batteries, and certain types of capacitors are susceptible to chemical aging and biological growths.

Materials widely separated in the electromotive series are subject to galvanic action, which occurs when two dissimilar metals are in contact in a liquid medium. The most active metal dissolves, hydrogen is released, and an electric current flows from one metal to the other. Coatings of zinc are often applied to iron so that the zinc, which is more active, will dissolve and protect the iron (a process known as *galvanization*). Galvanic action is known to occur within the same piece of metal, if one portion of the metal is under stress and has a higher free-energy level than the other. The part under stress will dissolve if a suitable liquid medium is present. Stress-corrosion cracking occurs in certain magnesium alloys, stainless steels, brass, and aluminum alloys. It has also been found that a given metal will corrode much more rapidly under conditions of repeated stress than when no stress is applied.

Corrosion-resistant materials should be used as much as possible. Although aluminum is excellent in this respect due to the thin oxide coating that forms when it is exposed to the atmosphere, it tends to

pit in moist atmospheres. Furthermore, aluminum may corrode seriously in a salt-laden marine atmosphere. Either anodization or priming with zinc chromate can provide additional protection.

Magnesium is sometimes used to minimize the weight of products but must be protected by surface additives against corrosion and electrolytic reaction. A coating of zinc chromate serves both purposes. Because magnesium is the most reactive metal normally used for structural purposes, the grounding of the magnesium structure requires careful selection of another metal for making the connection. Zinc- or cadmium-plated steel are the more commonly chosen connective materials.

Copper, when pure, is quite resistant to corrosion. However, under certain conditions, copper-made products will become chemically unstable. Transformers have occasionally failed due to impurities in the insulation and moisture. These conditions favor electrolytic reaction, which causes the copper to dissolve and eventually results in an open circuit.

Iron and steel are used in many products and structures because of their good magnetic and structural properties; however, only certain stainless steels are reasonably resistant to corrosion. Various types of surface plating are often added, but since thin coatings are quite porous, undercoatings of another metal such as copper are often used as a moisture barrier. Cadmium and zinc plating in some marine environments corrode readily, and often grow "whiskers", which can cause short circuits in an electronic product.

Proper design of a product therefore requires trade-offs in

- Selecting corrosion-resistant materials
- Specifying protective coatings if required
- Avoiding use of dissimilar metallic contacts
- Controlling metallurgical factors to prevent undue internal stress levels
- Preventing water entrapment
- Using high-temperature resistance coatings when necessary
- Controlling the environment through dehydration, rust inhibition, and electrolytic and galvanic protective techniques

Biological Growth Control

High humidity and warm temperatures often favor the growth of fungus, which can lead to deterioration of many electrical and mechanical properties. Products designed for use under tropical conditions can receive a moisture- and fungus-proofing treatment, which consists of applying a moisture-resistant varnish containing a fungicide. Air-drying varnishes generally are not as moisture-proof as are the baked-on types. This treatment is usually quite effective, but the useful life of most fungicides is less than that of the varnish, and retreatments may be necessary.

Moisture Control

Moisture, and impurities that may be contained with it, are known to cause corrosion of many metal systems. In addition, mated products can be locked together, especially when moisture condenses on them and then freezes. Similarly, many materials that are normally pliable at low temperatures become hard and brittle if moisture has been absorbed and subsequently freezes. Condensed moisture acts as a medium for the interaction between many, otherwise relatively inert, materials. Most gases readily dissolve in moisture. The volume increase from water freezing (i.e., converting from a fluid to solid state) can also physically separate components, materials or connections. The chlorine released by PVC plastic, for example, forms hydrochloric acid when combined with moisture.

Although the presence of moisture may cause deterioration, the absence of moisture also may cause reliability problems. The useful properties of many nonmetallic materials such as leather and paper, which become brittle and crack when they are very dry, depend upon an optimum level of moisture. Similarly, fabrics wear out at an increasing rate as moisture levels are lowered, and fibers become dry and brittle. Environmental dust can cause increased wear, friction, and clogged filters due to lack of moisture.

Moisture, in conjunction with other environmental factors, creates difficulties that may not be characteristic of the factors acting alone. For example, abrasive dust and grit, which would otherwise escape, can be trapped by moisture. The permeability (to water vapor) of some plastics (PVC, polystyrene, polyethylene, etc.) is related directly to their temperature. The growth of fungus is enhanced by moisture, as is the galvanic corrosion between dissimilar metals. Some design techniques that can be used separately or combined to counteract the effects of moisture are

- Elimination of moisture traps by providing drainage or air circulation
- Using desiccant products to remove moisture when air circulation or drainage is not possible
- Applying protective coatings
- Providing rounded edges to allow uniform coating of protective material
- Using materials resistant to moisture effects, fungus, corrosion, etc.
- Hermetically sealing components, gaskets, and other sealing products
- Impregnating or encapsulating materials with moisture-resistant waxes, plastics, or varnishes
- Separation of dissimilar metals or materials that might combine or react in the presence of moisture or of components that might damage protective coatings.

The design team also must consider possible adverse effects caused by specific methods of protection. Hermetic sealing, gaskets, protective coatings, etc. may, for example, aggravate moisture difficulties by sealing moisture inside or contributing to condensation. The gasket materials must be evaluated carefully for outgassing of corrosive volatiles or for incompatibility with adjoining surfaces or protective coatings.

Sand and Dust Protection

In addition to the obvious effect of reduced visibility, sand and dust can degrade a product by abrasion leading to increased wear, friction causing both increased wear and heat, and clogging of filters, small apertures, and delicate products. Thus, products having moving parts require particular care when designing for sand and dust protection. Sand and dust will abrade optical surfaces, either by impact when being carried by air or by physical abrasion when the surfaces are improperly wiped during cleaning. Dust accumulations have an affinity for moisture and when combined may lead to corrosion or the growth of fungus.

In relatively dry regions, such as deserts, fine particles of dust and sand can readily be agitated into suspension in the air, where they may persist for many hours, sometimes reaching heights of several thousand feet. Thus, even though there is virtually no wind present, the speeds of vehicles or vehicle-transport product through these dust clouds can also cause surface abrasion by impact.

Although dust commonly is considered to be fine, dry particles of earth, it also may include minute particles of metals, combustion products, and solid chemical contaminants. These other forms may provide direct corrosion or fungal effects on products, because this dust may be alkaline, acidic, or microbiological.

When products require air circulation for cooling or removing moisture, the question is not whether to allow dust to enter, but rather how much or what size dust can be tolerated. The problem becomes one of filtering the air to remove dust particles above a specific nominal size. The nature of filters, however, is such that for a given working filter area, as the ability of the filter to stop increasingly smaller dust particles is increased, the flow of air or other fluid through the filter is decreased. Therefore, the filter surface area either must be increased, the flow of fluid through the filter decreased, or the allowable particle size increased (i.e., invariably, there must be a compromise). Interestingly enough, for aircraft engines, the amount of wear is proportional to the weight of ingested dust, but inversely proportional to dust size.

Sand and dust protection must be planned in conjunction with protective measures against other environmental factors. For example, it is not practical to specify a protective coating against moisture if sand and dust will be present, unless the coating is carefully chosen to resist abrasion and erosion or is self-healing.

Explosion Control

Protection against explosion is both a safety and reliability problem. An item that randomly exhibits explosive tendencies is one that has undesirable design characteristics and spectacular failure modes. This type of functional termination, therefore, requires extreme care in design and reliability analyses.

Explosion protection planning must be directed to three categories (not necessarily mutually exclusive) of products:

- Items containing materials susceptible to explosion
- Components located near enough to cause the explosive items to explode
- Product that might be damaged or rendered temporarily inoperative by overpressure, flying debris, or heat from an explosion

The first category includes products containing flammable gases or liquids, suspensions of dust in the air, compounds that spontaneously decompose in certain environments, product containing or subjected to high or low extremes of pressure (includes implosions), or any other products capable of creating an explosive reaction. Keep in mind that even basically inert materials such as glass or metals can explode when subjected to rapid environmental changes or extremes such as temperature or stress.

The second category includes many variations on methods for providing an energy pulse, a catalyst, or a specific condition that might trigger an explosion. A nonexplosive component, for example, could create a corrosive atmosphere, mechanical puncture, or frictional wear on the side of a vessel containing a high-pressure and thereby cause the container to explode.

The third category is important because a potentially explosive product (such as a high-pressure air tank) can be damaged or made to explode from another explosion. Thus, some reasoning must be applied when considering products not defined by the first two categories. From a practical standpoint, explosion protection for items in the third category should be directed to product that might possibly be near explosions.

The possibility of an explosive atmosphere leaking or circulating into other product compartments must also be recognized. Lead-acid batteries, for example, create hydrogen gas that, if confined or leaked into a small enclosure, could be exploded by electrical arcing from motor brushes, by sparks from metallic impacts, or by exhaust gases. Explosive environments, such as dust-laden air, might be circulated by air distribution products. Dust from common ingredients such as wheat flour has been the source of massive, catastrophic explosions.

Explosion protection and safety are very important for design and reliability evaluations and must be closely coordinated and controlled. Just as a safe product is not necessarily reliable, neither is a reliable product necessarily safe; but the two can be compatible.

Electromagnetic Radiation Control

Protection against the effect of electromagnetic radiation has become a sophisticated engineering field of electromagnetic compatibility design. The radiation environment in space near the earth is composed primarily of Van Allen, auroral, solar flare, and cosmic phenomena. Of lesser importance are solar wind, thermal energy atoms in space, neutrons, naturally occurring radon gas, albedo protons, plasma bremsstrahlung, and man-made nuclear sources. In the electromagnetic spectrum are gamma rays, X-rays, ultraviolet, and Lyman-alpha radiation. Damage near the surface of the earth is caused by the electromagnetic radiation in the wavelength range from approximately 0.15 to 5 m. This range includes the longer ultraviolet rays, visible light, and up to about the midpoint of the infrared band. The most direct approach to protection is to avoid the limited region in which high radiation levels are found. When exposure cannot be avoided, shielding and filtering are important protective measures. In other cases, material design changes or operating procedural changes must be instituted in order to provide protection.

High Vacuum Control

In a high vacuum, materials with a high vapor pressure will sublimate or evaporate rapidly, particularly at elevated temperatures. In some plastics, the loss of plasticizer by evaporation will cause cracking, shrinking, or increased brittleness. Metals such as magnesium, which would normally evaporate rapidly (1 g/cm^2/year at 250°C), can be protected by inorganic coatings with low vapor pressures.

In a high vacuum, adjoining solid surfaces can become cold-welded after losing adsorbed gases. Some form of lubrication is therefore necessary. Conventional oils and greases evaporate quickly. Graphite becomes unsatisfactory (actually an abrasive) because of the loss of absorbed water. However, thin films of soft metals, such as lead, silver, or gold, are effective lubricants in a high vacuum. Thin films of molybdenum disulfide are often sprayed over chrome or nickel plating, forming easily sheared layers. The film also releases sulfur at interfaces during sliding, performing the same function as water vapor does for graphite.

Human Factors and Operability

Humans are active participants in the operating of many products, and can be traded as an external "stress." Consequently, the interaction of humans with products must be weighed against safety, reliability, maintainability, and other product parameters to assess product reliability, maintainability time and performance, system and subsystem safety analyses, and specific human engineering design criteria. For convenience and clarity, four types of human interactions with a product are identified:

- Design and production of a product
- Operators and repairers as mechanical elements (human engineering)
- Operators and repairers as decision elements (human performance reliability)
- Bystanders (this classification is not considered further because it is largely a safety matter, unless they consciously or inadvertently operate or affect the operation of a product)

Designing for Operability

While product design teams, planners, and managers would hope to have well-above-average people in every position associated with product operation, product design must accommodate the realities of the product's life cycle use. The complexity of the product that is presented to the operator, the array of components, including ancillary product, cable connectors, patch panels, switches, knobs, controls, panel markings, meters, oscilloscopes, horns, bells, panel lights, etc., must be of concern in design. The various components comprising the product should be clearly labeled for easy identification. Those items that must be manipulated in order to connect the product (cable connectors, patch panels, switches) should be arranged in a simple and logical order and should be plainly marked. Typical constraints are that

- An operator should be within the physical capabilities of the complete range of potential operators.
- A person should not be required to do something that his or her coordination will not allow him or her to do.
- In times of psychological stress, people cannot easily use, read, and respond to controls and displays.

Mock-ups under realistic conditions are very helpful in uncovering potential problems early in the design process. For example, if a product must be used at night in extremely cold weather, have a person try to use it in a freezing, poorly lit room for several hours.

Designing for Maintainability

Few operational products can be perfectly reliable while meeting other product trade-offs such as rust. Maintenance can thus be an important consideration in the long-term effectiveness of a product.

Maintainability is the probability that, when a specified maintenance action is initiated, a failed product will be restored to operable conditions in a specified downtime. Thus, design features that will expedite maintenance will enhance maintainability. Designing for maintainability means inclusion in the design of those features that can be conceived to assist the maintenance technician. Specific features include the degree of accessibility for product replacement, facilities for fault isolation, special tools or test-product requirements, the level of servicing skills required, servicing documentation requirements, and spare-part stocking requirements.

Critical rating factors include grouping of components by electrical function, use of integral fault indication for basic modules; components or functional assemblies removable without interruption of permanent electrical connections; elimination of tool requirements for mechanical disassembly; direct access to removable assemblies; products commonality; and identification of replaceable components.

In checking out a product, the maintenance technician must often also operate it. Therefore, the design considerations relating to operability are, in general, also applicable to maintainability. In addition, many design considerations relating to maintenance are more complex than those relating to operation.

The design team needs to consider how the product actually will be repaired in the field, perhaps under the pressures of understaffed maintenance crews, many of whom are inexperienced, or by field service personnel with limited knowledge about the product. The design team must always keep in mind that a product may be used and repaired by people who have other things in mind than "babying" the product. The design team must also realize the difference between what people will probably do and what the design team thinks they ought to do.

The design team, in acknowledging that a product could fail if not maintained, should provide means for ease of maintenance, ease of removal of a failed unit, trouble shooting, access to the failed unit, and repair or replacement. Such means, in addition to improving maintainability, will also improve reliability through the averting of subsequent failure due to human errors during maintenance. Many design details are important to the maintenance technician. A list of "Do's" and "Don'ts" in designing for maintainability is presented in Table 11.6.3.

TABLE 11.6.3 Warning to Design Teams: Some Common Design Errors Affecting Maintainability

Don't place products or maintenance structures (e.g., oil filter) where they cannot be removed without removal of the whole unit from its case or without first removing other products
Don't put an adjustment out of arm's reach
Don't neglect to provide enough room for the technician to get his or her gloved hand into the unit to make an adjustment
Don't screw subassemblies together in such a way that the maintenance technician cannot tell which screw holds what
Don't use chassis and cover plates that fall when the last screw is removed
Don't make sockets and connectors for modules of the same configuration so that the wrong unit can be installed
Don't provide access doors with numerous small screws or attachments
Don't use air filters that must be replaced frequently; don't place these filters so that it is necessary to shut down power and disassemble the product to reach them
Don't omit the guide from a screwdriver adjustment, so that while the technician is adjusting and watching a meter, the screwdriver slips out of the slot
Don't design frequent failure or highly adverse impact failure items in least accessible locations
Don't unnecessarily subject nonwear components to failure stress caused by maintenance actions

The Design Team

During the entire period of design, reliability should be continuously monitored by the design team. The membership of the design team and the technical matters requiring their attention are shown in Table 11.6.4. A generic guiding list is given in Table 11.6.5.

TABLE 11.6.4 Design Team

Members	Technical Considerations
Project engineer	Products lists and application
Electrical, mechanical, chemical, manufacturing, and design representations	Tolerance studies
Management representatives	Environmental and operational effects
Maintenance and logistics representatives	Drift, aging, and end-of-life parameters
User community representatives	Regression or worst-case analysis
	Reliability analysis
	Trade-off studies
	Maintenance factors
	Test data
	Availability and affordability analysis

TABLE 11.6.5 Design Reliability Check List Item

Are the requirements for performance, application, environment, and maintainability and reliability established for each product, interface, and structure?
Are the best available methods for reducing the adverse effects of operational environments on critical structures being utilized?
Have normal modes of failure and the magnitude of each mode for each component or critical product have been identified as to root cause?
Has shelf life of products chosen for final design been determined?
Have limited-life products been identified and inspection and replacement requirements specified?
Have critical products that require special procurement, testing, and handling been identified?
Are effective safety factors being used in the application of products, interfaces, and structures?
Have studies been made considering variability and degradation of parameters of products and structures?
Have all vital adjustments been classified as to factory, preoperational, or operator types?
Have adjustments been minimized?
Have stability requirements of all products and structures associated with each adjustment been established?
Are similar plugs and connectors adequately protected against insertion in wrong socket?
Are malfunction-indicating products being used extensively?
Are self-monitoring or self-calibration products installed in major products where possible?
Are mechanical support structures adequate?
Is there a concentrated effort to make the developmental model as near to the production model as possible?
Have packaging and mechanical layout been designed to facilitate maintenance and to reduce maintenance costs and downtime?

Summary

When a product is being designed, it is assumed that the required investment will be justified according to how well the product performs its intended function over time. This assumption cannot be justified when a product fails to perform upon demand or fails to perform repeatedly. It is not enough to show that a product can conduct a function but that it can do so repeatedly when needed by the product user.

The design of any product involves trade-offs, including, but not limited to, performance capability, size, weight cost, product maintenance activities, and other factors, depending upon the intended use. In cases where human life is at risk, reliability issues play a major role in design. However, it is equally important to ask how large can a safety factor be for a critical situation such as a spacecraft, where human life might be in jeopardy, yet weight is a governing element.

The demand for better performance over time, coupled with higher-life cycle costs and stricter legal liabilities, has made product reliability of great importance. As the attitude toward production of engineering products has changed, reliability has established itself as one of the key elements when designing and manufacturing a product. However, the application of reliability principles in the product design and manufacturing processes has not always kept pace with the evolution of highly complex and dynamic engineering products. The design team must understand reliability theory and techniques, in conjunction

with design and manufacturing processes as well as the scenario for use of the product. The goal is to provide a scientific basis for design decisions considering product effectiveness requirements and the scenario for use, create a product design that will satisfy those requirements, and document those design decisions for both the hardware product and the recommended support product for sustaining product effectiveness during the life of the product.

11.7 Design of Manufacturing Systems and Processes

Leonard D. Albano

Design of Manufacturing Systems

Section 11.6 provides strategies for the design of products that meet the customer's needs, based on findings derived from market studies and product research and development. The success of such designs depends on the enterprise's ability to manufacture it, without compromising product performance or incurring noncompetitive production costs. Thus, the design of a manufacturing system must be done with a clear understanding of the functional requirements and physical design parameters for a product and an appreciation for the business goals and constraints.

The structure of a manufacturing system is hierarchical. At the highest level, there are two distinct subsystems: the *direct manufacturing operations* and the *indirect overhead functions*. The direct manufacturing operations consist of the employees and equipment needed to convert the input resource materials into the final desired products. The indirect overhead functions refer to the people, vendors, and capital that support and supervise the direct operations. At the lowest level, the manufacturing system is defined by many basic manufacturing operations, such as metal cutting and plastic forming, that are used to create specific part types (see Chapter 13).

Manufacturing systems can be classified in terms of the volume and variety of products produced. One possible classification scheme is as follows:

1. *Continuous flow processes*: high volume production of a single product type, such as sugar and oil refineries
2. *Assembly lines*: high volume production of a limited product variety; relies on standardized components and interchangeable parts; common system for automotive industry
3. *Batch processing*: relatively low volume production of multiple product types; concepts of group technology used to batch workpieces to increase efficiency of process routing; example applications include the manufacture of aircraft and heavy construction equipment
4. *Job shop*: low volume production of a variety of nonstandard parts; focuses on customized products; early reliance on craftsmen has shifted to cellular manufacturing systems in order to maximize flexibility and throughput

The design of a manufacturing system may be defined in terms of the concept of domains, as presented in Section 11.3, and the integration of three or more design fields; they are product design, organization design, and software design.

1. *Product design*: The design of the direct manufacturing operations is based on mapping the product's design parameters in the physical domain to process variables in the process domain.
2. *Organizational design*: The human and financial resources, which contribute to both direct operations and the indirect overhead, are provided to satisfy the goals and structure of the business organization.
3. *Software design*: Computer-based tools are easily available to control production and inventory levels, support information flow for decision-making, and automate manufacturing operations.

Several important advances in manufacturing can be identified from the above design model. *Concurrent engineering* refers to the integration of product design and manufacturing system design. This approach involves continuous mapping from the functional domain to the physical domain to the process domain. If the organizational structure changes to adapt to new customer needs, the single enterprise may be replaced by a highly flexible, virtual enterprise that pools resources from several qualified organizations for rapid response. This virtual enterprise corresponds to *agile manufacturing*. With a rationalized approach to system design, the role of the computers, information technology, robots, etc. can be better understood (see Chapter 13). Mitchell (1991) defines *computer-integrated manufacturing*

as "the use of computers to achieve an integrated flow of manufacturing activities, based on integrated information flow that links together all organizational activities."

A designer may develop many different manufacturing systems that are technically feasible. The designer must have some basis for the selection of a system and the layout of the various elements that comprise it. The evaluation of economic feasibility is one criterion for decision-making. Economic feasibility depends on the planned production volume, fixed resources, total production costs, projected revenue stream, and the desired income. The latter case involves consideration of the investment strategy. Because of the interrelations among the system performance and the economic factors, the suggested design procedure is to consider economic feasibility as a design constraint. The ideal to be achieved is one involving the design and production of reliable products that satisfy the customer's needs, while providing the desired profit and return on investment. See Chapter 13 for information on manufacturing system and enterprise management.

Manufacturing Process Design

The principal objective of manufacturing process design is to produce an organized plan for converting raw materials into useful products. It involves the selection of timely and cost-effective methods to produce a product without compromising quality and reliability. As part of the product development process, good manufacturing process design contributes to the industrial competitiveness of a manufacturing enterprise, while poor process design contributes to cost and schedule overruns and the delivery of products that fail to meet some or all of the customers' needs.

Manufacturing process planning often requires the consideration of several manufacturing processes for a specific part. In addition to considering manufacturing costs and production time, rational planning should also involve evaluation of how well a particular process satisfies the design requirements, which are delineated within the engineering drawings and reference specifications. The suitability of a given process may be based on many factors, such as

1. The dimensions and geometric precision that can be obtained
2. The surface roughness that can be attained
3. The changes that may be produced in material properties and part performance

Unfortunately, there is seldom much time to conduct an exhaustive laboratory or computer-based study and evaluation of all solution alternatives. A systematic approach to design that provides fundamental principles for decision-making would facilitate process design while enabling the designer to consider all important factors. Section 11.4, for instance, describes the concept of axiomatic design as a scientific framework for design and decision-making.

Metals Processing

Metal shapes and components can be produced by various casting, forming, and metal-removal processes (see Chapter 13). In the case of metal removal, process planning involves selecting and sequencing the appropriate machine tools and operations so as to convert a solid piece part from its initial shape to a final, desired geometry. This involves matching machine and tool data to the design requirements, subject to certain constraints imposed by the manufacturing organization and facilities. In practice, it consists of five or more steps:

1. Interpretation of the engineering drawing and reference specifications
2. Selection of machining operations to form the specified surfaces
3. Selection of machine tools for each machining operation
4. Selection of jigs and fixtures to guide or facilitate machining
5. Sequencing the machining operations

The initial material shape may be one of any number of geometries, ranging from simple bar stock to a complex casting. Basic machine tool operations are discussed in Chapter 13, and they include shaping, planing, turning, grinding, sawing, and drilling.

Process planning is performed by either experienced planners or automated software systems. There are at least two major difficulties associated with relying solely on human planners. First, they often rely on intuition gained through experience, and this experience requires a significant period of time to accumulate. Consequently, the number of truly skilled planners in any given industry is limited from generation to generation. Second, the capacity of a manufacturing enterprise to adopt new processes and new systems is limited by the knowledge background and creativity of the process planner. In order to address these problems, computer-aided process planning (CAPP) systems (see Chapter 13) have been developed.

The two fundamental strategies for CAPP are the *variant approach* and the *generative approach*. The variant approach is closely related to the automation of manual process planning techniques, i.e., the process plan for a specific part is created by computer-based retrieval of an existing process plan from a data base. Thus, the role of the computer in a variant system is primarily to manage a data base of process knowledge. Generative systems synthesize manufacturing and planning knowledge to generate specific process plans for a specific part. The reasoning mechanism for generative systems varies from algorithms to decision trees to artificial intelligence techniques. The variant approach is the basis for the overwhelming majority of computer codes for process planning because of a number of practical computational advantages. Nevertheless, several generative systems have been developed by industry, and this area will continue to be the focus of research and development, especially for large companies that can support the considerable investment needed for software development and hardware procurement.

Polymer Processing

There are basically two major categories of plastics: *thermoplastics* and *thermosetting resins* (see Chapter 12). Each group contains thousands of specific formulations with a wide range of mechanical, physical, and chemical properties. The scope of applications includes the automotive, houseware, and packaging industries. For example, government regulations pertaining to energy conservation have forced the automotive manufacturers to reduce the weight of automobiles. As a result, lightweight plastics have replaced traditional steel bumpers and outer panels while fulfilling specific performance requirements for mechanical strength, thermal resistance, and environmental durability.

To design with plastics, the product engineer selects an appropriate plastic material by considering a number of technical and economic factors in concert with specific data compiled in manufacturer's literature and encyclopedic data sources, such as the *Modern Plastics Encyclopedia*. To select the appropriate manufacturing process, the process engineer must understand the impact of the processing techniques on the material structure and, ultimately, the desired technical performance, e.g., mechanical strength and physical properties. Although a considerable number of plastic material alternatives are available, the variety of forming operations is limited. The basic set of processes includes compression molding, transfer molding, injection molding, extrusion, cold molding, thermoforming, and blow molding. The reader is referred to Chapter 13 for specific information on the production of thermoplastics and thermosetting resins.

Because of the interrelations between processing techniques and material structure, the axiomatic approach to design (see Section 11.4) provides helpful information for concurrent engineering. In this context, the use of plastic parts involves the successive mapping of engineering properties in the functional domain, to a plastic material structure in the physical domain, to processing techniques in the process domain. This mapping can be written in the form:

$$\{\mathbf{FRs}\} = [\mathbf{A}]\{\mathbf{DPs}\} \tag{11.7.1}$$

$$\{\mathbf{DPs}\} = [\mathbf{B}]\{\mathbf{PVs}\} \tag{11.7.2}$$

in which the desired material properties are contained in the vector of functional requirements {**FRs**}, the material structure is described in {**DPs**}, and the manufacturing process is defined by {**PVs**}. Equations (11.7.1) and (11.7.2) display the general structure of the equations for materials design and process planning. The design matrices [**A**] and [**B**] are used to determine whether the proposed mapping satisfies the Independence Axiom: they must be either diagonal or triangular to allow for the manufacture of a plastic part with the desired properties (see Section 11.4.1, "The First Axiom: The Independence Axiom"). The production of microcellular plastics of MIT (Suh, 1990) is an example that illustrates design of a manufacturing process to yield the desired polymer structure.

11.8 Precision Machine Design

Alexander Slocum

Any machine, from a machine tool to a photocopier to a camera, is an assembly of components that are designed to work together to achieve a desired level of performance. Each machine has a budget for cost and performance, and achieving the best balance between the two, regardless of the function of the machine, is the essence of *precision machine design.*

In order to be able to effectively develop a design for a precision machine, the design engineer must simultaneously envision in his/her head the functions the machine must perform (e.g., milling, turning, or grinding) alongside a pictorial library of component technologies (e.g., bearings, actuators, and sensors), generic machine configurations (e.g., cast or welded articulated and/or prismatic structures), analysis techniques (e.g., back-of-the-envelope and finite element methods), and manufacturing methods (e.g., machine, hand, or replication finished). In addition, the machine design engineer must be aware of the basic issues faced by the sensor and electronics engineer, the manufacturing engineer, the analyst, and the controls engineer. Only by a simultaneous consideration of all design factors can a viable and effective design be rapidly converged upon. Awareness of current technological limitations *in all fields* can also help a design engineer to develop new processes, machines, and/or components.

The goal of the precision machine design engineer is to make all the components of a precision machine in proper proportion of each other, both in relation to their physical size and the capabilities of the servocontroller and power systems. If a component is oversized, it may increase the cost of the machine while performance may not be increased. If a component is too small, the rest of the machine's components may never reach their potential and machine performance will suffer. Note that size is a function of static and dynamic qualifiers. Components that behave well statically do not necessarily have good dynamic performance.

In today's world where rapid time to market is essential, the design of quality precision machines depends on the ability of the design and the manufacturing engineers to predict how the machine will perform before it is built. Kinematics of a machine are easily tested for gross functionality using mechanism synthesis and analysis software. Wear rates, fatigue, and corrosion are often difficult to predict and control, but for the most part are understood problems in the context of machine tool design. Hence perhaps the most important factors affecting the quality of a machine are the accuracy, repeatability, and resolution of its components and the manner in which they are combined. These factors are critical because they affect every one of the parts that will be manufactured using the machine. Accordingly, minimizing machine cost and maximizing machine quality mandate predictability of accuracy, repeatability, and resolution. As noted by Donaldson*: "A basic finding from our experience in dealing with machining accuracy is that machine tools are deterministic. By this we mean that machine tool errors obey cause-and-effect relationships, and do not vary randomly for no reason."

In this section, the design of precision machines will be studied by following a path of analysis of the overall system's potential for accuracy, as well as applying this perspective to the understanding of the operation of the components that make up a precision machine:

- Analysis of errors in a precision machine
- Structures
- Bearings

It is important to realize that the design of precision machines is like any other endeavor. The better one understands the fundamental principles and concepts, the better one will be able to integrate components into a precision system. In the light of understanding the science of design, one must always consider practical applied philosophy. A few broad design guidelines for the precision machine designer include:

* Donaldson, R. November 1972. The deterministic approach to machining accuracy. *SME Fabricat. Technol. Symp.* Golden, CO (UCRL Preprint 74243).

- Subject all decisions to an "is there a better way" value analysis based on system considerations.
- Always picture in your mind how the system will be manufactured, assembled, used, and maintained.
- Minimize the number of parts in an assembly and minimize their complexity.
- Maximize the number of instances where reference surfaces and self-locating "snap together" parts can be used.
- Whenever possible, take advantage of kinematic design principles.
- Utilize new materials and technologies to their fullest potential.
- Read continuously and familiarize yourself with technologies in many areas.
- Observe continuously and familiarize yourself with products in many areas.

Analysis of Errors in a Precision Machine

The first step in the design of a precision machine is to understand the basic definitions and principles that characterize and govern the design of all precision machines. Some of the more basic definitions and principles include

- The principle of reversal
- Modeling the errors in a machine
- Determination of the relative errors between the tool and the workpiece
- Linear motion system errors
- Estimating position errors from modular bearing catalog data
- Axis of rotation errors
- Error budgets

Accuracy, Repeatability, and Resolution

There are three basic definitions to remember with respect to how well a machine tool can position its axes: *accuracy, repeatability (precision),* and *resolution. Accuracy* is the maximum translational or rotational error between any two points in the machine's work volume. *Repeatability (precision)* is the error between a number of successive attempts to move the machine to the same position, or the ability of the machine to make the same motion over and over. Bidirectional repeatability is the repeatability achieved when the point is approached from two different directions. This includes the effect of backlash in a leadscrew. Accuracy is often defined in terms of the mean, and repeatability in terms of the standard deviation. For a set of N data points with a normal (Gaussian) distribution, the mean x_{mean} and the standard deviation σ are defined as

$$x_{\text{mean}} = \frac{1}{N}\sum_{i=1}^{N} x_i \qquad \sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left(x_i - x_{\text{mean}}\right)^2} \tag{11.8.1}$$

The standard deviation is used in the determination of the probability of occurrence of an event in a system that has a normal distribution. Table 11.8.1 gives the percent chance of a value occurring within a number of standard deviations of its expected value.* One must be very careful not to confuse an offset of the mean with the allowed random variation in a part dimension. For example, precision-molded plastic lenses for cameras have their molds hand finished to make the mean size of lenses produced equal to the nominal size required.

* The equation for the computation of the percent chance was obtained from Drake, A. 1967. *Fundamentals of Applied Probability Theory.* McGraw-Hill, New York. p. 211. Values ϕ (k) were computed using Mathematics™. Another valuable reference to have is Natrella, M. *Experimental Statistics,* NBS Handbook 91.

TABLE 11.8.1 Chance of a Value Falling within kσ of its Expected Value

k	% chance of occurrence
1.0	68.2689
2.0	95.4500
3.0	99.7300
4.0	99.9937
5.0	99.9999
6.0	100.0000

It is interesting to note, however, Bryan's* observation of the issue of using probabilistic methods to characterize repeatability: "The probabilistic approach to a problem is only a tool to allow us to deal with variables that are too numerous, or expensive to sort out properly by common sense and good metrology." One must not belittle probability, however, for it is a mathematical tool like any other that is available to the design engineer. Required use of this tool, however, might be an indication that it is time to take a closer look at the system and see if the system can be changed to make it deterministic and therefore more controllable. Often the key to repeatability is not within the machine itself, but in isolating the machine from variations in the environment.**

Resolution is the larger of the smallest programmable step or the smallest mechanical step the machine can make during point-to-point motion. Resolution is important because it gives a lower bound on the repeatability. When a machine's repeatable error is mapped, the resolution becomes important if the mapped errors are to be compensated for by other axes.

Amplification of Angular Errors

Perhaps the most overlooked error in machine design is the amplification of an angular error over a distance to create a large translational error at some point in the machine. Mathematically, this error has a magnitude equal to the product of the distance between the point and the rotation source and the sine of the included angle. Hence this type of error can be referred to as a *sine error.* This principle extends to locating bearing surfaces far from the workpiece area of the machine tool.*** Errors in the bearing's motion can be amplified by the distance between the bearing and the workpiece, and can be transmitted to the workpiece. This can result in horizontal and vertical straightness errors and axial position errors. The same is true for the effects of all other types of errors on machine components. A *cosine error*, on the other hand, is the error made when the measurement of the distance between a point and a line is not made along a path orthogonal to the line.

With respect to dimensional measurements. In the late 1800s, Dr. Ernst Abbe noted *"If errors in parallax are to be avoided, the measuring system must be placed coaxially with the axis along which displacement is to be measured on the workpiece."* The Abbe principle can be visualized by comparing measurements made with a dial caliper and a micrometer as shown in Figure 11.8.1. The dial caliper is often used around the shop because it is easy to use, the head slides back and forth to facilitate quick measurement. However, note that the measurement scale is located at the base of the jaws. When a part is measured near the tip of the jaws, the jaws can rock back slightly, owing to their elasticity and imperfections in the sliding jaw's bearing. This causes the caliper to yield a slightly undersize

* Bryan, J. The Power of Deterministic Thinking in Machine Tool Accuracy, 1st Int. Mach. Tool Eng. Conf. November 1984. Tokyo (UCRL Preprint 91531).

** *"In designing an experiment the agents and phenomena to be studied are marked off from all others and regarded as the field of investigation. All others are called disturbing agents. The experiment must be so arranged that the effects of disturbing agents on the phenomena to be investigated are as small as possible."* James C. Maxwell.

*** See Bryan, J.B. 1989. The Abbe principle revisited — an updated interpretation, *Precis. Eng.* 1(3):129–132. An extension of the Abbe principle to this type of situation is referred to as the *Bryan principle*, which is discussed in Section 5.2.1 along with a discussion on where to mount sensors for various types of measurements.

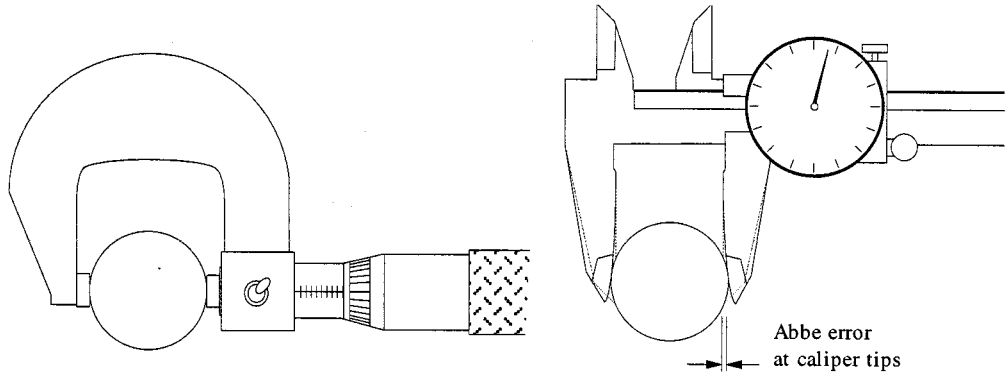

FIGURE 11.8.1 Abbe error illustrated through the use of a dial caliper and a micrometer.

measurement. The micrometer, on the other hand, uses a precision measuring device located in line with the part dimension, so there is no Abbe error. Both instruments are sensitive to how hard the jaws are closed on the part. A micrometer often has a torque limiting adjustment to provide a very repeatable measuring force. It is impossible to overstress the importance of Abbe errors.

The micrometer is more difficult to use and less versatile than the caliper, yet it has greater accuracy because of its more robust structural loop. So it is in the design of precision machines. Often one has to sacrifice ergonomics for performance. The goal, therefore, is to minimize the extent of the sacrifice.

Sensitive Directions

It is important to note that there are *sensitive directions* in a machine, and it is along these directions that the most effort must be expended to minimize errors. For example, as illustrated in Figure 11.8.2 an error motion ε of a tool tangent to the surface of a round part of radius r in a lathe results in a radial error in the workpiece of magnitude ε^2/r, which is much smaller than ε. Sensitive directions can be *fixed*, such as when the tool is stationary and the part is moving (e.g., a lathe), or *rotating*, such as when the tool is rotating and the part is fixed (e.g., a jig borer).

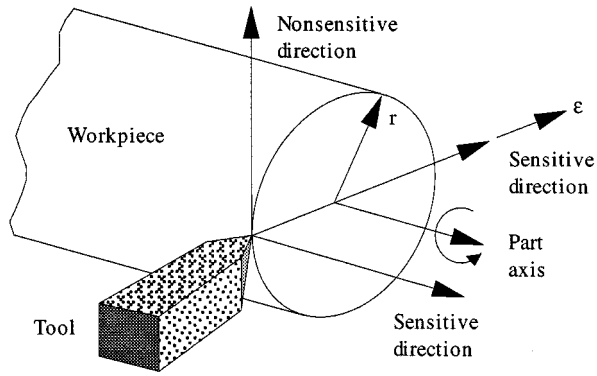

FIGURE 11.8.2 Illustration of sensitive directions.

The Reversal Principle

How were the first accurate machines developed? Machines were first made repeatable, which can be done by paying special detail to surface finish of bearings, prevention of lost motion (e.g., backlash), and by making the forces on the machine repeatable. Once a machine is made repeatable, it can be used to measure the accuracy of another component or machine using the principle of reversal. This is illustrated in Figure 11.8.3.

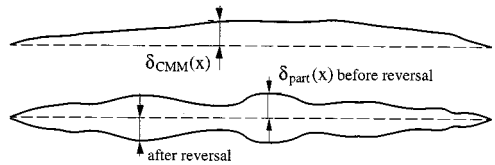

FIGURE 11.8.3 Illustration of the principal of reversal.

The machine is used to measure a part from one side, obtaining a reading of

$$Z_{\text{probe before reversal}}(x) = \delta_{CMM}(x) - \delta_{\text{part}}(x)$$

The part is then turned over, taking care to keep its axial position justified, then the machine is used to remeasure the part, obtaining a reading of

$$Z_{\text{probe after reversal}}(x) = \delta_{CMM}(x) - \delta_{\text{part}}(x)$$

By subtracting the measurements from each other, the repeatable error in the measuring machine is removed:

$$\delta_{\text{part}}(x) = \frac{-Z_{\text{probe before reversal}}(x) + Z_{\text{probe after reversal}}(x)}{2}$$

There are many variations (e.g., for roundness measurements), and the principle shows how repeatability is often the most important characteristic of a precision machine. In fact, the principle can be applied to the design of the machine itself. For example, two bearing rails can be ground side by side, and then placed end to end on a machine. If the carriage that rides on them has the same bearing spacing as the individual rail length, then as the carriage moves on the end-to-end rails, it will not pitch or yaw, it will only have a straightness error. This straightness error can then be more readily compensated for by the motion of an orthogonal axis via an error compensation algorithm in the controller.

Modeling the Errors in a Machine

In order to determine the effects of a component's error on the position of the toolpoint or the workpiece, the spatial relationship between the two must be defined. Figure 11.8.4 illustrates the issue: the tool is connected to the workpiece through the linkage that is the machine. Any errors between the machine's links create error between the tool and the workpiece. The essential goal of precision machine design is to be able to model and predict these errors, so they can be addressed during the design state of the machine.

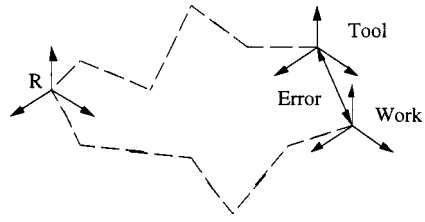

FIGURE 11.8.4 The goal is to be able to model the errors in the machine to predict the error between the tool and the work during the design phase so appropriate action can be taken before the machine is built.

To represent the relative position of a rigid body in three-dimensional space with respect to a given coordinate system, a 4×4 matrix is needed. This matrix represents the coordinate transformation to the reference coordinate system (X_R Y_R Z_R) from that of the rigid body frame (X_n Y_n Z_n), and it is called the *homogeneous transformation matrix* (HTM).* The first three columns of the HTM are direction cosines (unit vectors i, j, k) representing the orientation of the rigid body's X_n, Y_n, and Z_n axes with respect to the reference coordinate frame, and their scale factors are zero. The last column represents the position of the rigid body's coordinate system's origin with respect to the reference coordinate frame. P_s is a scale factor, which is usually set to unity to help avoid confusion. The presuperscript represents the reference frame you want the result to be represented in, and the postsubscript represents the reference frame from which you are transferring:

$$R_{\mathbf{T}_n} = \begin{bmatrix} O_{ix} & O_{iy} & O_{iz} & P_x \\ O_{jx} & O_{jy} & O_{jz} & P_y \\ O_{kx} & O_{ky} & O_{kz} & P_z \\ 0 & 0 & 0 & P_s \end{bmatrix} \tag{11.8.2}$$

Thus, the equivalent coordinates of a point in a coordinate frame n, with respect to a reference frame R, are

$$\begin{bmatrix} X_R \\ Y_R \\ Z_R \\ 1 \end{bmatrix} = R_{\mathbf{T}_n} \begin{bmatrix} X_n \\ Y_n \\ Z_n \\ 1 \end{bmatrix} \tag{11.8.3}$$

For example, if the X_1 Y_1 Z_1 coordinate system is translated by an amount x along the X axis, the HTM that transforms the coordinates of a point in the X_1 Y_1 Z_1 coordinate frame into the XYZ reference frame is

$$XYZ_{\mathbf{T}_{X_1Y_1Z_1}} = \begin{bmatrix} 1 & 0 & 0 & x \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.4}$$

If the X_1 Y_1 Z_1 coordinate system is rotated by an amount θ_x about the X axis, the HTM that transforms the coordinates of a point in the X_1 Y_1 Z_1 coordinate frame into the XYZ frame is

$$XYZ_{\mathbf{T}_{X_1Y_1Z_1}} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x & 0 \\ 0 & \sin\theta_x & \cos\theta_x & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.5}$$

Machine structures can be decomposed into a series of coordinate transformation matrices describing the relative position of each axis and any intermediate coordinate frames that may assist in the modeling

* The HTM representation of structures has existed for many decades. See, for example, Denavit, J. and Hartenberg, R. June 1955. A kinematic notation for lower-pair mechanisms based on matrices. *J. Appl. Mech.* Perhaps the most often referenced work with respect to its application to manufacturing tools is Paul, R. 1981. *Robot Manipulators: Mathematics, Programming, and Control.* MIT Press, Cambridge, MA.

process, starting at the tip and working all the way down to the base reference coordinate system (n = 0). If N rigid bodies are connected in series and the relative HTMs between connecting axes are known, the position of the tip (Nth axis) in terms of the reference coordinate system will be the sequential product of all the HTMs:

$$ {}^{R}\mathbf{T}_{N} = \prod_{m=1}^{N} {}^{m-1}\mathbf{T}_{m} = {}^{0}\mathbf{T}_{1}\,{}^{1}\mathbf{T}_{2}\,{}^{2}\mathbf{T}_{3}\ldots \tag{11.8.6} $$

It can be difficult to determine how a part modeled as a rigid body actually moves; thus care must be taken when evaluating the error terms in the HTMs of systems with multiple contact points. Nonserial link machines (e.g., a four-bar linkage robot) require a customized formulation to account for interaction of the links.

Determination of the Relative Errors Between the Tool and the Workpiece

Ideally, the HTM products (Equation 11.8.6) for the position of the point on the workpiece the tool contacts and the location of the toolpoint with respect to the reference frame will be identical. The relative error HTM $\mathbf{E}_{\text{rel}}$, representing position and orientation errors between the tool and workpiece, is determined for ${}^{R}\mathbf{T}_{\text{work}} = {}^{R}\mathbf{T}_{\text{tool}}\mathbf{E}_{\text{rel}}$:

$$ E_{\text{rel}} = {}^{R}\mathbf{T}_{\text{tool}}^{\;-1}\,{}^{R}\mathbf{T}_{\text{work}} \tag{11.8.7} $$

The relative error HTM is the transformation in the toolpoint coordinate system that must be done to the tool in order to be at the proper position on the workpiece. For implementation of error correction algorithms on numerically controlled machines, as illustrated in Figure 11.8.5 one must consider how the axes will be required to move in order to create the desired motion, specified by Equation 11.8.7 in the tool reference frame. For the general case of a machine with revolute and translational axes (e.g., a five-axis machining center), one would have to use inverse kinematic solutions such as those developed for robot motion path planning. Most machine tools and CMMs have only translational axes, and thus the error correction vector ${}^{R}\mathbf{P}_{\text{correction}}$ with respect to the reference coordinate frame can be obtained from

$$ {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{correction}} = {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{work}} - {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{tool}} \tag{11.8.8} $$

Because of Abbe offsets and angular orientation errors of the axes, ${}^{R}\mathbf{P}_{\text{correction}}$ will not necessarily be equal to the position vector $\mathbf{P}$ component of $\mathbf{E}_{\text{rel}}$. ${}^{R}\mathbf{P}_{\text{correction}}$ does represent the incremental motions the X, Y, and Z axes must make on a Cartesian machine in order to compensate for toolpoint location errors.

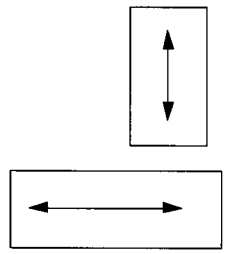

FIGURE 11.8.5 Repeatable error motions in one axis can be mapped and compensated for by motion of an orthogonal axis.

Compensating for errors in a machine can be a good thing; however, electronic compensation can only do so much. One has to start with a good design. The error in a machine can be minimized in general by maximizing the efficiency of the machine's *structural loop*. The structural loop is defined as the structure that joins the tool to the fixture to which the workpiece is attached. During cutting operations, the contact between the tool and workpiece can change the structural loop's characteristics. Maximizing the efficiency of the structural loop generally requires minimizing the path length of the mechanism. As can be seen from Abbe's principle or the HTM analysis method, the shorter the path length, the less the error amplification and the total end point error.

Linear Motion System Errors

Consider the case of an ideal linear motion carriage shown in Figure 11.8.6 with x, y, and z offsets of a, b, and c, respectively, All rigid bodies have three rotational (ε_X, ε_Y, ε_Z) and three translational (δ_X, δ_Y, δ_Z) error components associated with their motion. These errors can be defined as occurring about and along the reference coordinate system's axes, respectively. Often the errors will be a function of the position of the body in the reference frame.

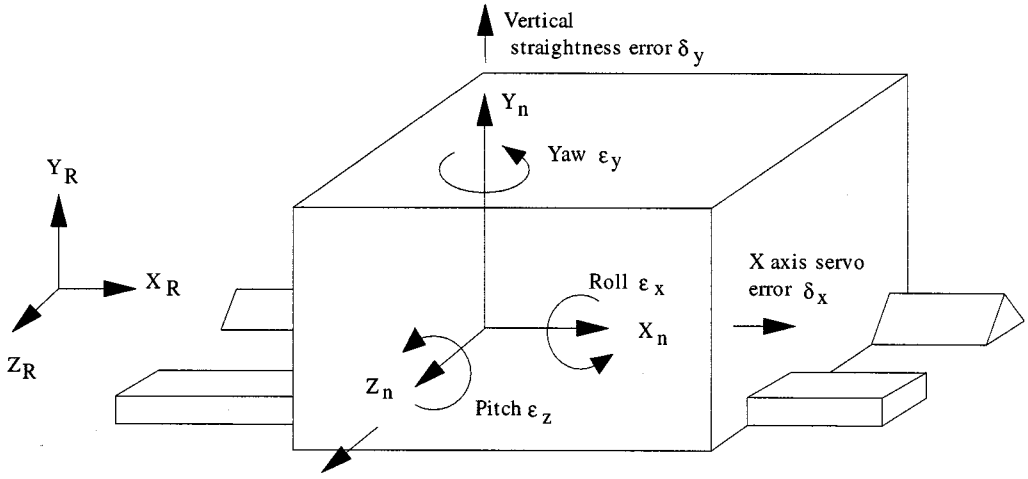

FIGURE 11.8.6 Motion and errors in a single-axis linear motion carriage (prismatic joint).

For the linear carriage, the HTM (see Equation (11.8.2)) that describes the effects of errors on carriage motion can be obtained in the following manner. Observing the right-hand rule, a rotation ε_X, about the X axis (*roll*) causes the tip of the Y-axis vector to move in the positive Z direction by an amount proportional to sin ε_X, and in the negative Y direction by an amount proportional to $1 - \cos \varepsilon_X$. Since the error terms are very small, at most on the order of minutes of arc, small-angle approximations are valid and will be used. Hence the element $o_{ky} = \varepsilon_X$. The roll error ε_X also causes the tip of the Z-axis vector to move in the negative Y direction, so that the element $o_{jz} = -\varepsilon_X$. A rotation ε_Y about the Y axis (*yaw*) causes the tip of the X-axis vector to move in the negative Z direction, so that $o_{kx} = -\varepsilon_Y$, and causes the tip of the Z-axis vector to move in the positive X direction, so $o_{iz} = \varepsilon_Y$. Similarly, a rotation ε_Z about the Z axis (*pitch*) causes the tip of the X-axis vector to move in the positive Y direction, so $o_{jx} = \varepsilon_Z$, and causes the tip of the Y axis vector to move in the negative X direction so that $o_{iy} = -\varepsilon_Z$. Translational errors δ_X, δ_Y, and δ_Z directly affect their respective axes, but care must be taken in defining them. Having neglected second-order terms, the HTM for the linear motion carriage with errors is

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} 1 & -\varepsilon_Z & \varepsilon_Y & a+\delta_X \\ \varepsilon_Z & 1 & -\varepsilon_X & b+\delta_Y \\ -\varepsilon_Y & \varepsilon_X & 1 & c+\delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.9} $$

Estimating Position Errors from Modular Bearing Catalog Data

The HTM method is powerful, but from where does one get estimates of the errors? For the linear motion system, the HTM assumes that the errors occur at the center of stiffness of the carriage. The *center of stiffness* is the point at which, when a force is applied to the system, no net angular motion results. For a symmetrical system, it is located at the center of the system. For other systems, the center of stiffness can be found in the same way that the *center of mass* is found:

$$ x_{\text{center of stiffness}} = \frac{\sum_{i=1}^{N} K_i x_i}{\sum_{i=1}^{N} K_i} \tag{11.8.10} $$

Indeed, the *center of friction* can also be defined, and when locating the point, where the actuation force of an axis is to be applied, one can see that ideally, the center of mass, the center of stiffness, and the center of friction should all be coincident. In the best case, they will also be concurrent with external loads applied to an axis.

Once the center of stiffness has been found, the error motions about the center of stiffness can be determined using the dimensions of the system and estimates for the errors in individual bearing elements (e.g., linear ball bearing catalogs often include data on the vertical and horizontal error motions that will occur between the bearing block and the rail). Figure 11.8.7 illustrates the model of a linear motion system supported by modular bearings.

It can be assumed that the translational errors are based on the average of the straightness errors experienced by the bearing blocks:

$$ \begin{aligned} \delta_x &= \delta_{\text{servo}} \\ \delta_y &= \frac{\delta_{y1}+\delta_{y2}+\delta_{y3}+\delta_{y4}}{4} \\ \delta_z &= \frac{\delta_{z1}+\delta_{z2}+\delta_{z3}+\delta_{z4}}{4} \end{aligned} \tag{11.8.11} $$

The angular errors are based on the differences in the average straightness errors experienced by pairs of bearing blocks acting across the carriage:

$$ \begin{aligned} \varepsilon_x &= \frac{\frac{\left(\delta_{y2}+\delta_{y3}\right)}{2} - \frac{\left(\delta_{y1}+\delta_{y4}\right)}{2}}{W} \\ \varepsilon_y &= \frac{\frac{\left(\delta_{z3}+\delta_{z4}\right)}{2} - \frac{\left(\delta_{z1}+\delta_{z2}\right)}{2}}{L} \\ \varepsilon_z &= \frac{\frac{\left(\delta_{y1}+\delta_{y2}\right)}{2} - \frac{\left(\delta_{y3}+\delta_{y4}\right)}{2}}{L} \end{aligned} \tag{11.8.12} $$

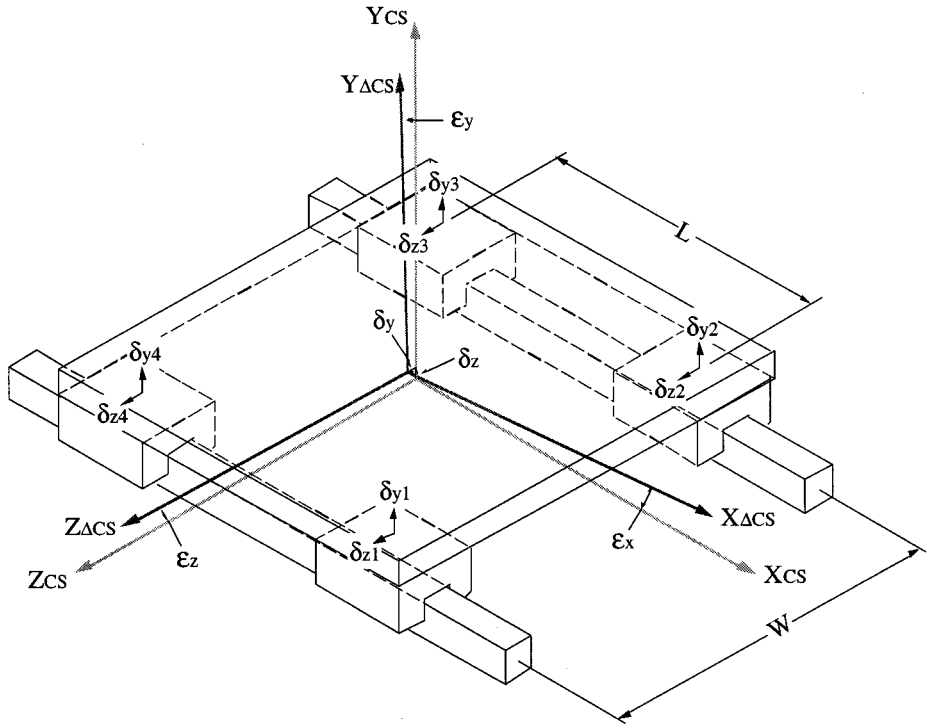

FIGURE 11.8.7 A linear motion system will have errors that act about the center of stiffness of the system.

When the bearing blocks are moving in unison to create the straightness error, they would not be creating the angular errors. However, to be conservative when modeling the errors in a machine, since it cannot be known which errors are going to occur, one should simultaneously incorporate both translational and angular error estimates into the error model of the machine.

Once a machine has been built, the error motions would be measured and analyzed to verify whether the machine meets its performance criteria. This is also a good time to evaluate the effectiveness of the model. For example, Figure 11.8.8 shows the straightness measurements for a linear motion axis supported by cam followers running on a vee and a flat. It is very difficult to tell what the source of the error is. Figure 11.8.9 shows a Fast Fourier Transform of the straightness data. Note that the FFT is plotted in terms of amplitude and wavelength (as opposed to the more commonly seen power and frequency plots used by electrical engineers). It can help identify the dominant sources of error, so design attention can be properly allocated. It can also show, as in this case, that the errors from a number of different sources are of similar magnitude, so if greater performance is required, one should probably seek an alternate design.

Axis of Rotation Errors*

Consider the rotating body shown in Figure 11.8.10. Ideally, the body rotates about its axis of rotation without any errors; however, in reality the axis of rotation revolves around an axis of the reference coordinate frame with radial errors δ_X and δ_Y, an axial error δ_Z, and tilt errors ε_X and ε_Y. All of these errors may be a function of the rotation angle θ_z. For a point in the spindle coordinate frame $X_nY_nZ_n$,

* Definitions used in this section were condensed from those provided in *Axis of Rotation: Methods for Specifying and Testing.* ANSI Standard B89.3.4M-1985, American Society of Mechanical Engineers, United Engineering Center, 345 East 47th Street, New York, NY 10017. This document also contains appendices which describe measurement techniques and other useful topics pertaining to axes of rotation.

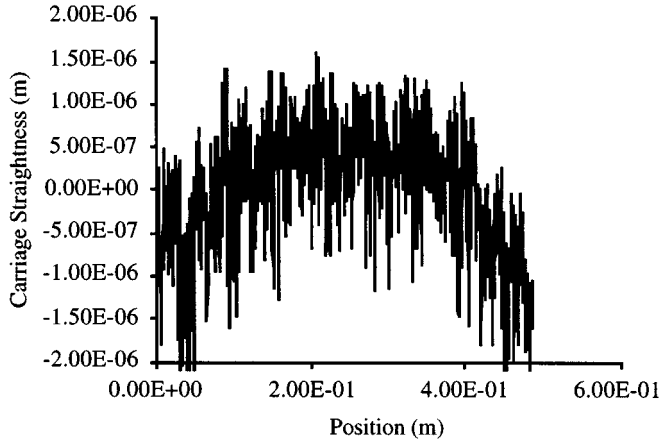

FIGURE 11.8.8 Strightness of a linear motion system.

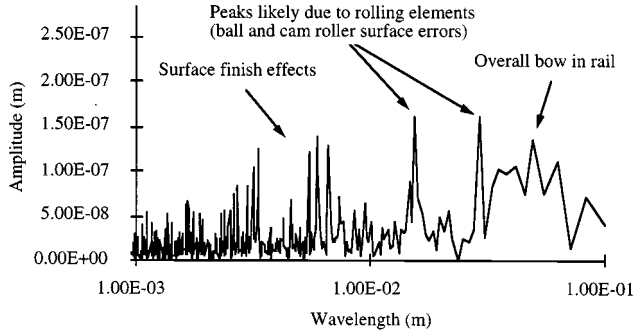

FIGURE 11.8.9 Fourier transform of the straightness of a linear motion system.

one would first use the rotation angle θ_z to transform the point roughly the reference frame. Then, since the other error motions are small, the order of multiplication of their HTMs would not be critical.

With the operators S = sine and C = cosine, the general result is

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} C\varepsilon_Y C\theta_Z & -C\varepsilon_Y S\theta_Z & S\varepsilon_Y & \delta_X \\ S\varepsilon_X S\varepsilon_Y C\theta_Z & C\varepsilon_X C\theta_Z - S\varepsilon_X S\varepsilon_Y S\theta_Z & -S\varepsilon_X C\varepsilon_Y & \delta_Y \\ -C\varepsilon_X S\varepsilon_Y C\theta_Z + S\varepsilon_X S\theta_Z & S\varepsilon_X C\theta_Z + C\varepsilon_X S\varepsilon_Y S\theta_Z & C\varepsilon_X C\varepsilon_Y & \delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.13} $$

Note that this general result may also be used for the case of a linear motion carriage if ε_Z is substituted for θ_Z. Most often, second-order terms such as $\varepsilon_X\varepsilon_Y$ are negligible and small-angle approximations (i.e., cos ε = 1, sin ε = ε) can be used, which leads to

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} \cos\theta_Z & -\sin\theta_Z & \varepsilon_Y & \delta_X \\ \sin\theta_Z & \cos\theta_Z & -\varepsilon_X & \delta_Y \\ \varepsilon_X \sin\theta_Z - \varepsilon_Y \cos\theta_Z & \varepsilon_X \cos\theta_Z + \varepsilon_Y \sin\theta_Z & 1 & \delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.14} $$

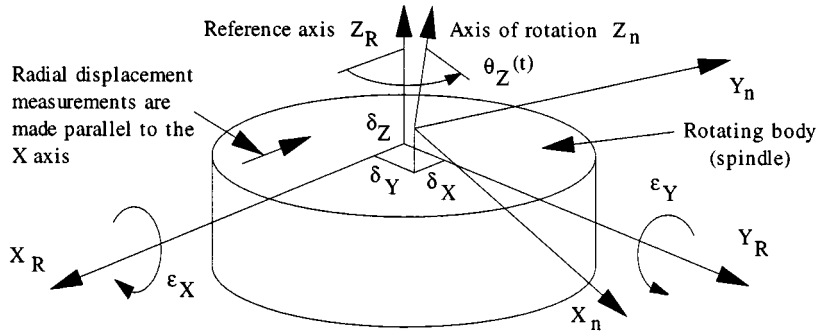

FIGURE 11.8.10 Motion and errors about an axis of rotation (revolute joint).

However, since this matrix is usually evaluated using a spreadsheet, it is best to use the exact form. When nanometer performance levels are sought, second-order effects can start to become important.

In the context of evaluating errors of rotating bodies, particularly when making measurements and discussing the results, it is necessary to consult the axis of rotation standard ANSI B89.3.4M. The "*error motion* of a spindle is the change in position, relative to the reference coordinate axes, of the surface of a perfect workpiece with its center line coincident with the axis of rotation." This definition excludes thermal drift errors. The *runout* is the total displacement measured by an instrument sensing against a moving surface or moved with respect to a fixed surface. The term total indicator reading (TIR) is equivalent to runout. Unfortunately, all too often an imperfect workpiece is eccentrically mounted to a spindle and used to evaluate the performance of a spindle; hence the runout can be a misleading measurement. The "*axial motion* is the error motion colinear with the Z reference axis." "Axial slip", "end camming", and "drunkenness" are nonpreferred terms which have been used in the past. The *tilt motion* is the error motion in an angular direction relative to the Z reference axis. Tilt motion creates sine errors on the spindle which is why the radial error motion is a function of Z position and face motion is a function of radius. Note that "coning", "wobble", and "swash" are sometimes used to describe tilt motion, but they are nonpreferred terms.

These errors are measured and then plotted using polar plots. The *error motion polar plot* is a polar plot of error motion made in synchronization with the rotation of the spindle. Error motion polar plots are often decomposed into plots of various error components. Some of the various types of error motion polar plots are shown in Figure 11.8.11. The *total error motion polar plot* is the complete error motion polar plot as recorded. The *average error motion polar plot* is the mean contour of the total error motion polar plot averaged over the number of revolutions. Note that asynchronous error motion components do not always average out to zero, so the average error motion polar plot may still contain asynchronous components. The average error motion value is a measure of the best roundness that can be obtained for a part machined while being held in the spindle (or the roundness of a hole the spindle is used to bore). The *fundamental error motion polar plot* is the best-fit reference circle fitted to the average error motion polar plots. The *residual error motion polar plot* is the deviation of the average error motion polar plot from the fundamental error motion polar plot. For radial error motion measurements, this represents the sum of the error motion and the workpiece (e.g., ball) out-of-roundness. The workpiece out-of-roundness can be removed using a reversal technique.* The *asynchronous error motion polar plot* is the deviation of the total error motion polar plot from the average error motion polar plot. Asynchronous in this context means that the deviations are not repetitive from revolution to revolution. Asynchronous

* The former was developed by Bob Donaldson at LLNL, and the latter by Spragg and Whitehouse. See Appendix B of ANSI B89.3.4M-1985 and the various cited references. Also see the ANSI standard *Measurement of Out-of-Roundness*, ANSI B89.3.1-1972(R1979).

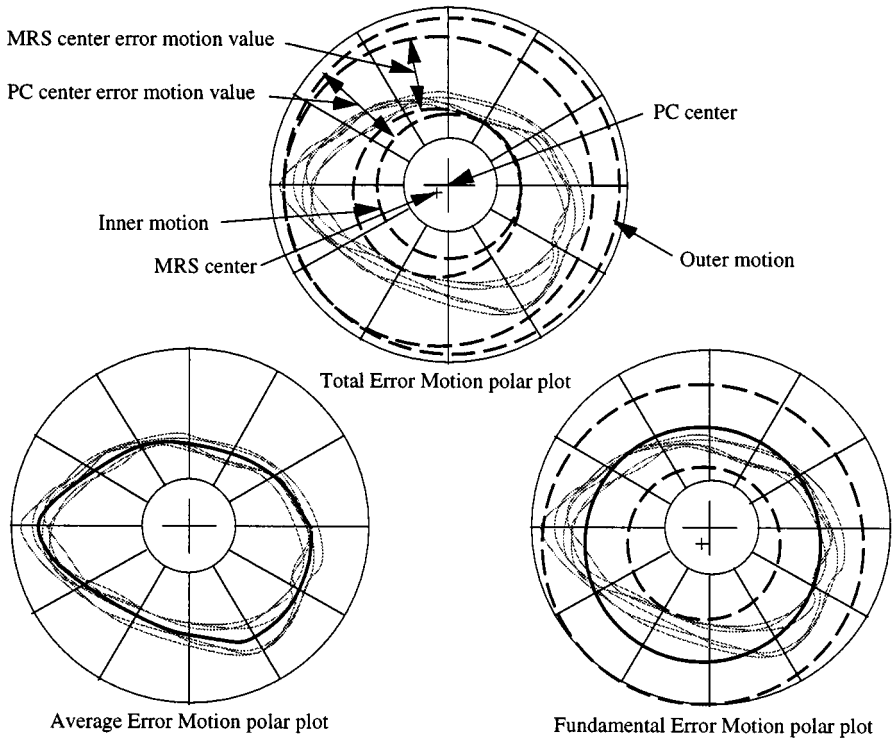

FIGURE 11.8.11 Examples of error motion and error motion component polar plots.

error motions are not necessarily random (in the statistical sense), but they do provide an indication of the attainable surface finish of the part.

Once again, the FFT is a vital tool for identifying the source of errors so that the designer can seek to minimize them. Figure 11.8.12 shows an FFT of a grinding spindle's error motion. The spindle speed was 1680 rpm (28 Hz), the bearing inner diameter was 75 mm, the outer diameter was 105 mm, the number of balls was 20, and the ball diameter was 10 mm. One of the dominant errors occurs at twice the rotation frequency, indicating that the bore in which the bearing is placed is most likely out-of-round.

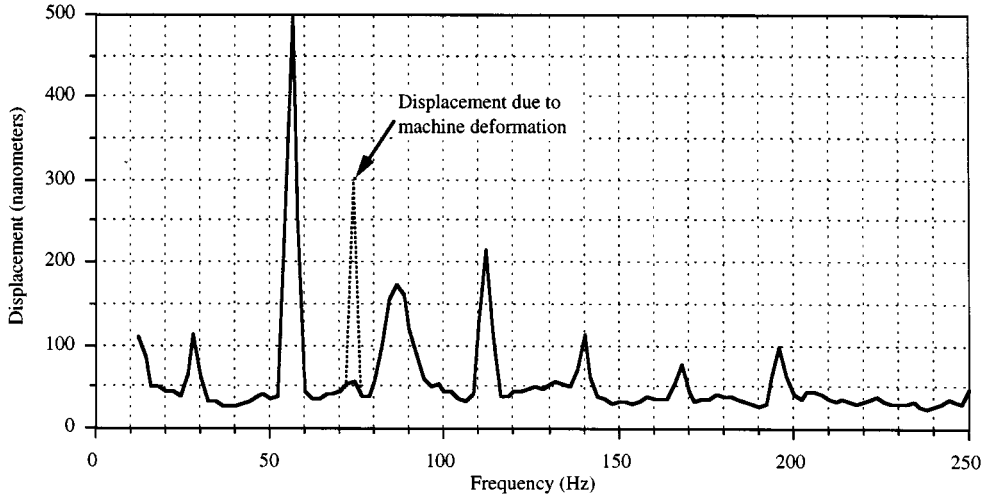

FIGURE 11.8.12 FFT of grinding spindle error motion.

Error Budgets

To define the relative position of one rigid body with respect to another, six degrees of freedom must be specified. To further complicate matters, error in each of the six degrees of freedom can have numerous contributing components. In fact, considering all the interacting elements in a typical machine tool, the number of errors that must be kept track of can be mindboggling. Therefore, the best way to keep track of and allocate allowable values for these errors is to use an *error budget*. An error budget, like any other budget, allocates resources (allowable amounts of error) among a machine's different components.* The goal is to allocate errors such that the ability of any particular component to meet its error allocation is not exceeded.

An error budget is formulated based on connectivity rules that define the behavior of a machine's components and their interfaces, and combinational rules that describe how errors of different types are to be combined. The first step in developing an error budget is to develop a kinematic model of the proposed system in the form of a series of homogeneous transformation matrices (HTM). The next step is to analyze systematically each type of error that can occur in the system and use the HTM model to help determine the effect of the errors on the toolpoint position accuracy with respect to the workpiece. The result is a list of all end point error components, their sources, and amplification-at-the-toolpoint factors (called the *error gains* or *sensitivities*). Different combinational rules can then be applied to yield upper and lower bound estimates of the total error in the machine.

Perhaps the most important step in assembling the error budget for a machine is the placement of the coordinate frames and the assignment of linear and angular errors corresponding to the axes. Angular motion errors suffer no ambiguity in their definition since they are unaffected by other errors and therefore can be defined with respect to any set of axes. Linear motion errors, on the other hand, must be carefully defined in terms of linear motion caused directly and linear motion that is the result of an Abbe error. During the design phase, the coordinate systems must be located at the origin of the angular errors, where pitch, yaw, and roll errors are the center of stiffness as defined above.

Combinational Rules for Errors

Different types of errors do not mix unless handled properly. Once all error components are multiplied by their respective error gains, a final combination of errors can then be made to yield an educated guess as to the machine's expected performance. There are three common types of errors, which are defined as:**

1. "*Random* — which, under apparently equal conditions at a given position, does not always have the same value, and can only be expressed statistically."
2. "*Systematic* — which always have the same value and sign at a given position and under given circumstances. (Wherever systematic errors have been established, they may be used for correcting the value measured.)" Systematic errors can generally be correlated with position along an axis and can be corrected if the relative accompanying random error is small enough.
3. "*Hysteresis* — is a systematic error (which in this instance is separated out for convenience). It is usually reproducible, has a sign depending on the direction of approach, and a value partly dependent on the travel. (Hysteresis errors may be used for correcting the measured value if the direction of approach is known and an adequate pretravel is made.)" Backlash is a type of hysteresis error that can be compensated for to the extent that is repeatable.

Systematic and hysteresis errors can often be compensated for to a certain degree using calibration techniques. Random error cannot be compensated for without real-time measurement and feedback into a correcting servoloop. Thus, when evaluating the error budget for a machine, three distinct *subbudgets*

---

* See Donaldson, R. Error budgets. In *Technology of Machine Tools,* Vol. 5. *Machine Tool Accuracy,* R.J. Hocken, (ed.), Machine Tool Task Force.

** These definitions are from the CIRP Scientific Committee for Metrology and Interchangeability, 1978. A proposal for defining and specifying the dimensional uncertainty of multiaxis measuring machines. *Ann. CIRP.* 27(2):623–630.

based on systematic, hysteresis, and random errors should be kept. Often inputs for the error budget are obtained from manufacturers' catalogs (e.g., straightness of linear bearings), and they represent the peak-to-valley amplitude errors e_{PV}. A peak-to-valley error's equivalent random error with uniform probability of occurrence is given by $\varepsilon_{\text{equiv. random}} = \varepsilon_{PV}/K_{PV}$. If the error is Gaussian, then $K_{PVrms} = 4$ and there is a 99.9937% probability that the peak-to-valley error will not exceed four times the equivalent random error.

In the systematic subbudget, errors are added together and sign is preserved so cancellation may sometimes occur. The same is true for the hysteresis subbudget. In the random subbudget, both the sum and the root-mean-square error should be considered, where the latter is given by

$$\varepsilon_{\text{irms}} = \left(\frac{1}{N} \sum_{i=1}^{N} \varepsilon_{\text{irandom}}^2 \right)^{1/2} \tag{11.8.15}$$

Note that in the random subbudget, all the random errors are taken as the 1σ values. For the final combination of errors, the 4σ value is typically used, which means that there is a 99.9937% chance that the random error component will not exceed the 4σ value. In this case the total worst-case error for the machine will be

$$\varepsilon_{\text{iworst case}} = \sum \varepsilon_{\text{isystematic}} + \sum \varepsilon_{\text{ihysteresis}} + 4 \sum \varepsilon_{\text{irandom}} \tag{11.8.16}$$

The best-case error for the machine will probably be

$$\varepsilon_{\text{ibest case}} = \sum \varepsilon_{\text{isystematic}} + \sum \varepsilon_{\text{ihysteresis}} + 4 \left(\sum \varepsilon_{\text{irandom}}^2 \right)^{1/2} \tag{11.8.17}$$

In practice, the average of these two values is often used as an estimate of the accuracy the design is likely to achieve.

Type of Errors

There are many types of errors that occur in a machine including:

Straightness. *Straightness* is the deviation from true straight-line motion. One generally thinks of the straightness error as primarily dependent on the overall geometry of the machine and applied loads. As shown in Figure 11.8.13 straightness error can be considered the deviation from a straight line motion along a linear axis. The unofficial term *smoothness* can be used to describe straightness errors that are dependent on the surface finish of the parts in contact, the type of bearing used, and the bearing preload. In other words, the smoothness of motion would be the deviation from the best-fit polynomial describing the straightness of motion. Smoothness is not intended to be a descriptor of surface finish, but rather a descriptor of high-frequency straightness errors whose wavelength is typically on the order of the magnitude of the error, normal to the surface of two moving bodies in contact.

Kinematic Errors. Kinematic errors are defined here as *errors in the trajectory of an axis that are caused by misaligned or improperly sized components.* For example, kinematic errors include orthogonality (squareness or perpendicularity) and parallelism of axes with respect to their ideal locations and each other. Translational errors in the spatial position of axes are also a form of kinematic error. The dimensions of an axis's components can also cause the tool or workpiece to be offset from where it is supposed to be and is also classified as a kinematic error.

As shown in Figure 11.8.14 given two machine axes of motion in the XZ plane with one machine axis aligned with the X reference axis, the orthogonality error is defined as the deviation ε_y from 90° between the machine's other axis and the reference X axis. This is a straightforward definition which is simple to specify on a drawing, but is not necessarily simple to measure or control in production. Parallelism between two axes has horizontal and vertical forms that define the relative taper and twist

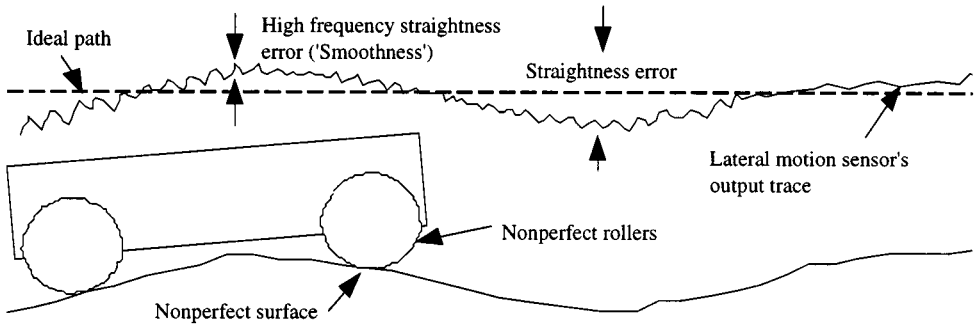

FIGURE 11.8.13 Strightness errors caused by surface form and finish errors.

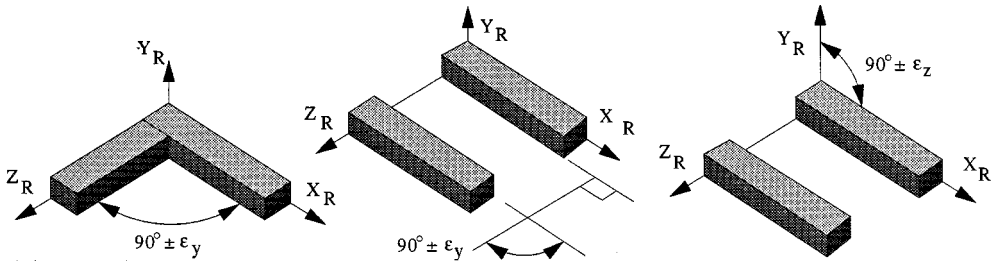

FIGURE 11.8.14 Orthogonality and horizontal and vertical parallelism errors.

between the two axes, respectively. An example of horizontal parallelism error (taper) would be an axis on a lathe that was not parallel to the spindle's axis of rotation. Using this axis to move a tool along the outer surface of a part would result in the part becoming tapered along its length. An example of vertical parallelism error is two axes used to support a milling machine bed. If one end of one of the axes is high, the bed itself will be warped when bolted to the axes, and parts machined while bolted to the bed will wobble.

Kinematic errors in a well-designed and manufactured machine would be very repeatable and can be compensated for if the controller is well designed. However, the fundamental principle of modern precision machine design is still to *maximize mechanical performance for a reasonable cost before using special controllers, algorithms, and sensors to correct for mechanical errors.*

External Load-Induced Errors. External loads that cause errors in a machine include gravity loads, cutting loads, and axis acceleration loads. The difficulty in modeling load-induced errors lies in their often distributed and/or varying effects. The types of errors discussed thus far have been geometrically induced and were a function of position. Thus, they could be relatively easily included in the HTM model of a machine. Load-induced errors, on the other hand, are often distributed throughout the structure. In order to incorporate them into the HTM model, a method for lumping them at discrete points must be devised. Depending on the structure, the bearing interface is often the most compliant part of the structure, and it can make sense to lump load-induced errors at the bearing interfaces. For more complex structures, it may be necessary to introduce additional coordinate frames into the HTM model.

In addition to increasing accuracy for enhancement of quality, machines are being required to move at greater speeds in order to increase productivity. Machine tools are usually thought of as big, bulky, slow-moving structures. The next generation of machine tools, however, will probably require axes to have acceleration capabilities in excess of 1 g. Deflections caused by accelerating the mass are acceptable for many drilling operations which would allow high spindle speeds and high axis feed rates to be used to increase productivity. Acceleration and deceleration rates of high-speed manufacturing equipment's

axes may one day routinely approach several g. In designing this type of equipment, accuracy along the path of motion may or may not be critical. However, final placement and settling time, where the maximum accelerations and inertial forces are present, will be important. Note that in the design of this type of machinery, cutting forces are often insignificant compared to inertial forces.

Another major contributor to load-induced errors in machine tools and some robots are cutting forces. Fortunately, high-speed cutting processes often generate low cutting forces, so the problems of high acceleration and high cutting force usually do not occur simultaneously. However, cutting forces are applied at the tool tip and act on every element in the machine. In order to estimate forces generated by the cutting process, actual cutting forces on machines with similar tools should be measured or appropriate handbooks consulted. In many cases, the rapid advance of new types of cutting tool materials and tool shapes will require the design engineer to consult with a tooling manufacturer or make experimental tests.

Load-Induced Errors from Machine Assembly. Even if all machine components are within required tolerance prior to assembly, additional load-induced errors can be introduced during assembly. The first type of error is forced geometric congruence between moving parts. An example is the bolting of a leadscrew to a carriage, where the nonstraightness of the leadscrew shaft creates a straightness error in the carriage with a period equal to the lead of the screw. A common example is mounting a mirror at its four corners, which often creates a visible distortion. The second type of error is the effect of the assembly process on the stiffness of the structure itself, and how the stiffness can be evaluated and incorporated into the HTM model. A third type of error, one that can be predicted, is the deformation of the machine when forces are applied to preload bearings and bolts. In addition, errors may also be caused by clamping or locking mechanisms.

Thermal Expansion Errors[*]. The need for ever-increasing accuracy and greater machine speeds makes thermal errors ever more important to control. Errors caused by thermal expansion are among the largest, most overlooked, and misunderstood form of error in the world of machine design. Thermal errors affect the machine, the part, and the tool. Even the warmth of a machinist's body can disrupt the accuracy of an ultraprecision machine. Figure 11.8.15 shows the thermal effects that must be accounted for in the design of a precision machine.[**] Thermal errors are particularly bothersome because they often cause angular errors that lead to Abbe errors.

Temperature changes induce thermal elastic strains ε_T, that are proportional to the product of the coefficient of expansion α, of the material and the temperature change, ΔT, experienced by the material:

$$\varepsilon_T = \alpha \Delta T$$

In addition, temperature gradients often cause angular errors, which lead to Abbe errors. If a machine, a tool, and a workpiece all expanded the same amount and could all be kept at the same temperature, then the system might expand uniformly with respect to the standard (always measured at 20°C) and everything would be within tolerance when brought back to standard temperature. However, different metals manufactured at different temperatures can experience serious dimensional metrology problems. Fortunately, standards have been developed (e.g., ANSI B89.6.2[***]) that define in great detail the effects of temperature and humidity on dimensional measurement and how measurements of these effects should be made. Although thermal strains can be minimized by using materials that do not expand very much,

[*] C° denotes temperature difference, whereas °C denotes an absolute temperature. This helps to avoid confusion, particularly when reference is made to temperature increases above ambient.

and by accurately controlling the environment; in practice, however, these can be difficult solutions to implement for economic reasons.

Structures

The detailed design of the machine structure requires an understanding of the errors in a machine and how they interact with the envisioned assemblage of components. When designing the structure, the engineer must have an overall philosophy in mind with respect to how to assemble the system and address principle types of errors.

For a precision machine, the engineer must first develop a strategy for attaining accuracy (these issues were addressed in the context of 11.8.1 “Analysis of Errors in a Precision Machine”):

- Accuracy obtained from component and assembly accuracy
  - Inexpensive once the process is perfected.
  - Accuracy is strongly coupled to thermal and mechanical loads on the machine.
- Accuracy obtained by error mapping a repeatable system
  - Inexpensive once the process is perfected.
  - Accuracy is moderately coupled to thermal and mechanical loads on the machine.
- Accuracy obtained from a metrology frame (measure the position of an inaccurate machine with respect to an accurate reference frame)
  - Expensive, but sometimes the only choice.
  - Accuracy is uncoupled to thermal and mechanical loads on the machine.

Next, a direction should be set regarding dynamic performance and how much is needed, by considering the following:

- System bandwidth requirements
- Effects of changing system parameters
- Methods to add damping
- Experimental modal analysis

Thermal errors are among the most difficult to predict and control, and an approach to address them should be established early on:

- Passive temperature control
- Active temperature control

With design approaches to the above, the next step is to consider structural materials and different machine configurations that are available:

- Materials
- Existing configurations

Finally, a decision should be made regarding the overall approach to be used with regard to how all the components are assembled:

- Elastically averaged design
- Kinematic design
- Bolted joint design
- Kinematic coupling design

These issues are discussed in greater detail below. Proper consideration of all the details takes a great deal of study* and practice, but these highlights should be useful as an introduction, or as a refresher.

Dynamic System Requirements

Engineers commonly ask "how stiff should the structure be?" A minimum specified static stiffness is a useful but not sufficient specification. For example, the machine can be made to not deflect too much under its own weight or the weight of a part. Fortunately, it can be predicted with reasonable accuracy. To obtain good surface finish or dynamic performance, the dynamic stiffness needs to be specified.

The dynamic stiffness of a system is the stiffness measured using an excitation force with a frequency equal to the damped natural frequency of the structure. The dynamic stiffness of a system is also equal to the static stiffness divided by the amplification at dynamic resonance. It takes a large amount of damping to reduce the amplification factor to a low level. There are several damping quantifiers that are used to describe energy dissipation in a structure. The quantifiers include:

η	Loss factor of material
η_s	Loss factor of material (geometry and load dependent)
$Q = A_r$	Resonance amplification factor
ϕ	Phase angle ϕ between stress and strain (hysteresis factor)
δ_{Ld}	Logarithmic decrement**
ΔU	The energy dissipated during one cycle
ζ	The damping factor associated with second-order systems

* See, for example, Slocum, A. 1997. *Precision Machine Design.* Society of Manufacturing Engineers, Dearborn, MI. Much of the contents of this section was derived from this book.

** Most texts on vibration refer to the log decrement as δ, however, to avoid confusion with discussions on displacement termed δ, the log decrement will be referred to here as δ_{Ld}.

The various damping terms are related (approximately) in the following manner:

$$\eta = \frac{1}{A_r} = \frac{\delta}{\pi} = \phi = \frac{\Delta U}{2\pi U} \tag{11.8.18}$$

The logarithmic decrement δ_{Ld} is an extremely useful measure of the relative amplitude between N successive oscillations of a freely vibrating system (one excited by an impulse):

$$\delta_{Ld} = \frac{-1}{N}\log_e\left(\frac{a_N}{a_1}\right) \tag{11.8.19}$$

The logarithmic decrement can also be related to the damping factor ζ, velocity damping factor b, mass m, and natural frequency ω_n of a second-order system model:

$$\zeta = \frac{\delta_{Ld}}{\sqrt{4\pi^2 + \delta_{Ld}^2}} \tag{11.8.20}$$

Note that the amplification at resonance of a second-order system is given by

$$Q = A_r = \frac{1}{2\zeta\sqrt{1-\zeta^2}} \quad (\zeta \le 0.707) \tag{11.8.21}$$

For example, Figure 11.8.16 shows the time decay of a fairly well-damped system. For this system, n = 4, a_5 = 0.5, a_1 = 1.5, δ_{ld} = 0.275, ζ = 0.44, and Q = 11.5.

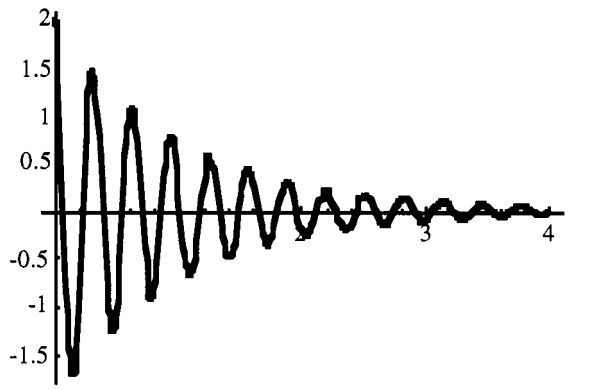

FIGURE 11.8.16 Time decay signal from a fairly well-damped system struck with an impulse.

Machines with good dynamic performance achieve damping by material selection and by the bolted joints and bearing interfaces in the structure. Unfortunately, material and joint damping factors are difficult to predict and are often too low. Thus the designer must consider the stiffness, mass, and damping of the system, and be prepared to alter them to achieve the desired level of performance. For high speed or high accuracy machines, damping mechanisms may have to be designed into the structure in order to meet realistic damping levels. The first step, however, is to try and determine the bandwidth required with an initial estimate of the stiffness, mass, and damping in the system. Then with these goals, one can try to change the parameter that has the greatest impact on performance.

System Bandwidth Requirements. An estimate of the system's servo bandwidth can be made by considering the motions the system is required to make. Most systems null high frequency disturbance forces with their own mass or added damping; however, lower frequency forces must be offset by forces from the controller/actuator. As a result, the servo bandwidth required is primarily a function of the types of moves that the system will be required to make. For start and stop moves (e.g., in a wafer stepper), the bandwidth should be on the order of

$$\omega(\text{hz}) = \frac{10}{2\pi t_{\text{settling time}}} \tag{11.8.22}$$

When contouring, the X and Y axis moves according to x = Rsinωt and y = Rcosωt, the frequency ω is a function of the linear velocity of the cutter through the material, and the radius of the contour:

$$\omega(\text{hz}) = \frac{v_{\text{linear}}}{2\pi r_{\text{path radius}}} \tag{11.8.23}$$

For example, for a large circle (e.g., 200 mm D) being cut at modest speeds (e.g., 0.1 m/sec), the bandwidth required is only 0.16 Hz. On the other hand, for a sharp turn in a corner, the radius of the cutter path trajectory may only be 1 mm, so ω > 16 Hz. The latter is a reasonable requirement for a large machine tool, where the spindle axis may weigh 1000 kg and thus require a critically damped system stiffness of 10 N/μm, which means a design stiffness on the order of 100 N/μm when one considers the limited damping that is obtainable.

In order to make a better assessment of what system parameters should be, a simple model can be used in the early stages of design. For example, a system with a motor driving a carriage can be modeled as shown in Figure 11.8.17.

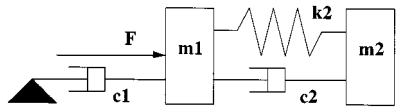

FIGURE 11.8.17 Effect of changing system mass on dynamic performance.

In this model:

- m_1 is the mass of a linear motor forcer or m_1 is the reflected inertia of the motor rotor and leadscrew (or just a linear motor's moving part):

$$M_{\text{reflected}} = \frac{4\pi^2 J}{l^2}$$

- m_2 is the mass of the carriage.
- c_1 is the damping in the linear and rotary bearings.
- c_2 is the damping in the actuator-carriage coupling and the carriage structure.
- k_2 is the stiffness of the actuator and actuator-carriage-tool structural loop.

The equations of motion of this system are

$$\begin{vmatrix} m_1 & 0 \\ 0 & m_2 \end{vmatrix} \begin{vmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{vmatrix} + \begin{vmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{vmatrix} \begin{vmatrix} \dot{x}_1 \\ \dot{x}_2 \end{vmatrix} + \begin{vmatrix} k_2 & -k_2 \\ -k_2 & k_2 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \end{vmatrix} + \begin{vmatrix} F(t) \\ 0 \end{vmatrix} \tag{11.8.24}$$

The transfer function x_2/F (dynamic response of the carriage) is

$$\frac{x_2}{F} = \frac{k_2 + c_2 s}{c_1 s\left(k_2 + c_2 s + m_2 s^2\right) + \left(m_1 + m_2\right) s^2 \left(k_2 + c_2 s\right) + m_1 m_2 s^4} \tag{11.8.25}$$

Note that the product of the masses term tends to dominate the system. To illustrate the design implications, consider four different calculated design options for a linear motion system shown in Figure 11.8.18.

Actuator	ballscrew	lin. motor	lin. motor	lin. motor
Bearings	linear ball	linear ball	air	air
Structural damping	no	no	no	yes
material damping zeta	0.005	0.005	0.005	0.1
actuator to ground zeta	0.05	0.03	0	0
m1 (actuator) (kg)	50	5	5	5
m2 (carriage), kg	50	50	50	50
c1 (N/m/s)	187	355	0	0
c2 (N/m/s)	19	19	19	374
k1 (N/m)	1.75E+08	1.75E+08	1.75E+08	1.75E+08
Bandwidth (Hz)	25	100	30	100

FIGURE 11.8.18 Calculated parameters of four possible linear motion systems.

As a guideline, the servo bandwidth of the system is generally limited by the frequency at which the servo can drive the system without exciting structural modes. Without special control techniques, the servo bandwidth can be no higher than the frequency found by drawing a horizontal line 3 dB above the resonant peak to intersect the response curve. This method is used only to initially size components. A detailed controls simulation must be done to verify performance and guide further system optimization. As an example, consider the response of the ballscrew-driven carriage supported by rolling element linear bearings, as shown in Figure 11.8.19. In this case, since preloaded linear guides and a ballnut are used, damping to ground will be high. The inertia of the ballscrew will lower the system frequency considerably (note the $m_1 m_2 s^4$ term in the transfer function). Going up 3 dB from the resonance peak and projecting to the left to intersect the response curve gives an estimate of the maximum bandwidth the machine can be driven at, without danger of exciting a resonance, of about 25 Hz.

Effects of Changing the System's Mass. Decreasing the mass of the system will enhance the ability of the machine to respond to command signals. However, the trade-off is that the system will lose the ability to attenuate high frequency noise and vibration as shown in Figure 11.8.20.

A system with decreased mass offers a higher natural frequency, which means that higher speed controller signals can be used without compromising the accuracy of the system. A low mass system also shows improved damping, a result of the increased loss factor [the loss factor $\zeta = c/(2m)$], but a low mass system shows less noise rejection at higher frequencies. This suggests that the machine will be less able to attenuate noise and vibration. Considering all the issues, in conclusion, the mass should be minimized to reduce controller effort and improve the frequency response and loss factor (ζ).

Effects of Changing the System's Stiffness. A system with higher stiffness will give a flatter response at low frequencies and give smaller displacements for a given force input. More importantly, the compromise of decreased noise attenuation is not as dramatic as is the case with lowering the system mass. This is shown by the similar shapes in the three curves at high frequencies in Figure 11.8.21. However, acoustical noise may be worsened by adding stiffness. In conclusion, the stiffness of the machine structure should be maximized to improve positioning accuracy.

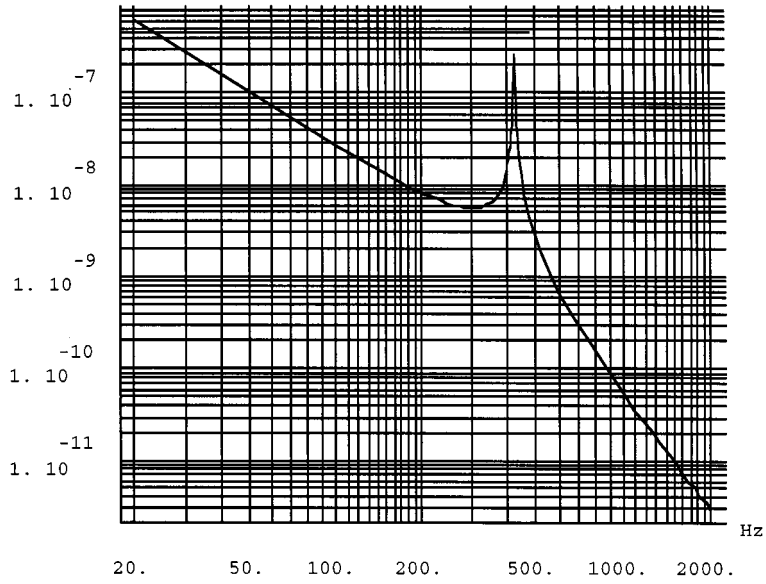

FIGURE 11.8.19 Frequency response of a ballscrew-driven system.

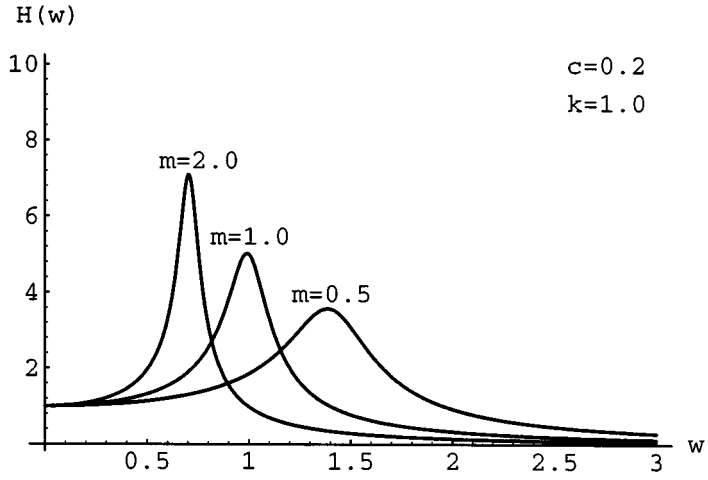

FIGURE 11.8.20 Effect of changing system mass on dynamic performance.

Effects of Changing the System's Damping. Increasing the system's damping can make a dramatic improvement in the system's response. The trend is for decreasing amplification of the output at resonance with increasing damping, although a damping coefficient of 0.4 may be difficult to obtain in practice. Figure 11.8.22 shows the dramatic improvement available by doubling the system's damping.

Methods of Achieving Damping

Although it has been extensively studied, the mechanism of damping in a material is difficult to quantify and one must generally rely on empirical results.* In fact, damping is highly dependent on alloy

* A discussion of the many different microstructural mechanisms that generate damping in materials is beyond the scope of this book. For a detailed discussion see Lazan, B.J., *Damping of Materials and Members in Structural Mechanics*. Pergamon Press, London.

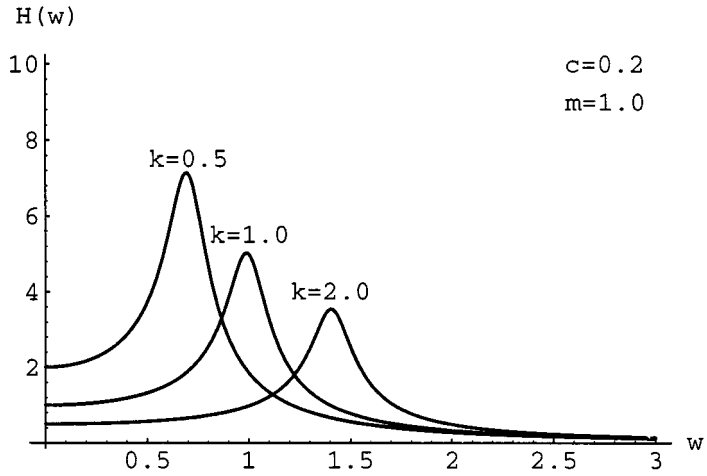

FIGURE 11.8.21 Effect of changing system stiffness on dynamic performance.

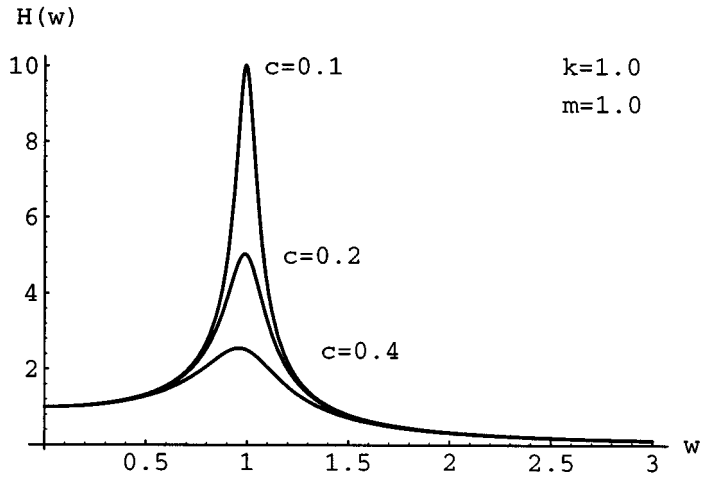

FIGURE 11.8.22 Effect of changing system damping on dynamic performance.

composition, frequency, stress level and type, and temperature. Structural damping levels are often quite low, and frequently the dominant source of damping is the joints in an assembly. In fact, one must be extremely wary of damping data that are presented in the literature, because often it is presented without a discussion of the design of the test setup.

The amount of damping one obtains from a material is very low compared to the amount of damping that one can obtain with the addition of a damping mechanism. Damping mechanisms can range from simple sand piles to more complex shear dampers or tuned mass dampers as discussed below. In general, cast iron is the best damped structural metal. Polymer concrete or granite make well-damped structures that tend to be more monolithic in nature; but ceramics have very poor damping.

Tuned Mass Dampers. In a machine with a rotating component (e.g., a grinding wheel), there is often enough energy at multiples of the rotational frequency (harmonics) to cause resonant vibrations in some of the machine's components. This often occurs in cantilevered components such as boring bars and some grinding wheel dressers. The amplification at a particular frequency can be minimized with the use of a tuned mass damper. A tuned mass damper is simply a mass, spring, and damper attached to a structure at the point where vibration motion is to be decreased. The size of the mass, spring, and damper

are chosen so they oscillate out of phase with the structure and thus help to reduce the structure's vibration amplitude.

Consider the single-degree-of-freedom system shown in Figure 11.8.23. The system contains a spring, mass, and damper. For a cantilevered steel beam, the spring would represent the beam stiffness, the mass would be that which combined with the spring yielded the natural frequency of the cantilevered beam, and the damper would be that which caused a 2% energy loss per cycle. As also shown in Figure 11.8.23, a second spring-mass-damper system can be added to the first to decrease the cantilevered beam's amplitude at resonance. The equations of motion of the system are

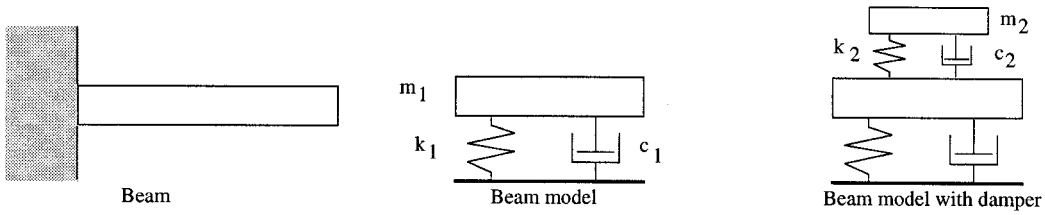

FIGURE 11.8.23 Cantilever beam, model, and model with tuned mass damper.

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{x}(t) + \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \dot{x}(t) + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} x(t) \tag{11.8.26}$$

In the frequency domain, in order to present a solution for the motion of the system, the following notation is introduced:

$$Z_{ij}(\omega) = -\omega^2 m_{ij} + i\omega c_{ij} + k_{ij} \qquad i, j = 1, 2 \tag{11.8.27}$$

The amplitudes of the motions of the component and the damper as a function of frequency are given by*

$$X_2(\omega) = \frac{-Z_{12}(\omega) F_1}{Z_{11}(\omega) Z_{22}(\omega) - Z_{12}^2(\omega)} \tag{11.8.28}$$

The design of a tuned mass damper system for a machine component may involve the following steps:

- Determine the space available for the damper and calculate the mass (m_2) that can fit into this space.
- Determine the spring size (k_2) that makes the natural frequency of the damper equal to the natural frequency of the component.
- Use a spreadsheet to generate plots of component amplitude as a function of frequency and damper damping magnitude (c_2).

Constrained Layer Dampers. The structural joints in a machine tool have long been known to be a source of damping by the mechanisms of friction and microslip. A study of structural joint damping has shown that numerous theories are available for predicting damping by these mechanisms,** however, the amount of damping obtained is still less than what is required for critical damping, and controlling the surface interface parameters at the joint to achieve uniform results from machine to machine is difficult. In addition, as far as the accuracy of the machine is required, it would be best if the joints behaved as

* Ibid., p 115.

** See, for example, Tsutsumi, M. and Ito, Y. September 1979. Damping mechanisms of a bolted joint in machine tools, *Proc. 20th Int. Mach. Tool Des. Res. Conf.*, pp. 443–448; and Murty, A.S.R. and Padmanabhan, K.K. 1982. Effect of surface topography on damping in machine joints. *Precis. Eng.* 4(4):185–190.

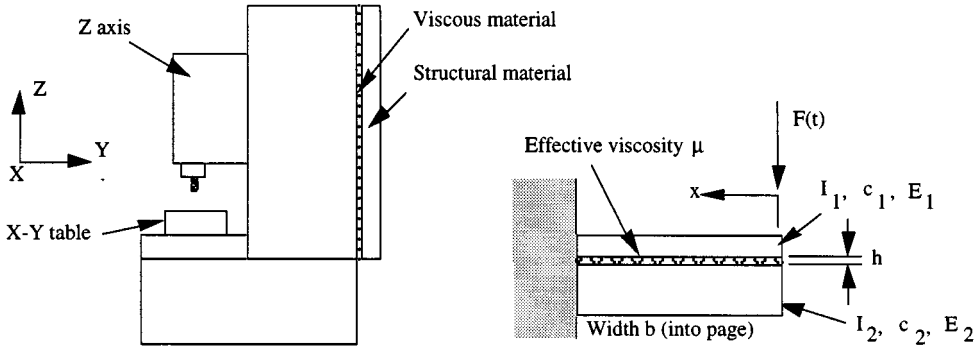

FIGURE 11.8.24 Increasing structural damping by adding alternate layers of viscous and structural materials.

a rigid interface which, as discussed below, can be obtained by bolting and grouting (or bonding) a joint. A better method is to add damping by applying alternate layers of viscoelastic and structural materials to a machine tool structure,* as illustrated in Figure 11.8.24.

Experimental Modal Analysis of a Machine's Dynamic Performance

The manner in which a machine behaves dynamically has a direct effect on the quality of the process. It is vital to be able to measure a machine's dynamic performance to enable engineers to determine exactly which parts of a machine need to be strengthened or made to be better damped.

Experimental modal analysis allows the study of vibration modes in a machine tool structure. An understanding of data acquisition, signal processing, and vibration theory is necessary to obtain meaningful results. For a modest-sized company (50 employees), it is feasible and reasonable to have one person dedicated to metrology, including experimental modal analysis. Companies routinely invest $100,000 or more in precision measurement devices (e.g., gauges, autocollimator, laser interferometer, ball bar, surface roughness, etc.). The dynamic performance of a machine is every bit as important, and requires only a modest investment (about $40K).

When a company's metrologist is trained in modal analysis, results can be rapidly obtained and presented to the design department. For example, suppose a new machine is being designed where axial stiffness of the drive system is of extreme importance (e.g., a centerless grinder). The design engineer wants to know if a rollerscrew will give better performance than a ballscrew. Not completely trusting catalog data, and not knowing the primary source of compliance (the mounting, the bearings, the shaft, or the nut), the engineer replaces a ballscrew — in a known good machine — with a rollerscrew. The metrologist does the modal analysis and the engineer learns in "real time" what the result is. Similarly, the engineer can look to other machines on the shop floor for physical models of elements to be used in a new design, and the metrologist can make the measurements in a short time.

All too often a modal analysis is done after a design is complete to help solve a problem. The results can often be used to help repair the problem; however, done before hand, modal testing of similar machines or test-subassemblies would have led to a better design approach that in the end would have resulted in a better integrated system. The results of a modal analysis yield important information regarding the machine's dynamic properties, including:

- Modal natural frequencies
- Modal damping factors
- Vibration mode shapes

* See, for example, Haranath, S., Ganesan, N., and Rao, B. 1987. Dynamic analysis of machine tool structures with applied damping treatment. *Int. J. Mach. Tools Manuf.* 27(1):43–55. Also see Marsh, E.R., Slocum, A.H. 1996. An integrated approach to structural damping. *Precis. Eng.*, 18(2,3):103–109.

This information is vital to a designer, who may use the information to

- Locate sources of compliance in a structure.
- Characterize machine performance.
- Optimize design parameters.
- Identify the weak links in a structure for design optimization.
- Identify modes which are being excited by the process (e.g., an end mill) so that structure can be modified accordingly.
- Identify modes (parts of the structure) which limit the speed of operation (e.g., in a coordinate measuring machine).

A manager may ask "why should we start doing this if we have not done it in the past, and were very successful?" The engineering answer is that faster and more accurate machines are needed in the future, and the materials being processed are getting harder and harder (e.g., ceramics). The business answer is that the problems are getting tougher to solve, and engineering time is expensive. Also, international competition is more widespread and much tougher. History has shown that application of new advanced tools virtually always guarantees an increase in performance and competitive edge.

Identification, Control, and Isolation of Heat Sources*

Heat that causes thermal errors is introduced into the machine from a number of sources including moving parts (e.g., high-speed spindles, leadscrew nuts, linear bearings, transmissions), motors, the material removal process, and the external environment (e.g., sunshine through a window, direct incandescent lighting, heating ducts, the floor, operators' body heat, etc.). Heat transfer mechanisms in a machine include conduction, convection, evaporation,** and radiation. They are executed by recirculating lubricating oil and cutting fluid, chips from the cutting process, conduction through the frame of the machine, convection of air in and around the machine, and internal and external sources of radiation.

There are three schools of thought regarding minimization of thermally induced errors. The first is to prevent thermal expansion in the first place. The second is to minimize the time it takes for the machine to reach its equilibrium temperature, or in some cases, bring the entire machine to a uniform temperature (e.g., circulate, temperature-controlled fluid through the machine), which can help to minimize differential expansion. The third is to disregard the effects of thermal errors and simply map them, which is a very difficult and often impractical thing to do. Regardless of the methodology followed, a thorough understanding of the effects of heat sources and transfer mechanisms is required, which is beyond the scope of this work.

The manner in which the temperature of a machine is to be controlled can have a large impact on the machine's design. In summary, there are many options available to the design engineer:

- Passive temperature control:
  - Minimize and isolate heat sources.
  - Minimize coefficient of thermal expansion.
  - Maximize thermal conductivity to minimize thermal gradients.
  - Maximize thermal diffusivity to quickly equilibrate transient thermal effects.
  - Minimize thermal emissivity of the structure to minimize radiant coupling to the environment, or maximize the emissivity to couple the structure to an environmental control enclosure.

* An important reference to have that discusses many of the issues discussed here in greater detail is *Temperature and Humidity Environment for Dimensional Measurement*, ANSI Standard B89.6.2-1973.

** Evaporation cooling occurs when aqueous fluids are used. Evaporative cooling is usually uneven and represents one of the biggest temperature control problems facing the precision machine design engineer.

- Active temperature control:
  - Air showers
  - Circulating temperature-controlled fluid within the machine
  - Oil showers
  - Thermoelectric coolers for localized temperature control of hot spots

Each conceptual design option must consider how the temperature within the machine will vary if each of these different temperature control strategies were applied.

Material Considerations

For the conceptual design phase, one should design the structure using differently available materials, and then also design a multimaterial hybrid. For example, cast iron can be made into virtually any shape, so the design engineer has greater freedom, but large sections are expensive to thermally anneal, which must be done to achieve material homogeneity and stability. Granite is usually used in the form of simple rectangular, circular, or planar shapes. Ships are made from welded steel plate and thus conceivably any size of machine tool could also be welded together. Polymer concrete can be cast into virtually any shape and requires no stress relief or prolonged aging cycle. With new ceramics and composite materials, the choices become even more varied, so one really must be alert and consider all options.

Cast Iron Structures

The good general properties of cast iron and the ease with which parts can be cast have made cast iron the foundation of the machine tool industry. Generally, when a machine tool component is smaller than a compact car, it is a candidate for being made of cast iron, although castings weighing hundreds of tons have been made. For larger parts or where economy is of prime importance, one should consider welding together plates and standard structural shapes (e.g., boxes, angles, I-beams, and channels), as discussed below.

Sand casting can be used to make virtually any size part, and it basically involves making a pattern out of a suitable material (e.g., foam, wood, or metal) and packing sand around it. Parting lines are used to allow the sand mold components to be disassembled from around the pattern and then reassembled after the part is removed. Sand cores are often inserted into the mold to form cavities inside the mold (e.g., the cylinders of an engine casting). Regardless of the design of the part, one must also consider that as the metal cools it shrinks (on the order of 5 to 10% for most metals), and that in order to remove the part from the mold without breaking the mold, a taper (draft) of about 1:10 is required. In addition, extra metal should be added to surfaces that will have to be machined (a machining allowance), and locating surfaces should be added so that the part can be fixtured to facilitate machining. Thus in order to specify a casting, there are a few basic guidelines one needs to know in order to minimize the work that a professional mold design engineer has to do to clean up your design. These guidelines are discussed below.*

Granite Structures**

Granite is used as a structural material in machines that are generally used in dry environments because granite can absorb moisture and swell. Thus it may not be appropriate to use granite in a machine where cutting fluid splashes all over it, although there is some debate as to how susceptible to swelling granite actually is. Granite can be sawed into a part of virtually any shape or size (deviations from round slabs

* See, for example, the handbook *Casting Design as Influenced by Foundry Practice.* Mechanite Metal Corp., Marietta, GA.

** A good source of design information about what shapes and sizes can be made is available from Rock of Ages Corp., Industrial Products Group, P.O. Box 482, Barre, VT 05641.

or rectilinear shapes can be expensive). Since it is a brittle material, sharp corners are not allowed, and most structures are built from pieces that are bolted (using inserts) and grouted or bonded together. Since granite is brittle, threaded holes cannot be formed, and thus threaded inserts must be glued or press-fit into round holes in the granite. Common applications of granite components in machine tools include structural members and air-bearing ways in coordinate measuring machines and other inspection machines. Note that the porosity of some granite makes it unsuitable for air bearings even after it has been polished.

The low thermal conductivity of granite makes it slow to absorb heat. This makes granite, particularly black granite, susceptible to thermal distortions caused by the top surface absorbing heat from overhead lights. Granite's coefficient of thermal expansion is less than that of most metals, so in the process of manufacture, shipping, and use, one must consider how differential thermal expansion will affect a machine's performance if metal components have been bolted to it. Although granite has been sitting in the ground for millions of years and thus may seem to possess the ultimate stability, one must consider the effects of relieving the stress upon the granite's dimensional stability after it has been quarried. There are suppliers of very stable granite components, so the design engineer must carefully shop around. A very desirable property of granite (or any other brittle material) is that it will chip when banged instead of forming a crater with a raised lip (Brinell). Granite is also relatively inexpensive to quarry, cut, and lap. Hence granite is often the material of choice for coordinate measuring machine tables.

Welded Structures*

Welded structures can be made from any weldable alloy (e.g., iron alloys such as 1018 structural steel or Invar). Welded structures (weldments) are commonly used, for example, where (1) the cost of a large structure is to be minimized, (2) a high degree of material damping is not needed or the structure will be filled with a damping material, and/or (3) the part is too large to be cast and thermally stress relieved economically. If welded properly, so that the weld material is in a metallurgically stable form, residual stresses can sometimes be removed using vibratory stress-relief methods.

A welded structure is similar to a cast structure, in that strength and stiffness are achieved through the use of sections that are reinforced with ribs; consequently, structural analysis can be difficult and beyond the conceptual design phase often requires the use of finite element methods. Damping and heat transfer characteristics across welded joints are also difficult to model because they are dependent on depth of weld penetration, composition of the weld material, and contact pressure between member surfaces at the joints where the weld does not penetrate. One solution is to specify full penetration welds. To minimize the cost of welded structures, the number of parts and linear meters of weld must be minimized. Furthermore, the more welds that are made, the greater the thermal distortion that is likely to occur as a result of the manufacturing process. However, if too few ribs are used, large plate sections can vibrate like drums. Damping and thermal performance of a welded structure can improve greatly if a viscous temperature-cooled fluid is recirculated throughout the structure, or if damping mechanisms are used as described above. A welded structure can also be used as a mold for a polymer concrete casting which creates a heavy but well-damped and stiff structure, but care must be taken to avoid bimaterial thermal deformation problems.

Ceramic Structures**

The first introduction of a machine that was made almost entirely of ceramics was in 1984 at the Tokyo machine tool show. Although all-ceramic machines generally perform admirably, they have yet to compete economically with machines made from cast iron or polymer concrete. However, in the future,

* A good reference to have is Blodgett, O. 1963. *Design of Weldments*. James F. Lincoln Arc Welding Foundation, P.O. Box 3035, Cleveland, OH 44104.

** See, for example, Ormiston, T. September 1990. Advanced Ceramics and Machine Design. *SME Tech. Paper* EM90-353.

as more and more ceramic components are made for use in consumer products (e.g., automobiles), it is likely that precision machines will contain more and more ceramic components.*

Hard materials (e.g., ceramics) offer advantages over conventional materials in terms of dimensional stability, strength, and stiffness over a wide range of temperatures. In applications ranging from adiabatic internal combustion engines for maximum efficiency to X-ray mirrors for X-ray photolithography, the ability to manufacture components from hard materials is clearly of vital importance to the future of the manufacturing industry. Unfortunately, most ceramic components are finish machined on machines built from cast iron and the abrasive nature of ceramics limits the life of these machines. Thus a new family of machine tools and machine tool components will have to be developed specifically for the manufacture of ceramic components. Consider several key properties of some ceramic materials that can help guide the design process for new machines:

- Most ceramic materials (e.g., aluminum oxide and silicon nitride) will not corrode in any fluid environment that might be used in the manufacture of ceramic components (i.e., fluids from oil to water).** Thus ceramics are key materials for water hydrostatic bearings.
- The more brittle a material is, the less plastic deformation that is generated during finish grinding or lapping; hence the surface is more likely to have a negative skewness. A surface with a negative skewness minimizes the need for a lubricant that has good wetting properties that allows for water to be considered as a lubricant. A surface with a negative skewness will also suffer less damage in the event that the lubricant is lost.
- The more brittle a material is, the less plastic deformation that is generated during finish grinding; hence the surface is less likely to contain high residual stress levels that can lead to dimensional instability. In addition, a precision machine should not be subjected to shock loads in the first place. For general machine tool applications, such as bearing rails, the element geometry generally provides more than enough strength to withstand impact loads generated when a machine crashes.
- Generous radii must be used in all corners, and threaded steel inserts must be used if parts are to be bolted to ceramic components. To bond two ceramic components together, conventional adhesives can be used, or for high-performance applications, ceramic parts can be frit bonded. In frit bonding, a glass powder is applied to the two mating surfaces and then fused by heating the parts above the melting point of the glass. The bond will not be as strong as the ceramic, but it will be almost as stiff.
- Unlike some metals, elements do not precipitate out of a ceramic material's microstructure with time (e.g., carbides do not form like in some iron alloys) so dimensional stability is enhanced. Thus ceramic components can also have virtually unmatched dimensional stability. For metrology masters (e.g., squares and straight edges), ceramics are much lighter than conventional materials, they are less likely to be damaged (dropped) in the first place, and they are less likely to become scratched or worn in everyday use.
- Most ceramics are pure and thus the achievable surface finish is limited only by the size of the grain structure formed during the sintering process; however, most advanced ceramic materials have submicron sizes and this effect is usually not a problem the way it can be with metals. Also note that metals contain discrete hard particles that are dragged across the softer surface during machining which degrades surface finish.

* Furukawa, Y. et al. 1986. Development of ultra precision machine tool made of ceramics. *Ann. CIRP.* 35(1): 279–282.

** Aluminum oxide components are subject to stress corrosion cracking in aqueous environments and thus care must be taken to minimize tensile stresses. Note that silicon-based ceramics, which have predominantly covalent molecules, are far less reactive with water. Only at high temperature and pressure do silicon-based ceramics become appreciably affected by aqueous environments.

- Ceramic materials have a high modulus that is good for machine stiffness, but some have poor thermal properties (e.g., alumina) that can lead to increased thermal deformations of the machine. Note that silicon carbide has very good thermal properties but it is considerably more expensive than alumina
- Ceramic materials in intimate contact will not gall or fret the way many metals often do; thus they make excellent bearing surfaces. However, when ceramic materials are in intimate sliding contact, traction forces can cause the local tensile strength to be exceeded, which produces surface cracks that lead to spalling. In such situations, it may be desirable to use a ceramic material with a high fracture toughness and tensile strength (e.g., silicon nitride). Thermal stresses can also initiate local or gross failure.
- Ceramic materials have a higher modulus of elasticity and lower density than do bearing steels; hence ceramic rolling elements have a smaller contact zone that leads to less heat generation. Hybrid bearings (e.g., metal rings and ceramic rolling elements) generate 30 to 50% less heat than do steel bearings. This means that grease can be used to lubricate the bearings at much higher speeds.* In general, for smaller diameter ultraprecision bearings, hybrid bearings can have up to three times the DN value of steel bearings (i.e., 4.5 million vs. 1.5 million).
- Aluminum oxide has good overall properties for structural applications such as fluidstatic bearing rails and CMM structures. Zirconia is very tough, and its coefficient of thermal expansion matches that of steel, so it can be used as a bearing rail liner for rolling element bearings without worrying about bimaterial expansion problems. However, most zirconias are multiphase materials and thus are not well suited for applications where high-dimensional stability is required (e.g., in precision bearings). Silicon nitride has the best overall properties including very high toughness, which makes it ideal for rolling element bearings, but it is too expensive to use for large structural components. Silicon carbide and tungsten carbide are extremely hard and wear-resistant and they are often used in cutting tool applications.
- Aluminum oxide components can be made by cold pressing followed by machining, firing, and grinding. Note that there is significant volume shrinkage during the firing process. Hence designing ceramic structural parts often requires assistance from the manufacturer. In general, the same shape design rules apply as for metal castings, and the wall thickness should not be greater than about 25 mm. Ceramics components (e.g., those made from silicon nitride) can also be made by hot pressing followed by grinding and lapping.

Polymer Concrete Castings**

Portland cement-based concrete is not dimensionally stable enough, due to its own internal structural variations with time and its hygroscopic nature, to allow it to be used for the main structure of a precision machine tool. Although in many applications, properly cured reinforced concrete on a stable, dry subgrade can provide a reasonably stable foundation for very large machines that are not self-supporting, unreinforced Portland cement concrete itself is not dimensionally stable due to (1) reaction shrinkage from cement hydration; (2) shrinkage due to loss of excess nonstoichiometric water, which leaves conduits for humidity-induced expansion or contraction; and (3) nonelastic dimensional changes (e.g., creep and microcracking in the inherent brittle/porous structure). Overall, strain variations with time may be as high as 1000 μm/m.

* Steel bearings require oil mist lubrication at higher speeds. Introducing an oil mist (oil dripped into a high-pressure air stream) into a bearing increases the chance that water and dirt particles might be introduced into the bearing, which can lead to premature failure. Actually, a precision bearing cooled by an oil mist should have its air cleaned and dried to a level usually associated with air bearings (e.g., 3-μm filter and H_2O < 50 to 100 ppm).

** See, for example, Capuano, T. September 10, 1987. Polymer concrete. *Mach. Des.* 133–135; Jablonowski, J. August 1987. New ways to build machine structures. *Am. Mach. Automat. Manuf.* 88–94; and McKeown, P.A. and Morgan, G.H. 1979. Epoxy granite: a structural material for precision machines. *Precis. Eng.* 1(4): 227–229.

Fortunately, a number of different types of polymer-based concretes have been developed which can be used to cast machine tool quality structures. For example, Fritz Studer AG, a prominent manufacturer of precision grinders in Switzerland, discovered that special polymers can be used to bind together specially prepared and sized aggregate to yield a stable, essentially castable, granite-like material with a damping coefficient much higher than that of cast iron.* By carefully controlling the manufacturing process and selection of binder and aggregate, properties can be varied somewhat to suit the user. The polymer concrete material and process developed by Studer is known as Granitan™ and its composition and manufacturing process was patented. Numerous companies have licensed the process and will make castings from Granitan™ to order. Other companies have developed their own proprietary polymer concretes with similar high performance properties.

For polymer concrete castings, the same rules for draft allowance apply as for metal castings if the mold is to be removed. Instead of ribs, polymer concrete structures usually use internal foam cores to maximize their stiffness-to-weight ratio. Unlike metal castings, a polymer concrete casting will not develop hot spots while curing even in thick, uneven sections. Polymer concrete castings can readily accommodate cast-in-place components such as bolt inserts, conduit, bearing rails, hydraulic lines, etc. It should be noted that a bolt will fail before a bonded-in-place insert.

With appropriate section design, polymer concrete structures can have the stiffness of cast iron structures and much greater damping than cast iron structures.** However due to polymer concretes' lower strength, heavily loaded machine substructures (e.g., carriages) are still best made from cast iron. Polymer concretes do not diffuse heat as well as cast iron structures and thus attention must be paid to the isolation of heat sources to prevent the formation of hot spots in a polymer concrete structure. In addition, their modulus of elasticity is about one fifth that of steel, and their strength is an order of magnitude less, so they are used primarily for machine bases.

Structural Configurations

For proper functioning of moving axes and operational stability, often it is important to minimize thermal and elastic structural loops. By this it is meant that the path length from the toolpoint to the workpiece through the structure should be minimal. The less material that separates the part of the structure that holds the tool and the part of the structure that holds the part, the more likely the entire system will quickly reach and maintain a stable equilibrium.

Open-Section (C or G) Frames

Most small machines are designed with an open frame, as shown in Figure 11.8.25 which greatly facilitates workzone access for fixturing and part handling. Note that the machine could be designed with the spindle oriented in the horizontal or the vertical direction. Unfortunately, open section frames are the least structurally and thermally stable. The lack of symmetry leads to undesirable thermal gradients and bending moments. The fact that a critical part of the structure is cantilevered means that Abbe errors abound; hence great care must be used when designing a precision machine with an open frame. Note that there are many different variations on this design for different types of machines (e.g., milling machines and lathes). The common feature of all is the fact that the structural loop is open.

Closed-Section (Bridge or Portal) Frames

Most large machines are designed with a closed frame as shown in Figure 11.8.26. When the Z motion is built into the bridge, a second actuator must often be slaved to the primary actuator that moves the

* Kreienbühl, R. September 19–20, 1990. Experience with synthetic granite for high precision machines. In *Proc. Symp. Mineralguss im Maschinenbau.* FH Darmstadt; and Renker, H.J. 1985. Stone based structural materials. *Precis. Eng.* 7(3): 161–164.

** See, for example, Weck, M. and Hartel, R. 1985. Design, manufacture, and testing of precision machines with essential polymer concrete components. *Precis. Eng.* 7(3): 165–170; and Salje, I. et al. 1988. Comparison of machine tool elements made of polymer concrete and cast iron. *Ann CIRP.* 37(1): 381–384.

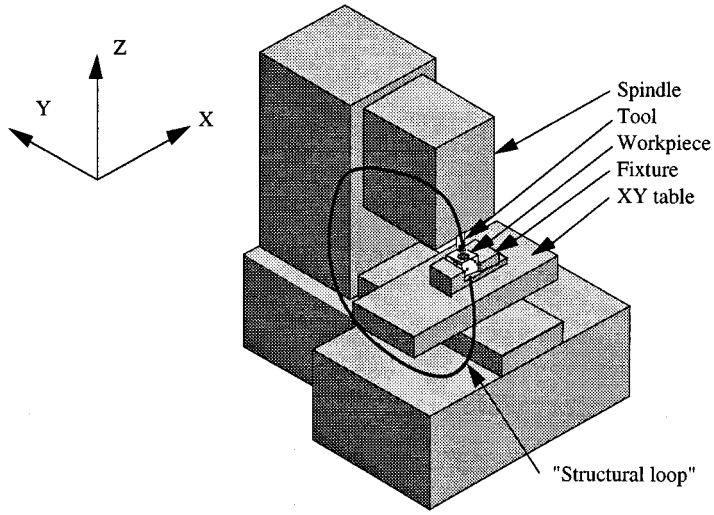

FIGURE 11.8.25 Structural loop in an open-frame machine tool.

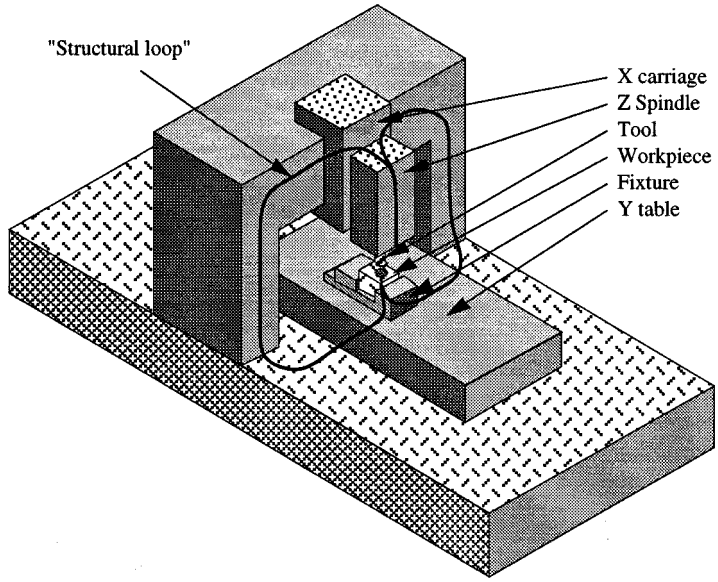

FIGURE 11.8.26 Structural loop in a closed-frame (bridge) machine tool.

bridge. This prevents the bridge from yawing (walking). Note that there are many different variations on this design for different types of machines (e.g., milling machines and lathes). The common feature of all is the fact that the structural loop is closed.

Tetrahedral Frames

Nature invented the tetrahedron and found it to be an immensely stable and powerful form (e.g., diamonds). In engineering and architecture, the tetrahedron represents the three-dimensional application of the age-old structure of stability, the triangle. Lindsey of NPL in England took these basic building blocks of nature and added well-engineered damping mechanisms to yield a major advancement in the

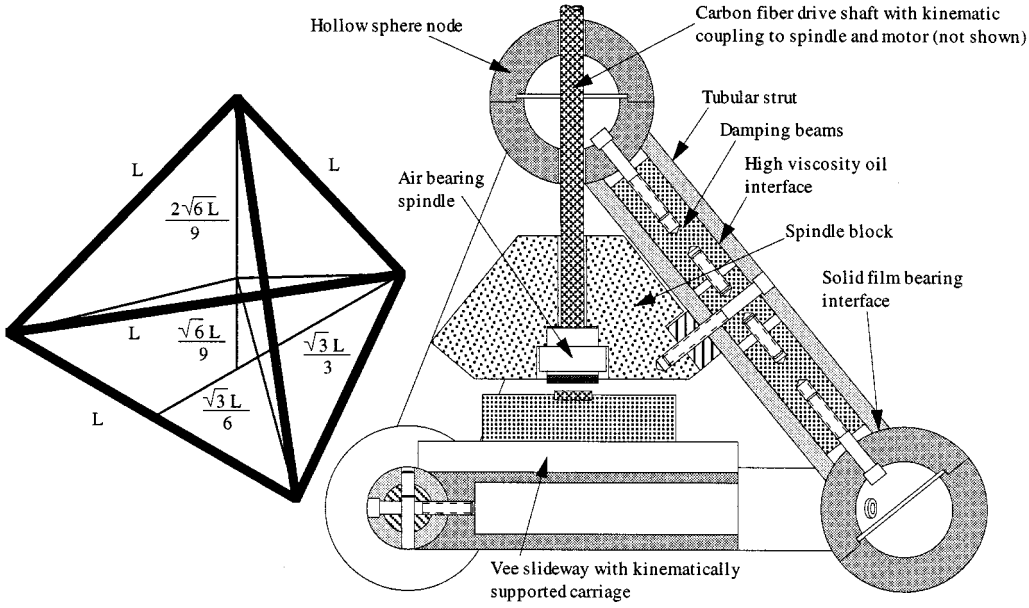

FIGURE 11.8.27 Tetraform structural concept for machine tools and instruments developed by Lindsey. (Courtesy of the National Physical Laboratory.)

structure of machine tools. The *Tetraform* machine tool concept is shown in Figure 11.8.27. The structures owes its exceptional dynamic performance to the following:*

- Damping in the legs is achieved through the use of inner cylinders which dissipate energy through viscous shear. Energy is dissipated via squeeze film damping and relative sliding motion damping.
- Damping at the joints is achieved by a sliding bearing (PTFE) interface.
- Microslip at the joints does not affect the dimensional stability of the machine because the minimum energy form of the tetrahedron wants to be preserved. Unlike a plane joint which can continue to slip and lead to dimensional instability, the tetrahedron's legs' spherical ends want to stay on the spherical joint nodes.

The latter point has even more profound consequences, in that it makes the use of composite materials in the structure an attractive alternative to metals or ceramics. Wound carbon fiber tubes can be designed to have a zero coefficient of thermal expansion along their length and they can have stiffness-to-weight ratios two times higher than are obtainable with metals. It would be difficult to design a conventional machine tool that made economical use of the desirable properties of carbon fibers.

Counterweights and Counterbalances

Counterweights, shown in Figure 11.8.28 can be used to minimize gravity loads. This helps minimize the holding torque required of servomotors, which in turn minimizes motor size and heat input to the machine. For a very high precision machine, however, the bearings used to guide the counterweights and support the pulley bearings should have negligible static friction. Counterweights also increase the mass of the system, which can decrease dynamic performance. In the case of quasistatic axes (e.g., large gantry-type surface grinders), the counterweight can increase the load on the structure that supports the axes, and if the structure is cantilevered, then as the counterbalanced axis moves, the deflection errors

* This concept is protected by worldwide patients. See, for example, U.K. patent 8,719,169, or contact the British Technology Group, 101 Newington Causeway, London, SE1 6BU, England.

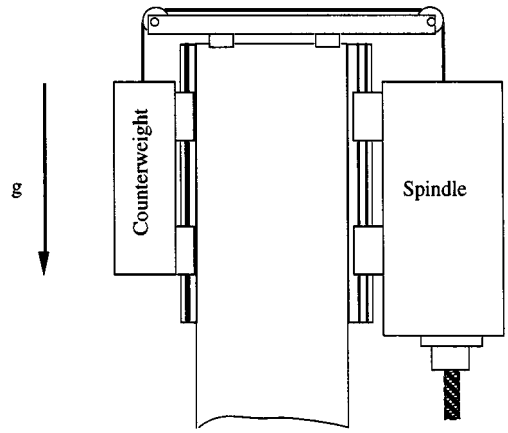

FIGURE 11.8.28 Use of a counterweight to balance the deadweight of an axis.

caused by the weight of the counterbalanced axis will change. Alternatively, a separate frame and low-accuracy slave carriage can be used to support the counterweights.

A counterbalance can be any passive means used to support the weight of an axis that moves in a vertical direction. Pistons have been used successfully but they can impart frictional and misalignment forces. A very effective counterbalance method is to use a float. This also provides viscous damping if the fluid used is a viscous oil.

Compensating Curvatures

All structures have finite stiffness, and when loads are applied, lateral and angular displacements will result. To compensate for these effects, it is possible to shape the otherwise straight ways of an axis so that the sum of the deflections and the intentional nonstraightness results in minimal net straightness error. This type of correction is known as a *compensating curvature*. Usually, it is very difficult to also compensate for angular errors. If the error budget is properly assembled, it can be used to plot the total error as a function of the position of an axis. Once the plot is found, it can be used to help design a shape (ideally, the inverse of the plot) that will cancel the lateral and hopefully also angular errors for the given bearing design. Compensating curvatures can easily be measured using an autocollimator.

When the load does not greatly change on parts moving along axes that are curvature compensated (e.g., axes that carry a measuring head), the method can be effective. If the loads do change greatly (e.g., a table carrying different weight parts and fixtures), the compensating curvature can sometimes decrease performance. One of its main attractions, however, is that once the correct compensated curvature and manufacturing process is found for a particular machine, it can be the least expensive way to correct for straightness errors.

With modern mapping techniques, compensating curvatures are used primarily on very large structures or when angular errors caused by deflection are too large and cannot be corrected for by another axis. For example, they might be used in a situation where otherwise the toolpoint would enter the workpiece at an angle rather than being perpendicular. A rotary axis would be required to compensate for this type of angular error, as opposed to just another linear axis, which can only be used to compensate for an Abbe error.

Structural Connectivity

The principle of kinematic design states that point contact should be established at the minimum number of points required to constrain a body in the desired position and orientation (i.e., six minus the number of desired degrees of freedom). This prevents overconstraint, and thus an “exact” mathematically continuous model of the system can be made. Kinematic locating mechanisms range from simple pins to Gothic arch-grooved three-ball couplings shown in Figure 11.8.29. Kinematic designs, however, are

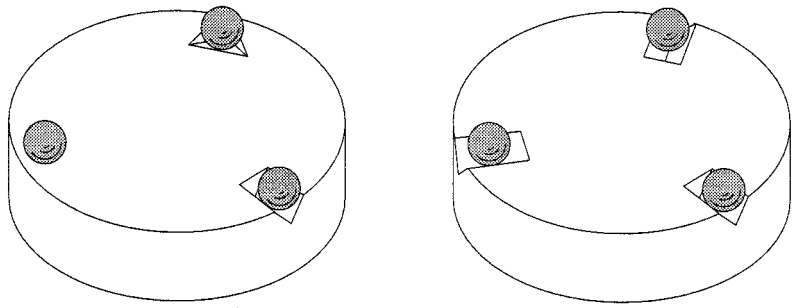

FIGURE 11.8.29 Flat-groove-tetrahendron (Kelvin clamp) and three-vee-groove kinematic couplings. In both cases, the balls are mounted to an upper plate (not shown) which is held in position with respect to the lower plate by the coupling.

subject to high-contact stresses, which often may require the use of ceramic components (e.g., silicon nitride balls and grooves) if the highest level of performance is to be achieved. If stress and corrosion fatigue are controlled, repeatability of a kinematic system can be on the order of the surface finish of the points in contact if the loads are repeatable or the preload high enough. Finite contact areas do exist, and they effectively elastically average out the local errors due to surface roughness. In addition, note that friction and microindentation will limit the accuracy of the kinematic model.

Kinematic support of a structure is often desired to ensure that the structure is not deformed by inaccuracies or instabilities of the mounting surface. For a small instrument, only one of the kinematic mounting points may be rigidly connected and the other two may consist of flexures that will allow for differential thermal growth between the instrument and the mounting surface. Friction does exist in kinematic couplings, and thus forces can be transmitted between a mounting surface and an instrument.

The principle of *elastic averaging* states that to accurately locate two surfaces and support a large load, there should be a very large number of contact points spread out over a broad region. Examples include curvic or Hirth couplings, which use meshed gear teeth (of different forms, respectively) to form a coupling. The teeth are clamped together with a very large preload. This mechanism is commonly used for indexing tables and indexing tool turrets. Figure 11.8.30 shows an indexing and clamping mechanism for a lathe tool turret. Note that many different types of clamping preload systems exist. However, this type of mechanism causes the system to be overconstrained; on the other hand, if an elastically averaged system is properly designed, fabricated, and preloaded, the average contact stress will be low, high points will wear themselves in with use, and errors will be averaged out by elastic deformation. The system itself will then have very high load capacity and stiffness. For a worn-in elastically averaged system, the repeatability is on the order of the accuracy of the manufacturing process used to make the parts divided by the square root of the number of contact points (i.e., teeth in a tooth coupling). Still, because of the large number of contact points, the chance of dirt contaminating the interface increases.

With respect to the connectivity between structural elements (e.g., a headstock and a bed), elements of a structure can either be connected together via:

- Kinematic design
  - Deterministic
  - Less reliance on manufacturing
  - Stiffness and load capacity limited
- Elastically averaged design
  - Nondeterministic
  - More reliance on manufacturing
  - Stiffness and load capacity not limited

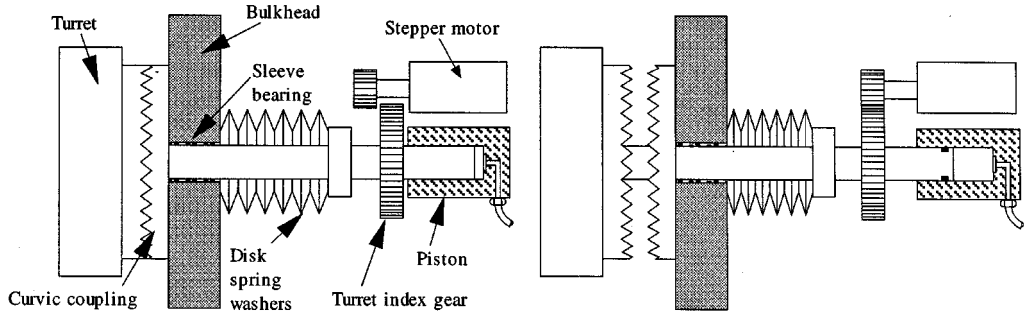

FIGURE 11.8.30 Typical turret indexing and locking mechanism in engaged and disengaged positions.

It should be noted that overconstrainted systems cannot accommodate differential thermal growth and hence are more prone to warping. Furthermore, finite deformation of the contact surface leads to micromechanical constraints that limit the true kinematicity of the structure. The use of hard materials (e.g., ceramics) helps to minimize the latter problem. For permanently connected components, one can align them using a kinematic location system and then inject epoxy or grout to create a bond between all the surfaces in close proximity, although with this method, one must make sure that the shrinkage of the bond material does not warp the components.

Bolted Joints*

Bolts can be used to prevent two parts from separating or sliding relative to one another. For the former, the tensile forces across the joint are transferred through the bolt shaft. For the latter, sliding motion is resisted by frictional forces generated from the normal load on the joint produced by tightening of the bolt and the coefficient of friction between the joint's parts. Because more than one bolt is usually used at a joint, it would be virtually impossible to ensure a tight fit of the bolt shafts in the holes, so it is not even worth trying. Sufficient lateral stiffness is usually provided by bolt preload and joint friction. For better resistance to shock loads, parts can be bolted in place and then holes drilled, reamed, and pinned with hardened steel dowels or roll pins. *In situ* drilling and reaming of the holes through both parts while they are bolted together maintains hole alignment, so multiple pins can be used.

Figure 11.8.31 illustrates the cross section of a typical portion of a bolted joint. A common bolt configuration used to bolt bearing rails for T-slides is shown in Figure 11.8.32. Many rails have a double row of bolts. In general, the cantilevered length should not exceed the bedded length. Ideally, the bedded length should be about 1.5 times the cantilevered length, but sadly this often takes up too much room. Furthermore, the stress cones under the boltheads should ideally overlap to maximize stiffness and minimize rail waviness. In practice, however, as shown in Figure 11.8.33 adequate stiffness can be obtained from a wider bolt spacing. The total stiffness for N segments of a bearing rail (e.g., N segments under a bearing pad) is given by**

$$K_{\text{Rail}} = \frac{N_{\text{Segments}}}{\dfrac{1}{K_{\text{Rail bend \& shear}}} + \dfrac{1}{K_{\text{Joint}} + \dfrac{1}{\dfrac{1}{K_{\text{Flange comp}}} + \dfrac{1}{K_{\text{Flange shear}}} + \dfrac{1}{K_{\text{Bed Shear}}} + \dfrac{1}{K_{\text{Bolt}}}}}}$$

* For a more detailed discussion, see, for example, Bickford, J.H. 1981. *An Introduction to the Design and Behavior of Bolted Joints.* Marcel Dekker, New York; as well as A. Blake's book.

** The theory and practical implementation implications of bolted joints for machine tool applications are beyond the scope of this work. These are discussed in greater detail in Slocum, A. 1997. *Precision Machine Design.* Society of Manufacturing Engineers, Dearborn, MI.

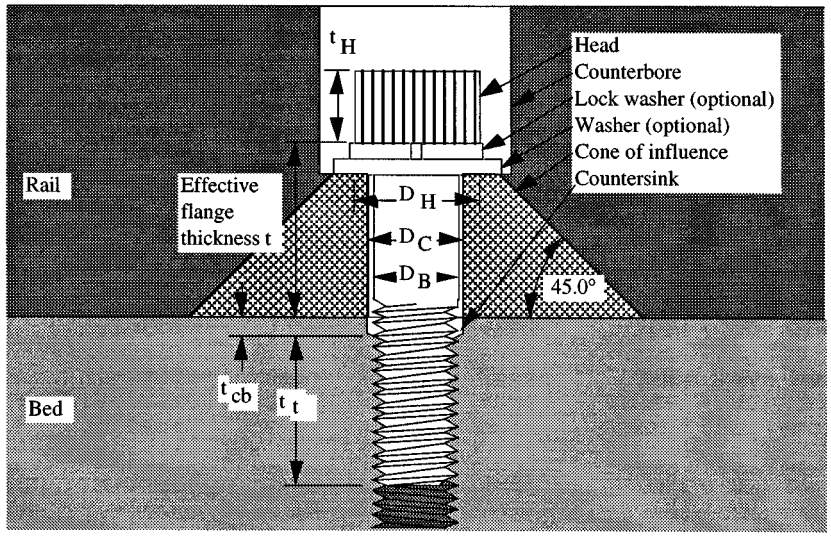

FIGURE 11.8.31 Typical components of a bolted assembly.

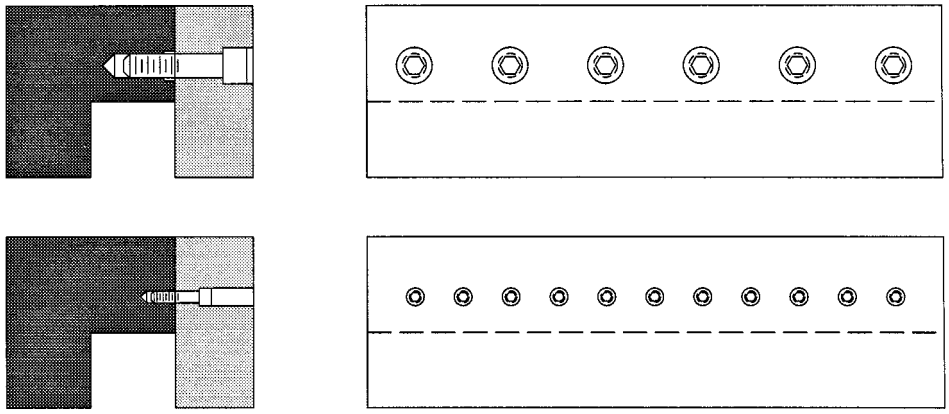

FIGURE 11.8.32 Counterbored and bolted bearing rails with equal stiffness.

Bolt diameter is not a sensitive parameter for stiffness when bolt spacing is made a function of the bolt diameter. When the length of the bolt and the cone are expressed as bolt lengths, bolt joint stiffness becomes linearly dependent on the bolt diameter. As a result, bolt diameter cancels out as shown in Figure 11.8.33.

Bearings

Since bearings are such a critical element in precision machines, one must *think* about the seemingly innumerable number of bearing design considerations that affect the performance of a machine, including:

- Speed and acceleration limits
- Range of motion
- Applied loads
- Accuracy
- Repeatability
- Sealability
- Size and configuration
- Weight
- Support equipment
- Maintenance

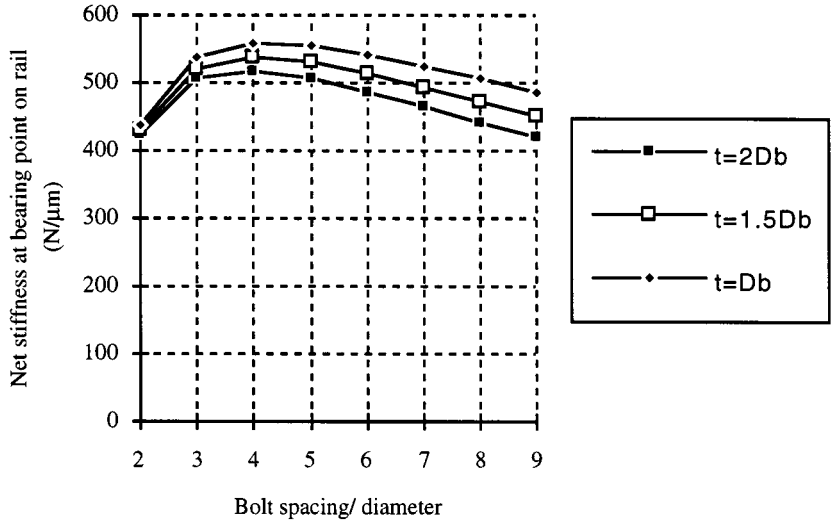

FIGURE 11.8.33 Relationships among stiffness and bolt spacing.

- Resolution
- Preload
- Stiffness
- Vibration and shock resistance
- Damping capability
- Friction
- Thermal performance
- Environmental sensitivity
- Material compatibility
- Mounting requirements
- Required life
- Availability
- Designability
- Manufacturability
- Cost

Because there are always design trade-offs in choosing a bearing for a precision machine, all of these factors must be considered simultaneously by the design engineer. In addition, there are several issues that are common to most types of bearings. These issues include surface roughness, preload, and replication of bearings in place.

Surface Roughness

Surface roughness is a characterization of the profile of the surface and often has an effect (although difficult if not impossible to characterize) on the smoothness of a bearing's motion. In terms of the manufacturing process, smoothness of motion of a bearing can only be quantified in terms of the surface roughness and bearing design:

- Sliding contact bearings tend to average out surface finish errors and wear less when the skewness is negative. A positive skewness (defined below) can lead to continued wear of the bearing.
- For rolling element bearings, if the contact area is larger than the typical peak-to-valley spacing, an elastic averaging effect will occur and a kinematic arrangement of rollers will produce smooth motion. If this condition is not met, the effect will be like driving on a cobblestone street. If numerous rolling elements are used, the effects of elastic averaging can help to smooth out the motion.
- Hydrostatic and aerostatic bearings are insensitive to surface finish effects when they are considerably less than the bearing clearance.
- Flexural and magnetic bearings are not sensitive surface finish.

There are three common parameters for specifying the surface finish or roughness*: the *root mean square* (rms or R_q), the *centerline average* (R_a), and the International Standards Organization (ISO) 10-point height parameter (R_z). The latter is with respect to the five highest peaks and five lowest valleys on a sample. A surface profile measurement yields a jagged trace. If a best fit straight line is drawn through a section of the trace of length L, then the R_q, R_a, and R_z, surface finishes are defined, respectively, from deviations y from the line as a function of distance x along the sample:

$$R_q = \sqrt{\frac{1}{L}\int_0^L y^2(x)\,dx} \qquad R_a = \frac{1}{L}\int_0^L y(x)\,dx \qquad R_z = \frac{\sum_{i=1}^{5} y_{\text{peak}}(i) - y_{\text{valley}}(i)}{5} \tag{11.8.29}$$

Unfortunately, these measures do not provide any information as to the topographical characteristics of the surface. As shown in Figure 11.8.34 the surface topography can be characterized by the *skewness*. The skewness is the ratio of the third moment of the amplitude distribution and the standard deviation σ from the mean line drawn through the surface roughness measurements. Hence the skewness provides a measure of the shape of the amplitude distribution curve. For a contact-type bearing, valleys separated by wide flat planes may be acceptable. This form would have a negative skewness value and is typically in the range –1.6 to –2.0 for bearing surfaces. Sharp spikes would soon grind off, creating wear debris and more damage, and hence positive skewness values are unacceptable for contact-type bearing surfaces. The skewness is defined mathematically from:

$$\text{skew} = \frac{\mu_3}{\sqrt{\mu_2}} = \frac{\mu_3}{\sigma} \qquad \mu_n = \int_{-\infty}^{\infty} (y-\mu)^n f(y)\,dy \qquad \mu = \int_{-\infty}^{\infty} y f(y)\,dy \tag{11.8.30}$$

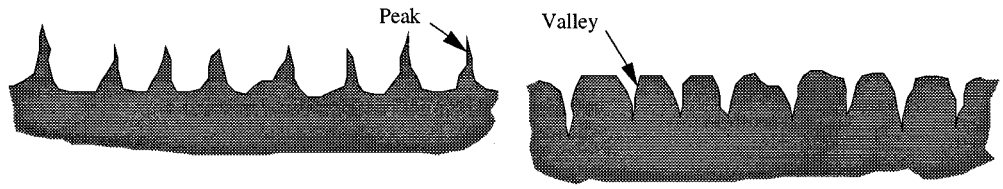

FIGURE 11.8.34 Surfaces with positive (left) and negative (right) skewness.

Numerous other methods exist for defining the shape and intensity of surface roughness features. For example, the autocorrelation function is used to check for the degree of randomness in a surface. This can be used to help track down periodic components (e.g., those caused by tool chatter), which can then sometimes be reduced in subsequently made parts. A frequency spectrum analysis can also be used to accomplish this. The science of surface metrology is constantly evolving as surface finish requirements increase, and the interested reader should consult the literature.**

* See, for example, Stout, K. May 1980. How smooth is smooth. *Prod. Eng.* The following discussion on surface roughness is derived from this article. For a detailed discussion of this subject, see *Surface Texture (Surface Roughness, Waviness, and Lay)*, ANSI Standard B46.1-1985, American Society of Mechanical Engineers, 345 East 47th St., New York, NY 10017. ** See, for example, *Journal of Surface Metrology*, edited by K. Stout and published by Kogan Page, London.

Bearing Preload

A preloaded bearing is one where one bearing pushes against another, thereby squeezing the bearing rail. This allows the bearing to resist bi-directional loads without motion nonlinearity (e.g., backlash) when the load reverses direction. As the force on a pair of opposing pads preloaded against each other is applied, one bearing pushes harder on the rail by an amount equal to the product of the pad stiffness and the carriage deflection, and one pushes less by the same amount.

Insufficient preload is synonymous with at least some of the bearing points periodically losing contact with the bearing surface. This results in difficult-to-map error motions and decreased stiffness, possibly leading to chatter of the tool. Tool chatter, in turn, degrades the surface finish of the part. However, with contact-type bearings, preload can accelerate wear and can lead to stiction, which decreases controllability. These issues lead to the desirability of externally pressurized fluid film bearings (air or fluid) where preload will not change with time.

Unless the axes of the machine are designed to utilize the weight of the machine itself as a preload, in many cases the preload will change with time. This is particularly true if contact-type bearing surfaces wear and if the structure relaxes, due to internal stress needed to maintain the preload. In an effort to counter these effects, the classic method has been to use a device known as a gib to generate the preload. In general, a gib can be defined as a mechanical device that can apply preload to a bearing. In the classical sense, a gib was a wedge-shaped part that was advanced by the action of a screw. When a gibbed machine wears, the gibs, bearings, and sometimes the ways must be rehand-finished and the gibs adjusted to provide the proper preload.

In many machines it is common to use modular rolling bearing components whose preload is set by using oversized balls or rollers, or by tightening bolts that push on a plate contacting the rollers. When the latter type of system wears, it is often discarded and replaced with a new unit. Hence large economies of scale can be obtained by some bearing component manufacturers.

Replicated Bearings*

Replication is a process whereby a very low shrinkage polymer is poured or injected around a master shape that has been coated with mold release. When the polymer cures, it has the shape of the master, which can then be removed and used again. This process can be used to form a bearing surface itself, such as a sliding bearing or a hydrostatic bearing with a pocket, or to form a mating surface between a modular bearing carriage and rough surface of a structure such as a casting.

Because hardening of many polymer resins is an exothrmic reaction, one of the important aspects of this process is to minimize the amount of polymer used, and to maximize the stiffness and thermal diffusivity of the master and the part. This is required to prevent the heat of polymerization from heating the structure, deforming it, and then the polymer hardening to the thermally deformed shape. Unlike bolted assemblies, once the polymer cures to form the desired shape (e.g., a trough in which a linear bearing rail is placed), alignment is no longer possible.

Figure 11.8.35 shows schematic details of surface preparation required to ensure the debonding does not occur. This sawtooth pattern can be obtained in a number of different ways. In addition to the rough surface finish required, the surface must also be thoroughly cleaned and a mold release applied to the master.

Sliding Contact Bearings

Sliding contact bearings are the oldest, simplest, least expensive bearing technology, and they still have a wide range of applications, from construction machinery to machines with atomic resolution. Sliding bearings are thus a very important element in the machine design engineer's tool kit. Sliding contact bearings utilize a variety of different types of lubricants between various interface materials. Lubricants

* See, for example, Devitt, A. October 1989. Replication techniques for machine tool assembly. In *East Manuf. Tech. Conf.* Springfield, MA. Available from Devitt Machinery Co., Twin Oaks Center, Suite G, 4009 Market Street, Aston, PA 19104.

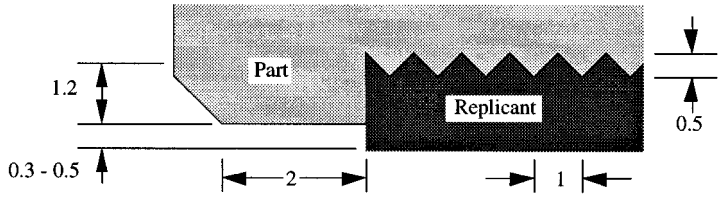

FIGURE 11.8.35 Details of surface and region for replication (dimensions are in mm).

range from light oil to grease to a solid lubricant such as graphite or a PTFE polymer. Because they often distribute loads over a large area, contact stresses and space requirements are often low, while stiffness and damping are usually high. In this section, general properties of sliding contact bearings are discussed followed by a discussion of design considerations.

There are numerous types of sliding contact bearings available and in the context of discussing their general properties, some specific categories will be discussed. In general, one should note that all sliding contact bearings have a static coefficient of friction that is greater (to some degree, no matter how small) than the dynamic coefficient of friction (static μ > dynamic μ). The difference between the static and dynamic friction coefficients will depend on the materials, surface finish, and lubricant.

Rolling Element Bearings

Figures 11.8.36 and 11.8.37 show representative types of ball and roller bearings. Typical linear rolling element bearing configurations are shown in Figure 11.8.38. Note that, in general, it is easier to make a ball spherical than a roller cylindrical; hence ball bearings are more commonly used in precision machines than are roller bearings, the exception being when very high loads must be withstood. A good roller bearing may be better than a moderate ball bearing, and hence in the end the most important thing is to compare manufacturers' specifications.

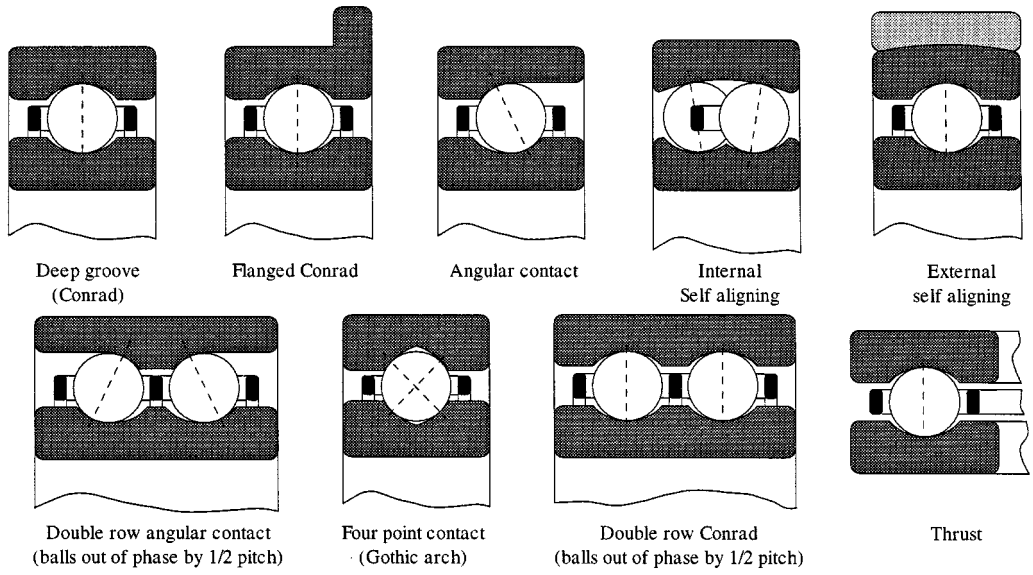

FIGURE 11.8.36 Typical ball bearing configurations for rotary motion bearings.

For linear motion applications, it is more difficult to maintain quality control of a curved surface a ball rides on than a planar surface a roller rides on because the latter can be self-checking. Note that machine-made linear bearing rails will have the same errors as the linear bearings on the machine that

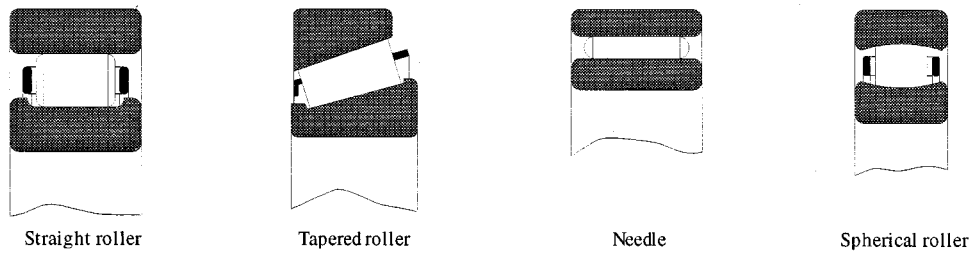

FIGURE 11.8.37 Typical roller bearing configurations for rotary motion bearings.

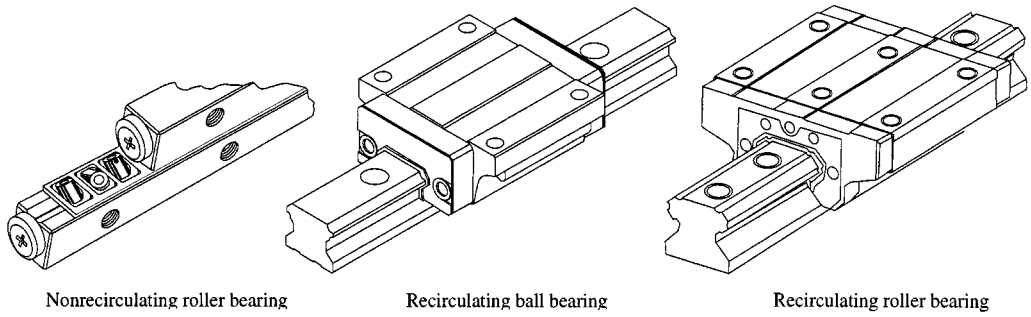

FIGURE 11.8.38 Typical linear rolling element bearing configurations.

was used to make them. For rotary axes, the raceway and the grinding tool can both be rotating at different speeds, which, combined with the random nature of precision spindle radial error motions, means that the form of the raceway can be uniform around is circumference. Thus rotary motion rolling element bearings can be made more accurate than linear motion rolling element bearings. Typical total radial error motion on a precision spindle is on the order of $^1/_4$ to 1 μm. For higher-performance linear or rotary motion bearings, one would typically move into the realm of aerostatic, hydrostatic, or magnetic bearings.

The design and production of a rolling element bearing requires careful analysis, materials selection, manufacturing quality control, and testing. Few companies other than bearing manufacturers have the resources for this type of effort. Whenever possible, one should use off-the-shelf bearing components. In addition, whenever possible, one should use modular components such as spindles and linear axes, particularly for nonsubmicron machines made in small lots (less than about 10 to 20 machines). The savings in design time, prototype testing, spare parts inventory, and repair and replacement costs often far outweigh the potential of saving a few dollars in manufacturing costs.

Designing with rolling element bearings can be intimidating because there are so many subtle details that can ruin a design if they are not considered. The best way to learn about how to handle these details is to think carefully about the physics of their design and the application and/or to work with others with experience, and if possible to experiment. In addition, manufacturers of precision bearing components are also usually willing to work with design engineers to integrate their bearing components into a design. Mapping and metrology frames can be used to increase accuracy given adequate repeatability, resolution, and controllability of the machine *if* the machine is designed with these error-reducing methods in mind.

Rolling Element Linear Motion Bearings

After the rotary motion rolling element ball bearing, the linear motion rolling element bearing ranks on the list of major inventions. Although not found in consumer products with anywhere near the frequency

of rotary ball bearings, linear rolling element bearings are vital for the manufacturing industry. They are critical elements in the design of today's high performance machine tools and factory automation systems.

Flexural Bearings*

Sliding, rolling, and fluid film bearings all rely on some form of mechanical or fluid contact to maintain the distance between two objects while allowing for relative motion between them. Since no surface is perfect and no fluid system is free from dynamic or thermal effects, all these bearings have an inherent fundamental limit to their performance. *Flexural bearings* (also called *fllexure pivots*), on the other hand, rely on the stretching of atomic bonds during elastic motion to attain smooth motion. Since there are millions of planes of atoms in a typical flexural bearing, an average effect is produced that allows flexural bearings to achieve atomically smooth motion. For example, flexural bearings allow the tip of a scanning tunneling microscope to scan the surface of a sample with subatomic resolution.** There are two categories of flexural bearings, monolithic and clamped-flat-spring, as shown in Figures 11.8.39 and 11.8.40.

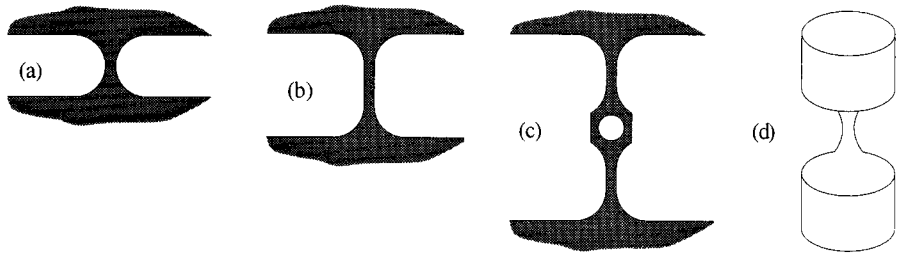

FIGURE 11.8.39 Monolithic flexural bearings.

Hydrostatic Bearings

Hydrostatic bearings utilize a thin film of high-pressure oil to support a load. In general, bearing gaps can be rather large, on the order of 5 to 100 μm. There are five basic types of hydrostatic bearings: single pad, opposed pad, journal, rotary thrust, and conical journal/thrust bearings. All operate on the principle of supporting a load on a thin film of high-pressure oil that flows continuously out of the bearing; hence a method is needed for supplying the pressurized oil and collecting and recirculating the oil that flows out of the bearing.

11.9 Robotics

Leonard D. Albano

The field of robotics is concerned with the design and development of mechanical devices that can be programmed to perform certain functions. Robots have been developed for a large variety of applications, such as material transport, automated assembly, and operations in controlled environments, such as high temperature and caustic surroundings. The semiconductor industry, for example, uses advanced robotic technology to fabricate IC chips. Many robots are simply relied on as a cost-effective alternative to human workers for certain highly repetitive tasks, such as spot welding and painting. For these applications, the robot must be able to undergo a range of accelerated motions while demonstrating the ability to position accurately its end effector. This must be done with minimum breakdowns and rapid repair. The control strategy involves solving the governing dynamic equations as the robot arm and end effector move through their operations. See Chapter 14 for further information.

11.10 Computer-Based Tools for Design Optimization

The range of computer applications in engineering design covers procedures from preliminary conceptual design to the production of manufacturing drawings and specifications (see Chapter 13). Most computer applications intended for production use can be classified into five or more major categories: analysis, computer-aided drafting and design, geometric modeling, data base management systems, and artificial intelligence. Traditional software for design optimization may be categorized as analytical applications, based on rational principles of mathematics and linear programming. Emerging computer-based tools for design optimization are an offshoot of research in artificial intelligence, capable of processing a variety of algorithmic, symbolic, deterministic, probabilistic, and fuzzy knowledge.

Design Optimization with Genetic Algorithms

Mark Jakiela

Introduction

One broad use of computer-based tools in design is to automate the design process itself. This is commonly done by modeling a design problem (or class of design problems) as a search problem. Such a model requires a representation and a search process. A representation is some set of parameters, either continuous or discrete, which can represent every possible design with appropriate values assigned to each parameter. We can call each possible parameter setting a design, and the set of all possible designs (possibly infinite in number) is called the design space. The search process is some method to investigate the design space and find some design that is acceptable or desired. When some acceptable designs are more desirable than others, the search process can be used to perform optimization.

Traditionally, the search and optimization technique that has been used most frequently for mechanical engineering problems has been a gradient-based search with continuous variables. When this representation and search method agrees with the problem being solved (the optimization model functions should be smooth and the objective preferably unimodal), this technique works exceedingly well. Currently, however, a variety of important problems are not amenable to this well-established technique because they cannot be modeled with only continuous variables (discrete or mixed discrete problems) and/or the objective and constraint functions do not exhibit appropriate characteristics. Other techniques are therefore required.

This subsection will provide an introduction to genetic algorithms ("GAs"), a search and optimization process that mimics the natural process of evolution. First, a brief tutorial on the fundamentals of GAs is given. This is followed by several examples drawn from a range of engineering problem domains. We hope that the variety of examples demonstrates the real strength and advantage of genetic algorithms: their versatility. They can be used to address almost any type of optimization problem. Requirements for their use are discussed in the tutorial. Some general and philosophical remarks conclude the subsection.

Genetic Algorithm Tutorial

Genetic algorithms are a simulation of a simplified process of evolution (Holland, 1975). The fundamental object of data used by a GA is referred to as a chromosome. Some number of chromosomes exist simultaneously in a population. The GA transforms one population into a succeeding population, creating a generation of children from a generation of parents. It does this with operators that are analogous to the biological operators of reproduction, recombination, and mutation. A measure of the quality of each chromosome, analogous to the fitness of a biological organism in an environment, is created and used to probabilistically select chromosomes that will serve as parents. With an increasing number of generations, the overall (e.g., average, single best) fitness of the population increases and the diversity represented in the population decreases.

For engineering purposes (see e.g., Goldberg, 1989), the chromosome is some type of encoding of the characteristics of a possible design. There is the notion, therefore, of a genotype (chromosome space) to phenotype (design space) mapping. Consider, as a simple example, a GA that is used to evolve optimal values of a set of parameters. A chromosome might be set up as a string of binary digits (i.e., bits), with concatenated substrings being binary encodings for each parameter. This is shown in Figure 11.10.1. Each bit position can be thought of as a gene and the value found there can be though of as an allele. The number of bits used to encode the parameter defines a resolution of the representation accuracy.

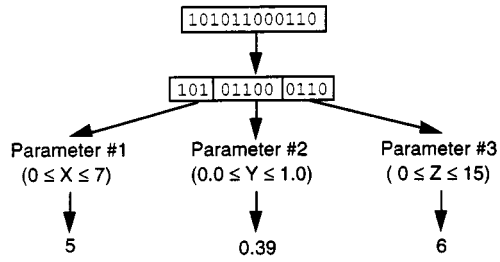

FIGURE 11.10.1 Binary chromosome representation.

Continuing with the explanatory parameter optimization example, the various processes of one iteration (i.e., generation) would proceed as follows. In a given generation, all chromosomes would be decoded to yield possible values for the parameters. These parameters would be used in an objective function of interest to yield a value measuring the quality of that set of parameters. This objective function value is used as the fitness measure of the chromosome. The probability of choosing a chromosome to serve as a parent is influenced by its fitness value: as in nature, the fittest are more likely to reproduce. Pairs of parents are randomly chosen with these weighting probabilities and mated. Copies of the parent chromosomes (i.e., reproduction) are used to build the chromosomes of the children. This is done by performing some type of recombination operation on them.

Figure 11.10.2 shows a simple one-point crossover recombination operation. First, a crossover point is randomly selected along the length of the chromosomes. Then, the front of one chromosome is appended to the back of the other chromosome and vice versa. This creates two children from two parents. Performing crossover with all the pairs of parents will create a tentative population of children that can replace the parents. The final step is to perform mutation on these children with a very low probability. One bit per 1000, for example, can be randomly chosen and inverted in value as an aid to maintaining diversity in the population. Finally, replacing the parents with the children brings the algorithm to the next generation.

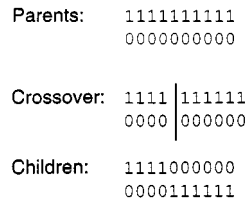

FIGURE 11.10.2 One-point crossover.

The procedure described above is commonly referred to as a “simple” GA (Goldberg, 1989) and can be thought of as a basic or canonical approach. In practice, several runtime parameters are required in its implementation. These include the probability of crossover (will two parents recombine, or will they proceed into the next generations unaltered?), the probability of mutation (on average, what fraction of genes are mutated?), a fitness scaling coefficient (an adjustment limiting the range of fitness values that

helps to prevent premature convergence), and population size (the number of chromosomes in a population). Note that a simple GA has the disadvantage of requiring a large number of function calls. This can be mitigated somewhat by using an "overlapping" population, in which a smaller number of parents will be chosen (i.e., fewer of the best) and the resulting children will replace the worst members of the parents' population. Regardless of the amount of overlap, note that a GA requires no derivative computations; the search is directed by the zeroth-order sampling of fitness function values. Because of this, a GA can perform well in ill-behaved multimodal search spaces (see Goldberg, 1989) and is relatively unlikely to become trapped in local suboptima. Equally important is the high degree of general flexibility of a chromosome representation. Although a binary encoding makes clear the general operation mechanisms and actually is used for a variety of problems, several other types of representations have been used and found to work well. In almost all cases, the evolutionary optimization strategy succeeds in producing improved designs. A variety of representations and fitness/objective functions will be described in the following examples.

Examples

Truss Parameter Selection. As a first example, we describe a problem that could readily be formulated as a continuous optimization problem (see Arora, 1989, pp. 23–31). The following genetic algorithm formulation, condensed from Wallace et al. (1995), will highlight the different approaches that are needed for a GA-based optimization.

Consider the symmetric truss shown in Figure 11.10.3. The truss is to be made of medium strength structural steel. We will assume that the load W and the truss height h are specified. The designer wishes to determine the truss base s and the inside and outside diameters of the members 1 and 2. A possible list of design variables and associated upper and lower limits for this problem are shown in Table 11.10.1. Note that the variables r_1 and r_2 allow the cross sections to vary continuously from solid rod stock to thin-walled pipe.

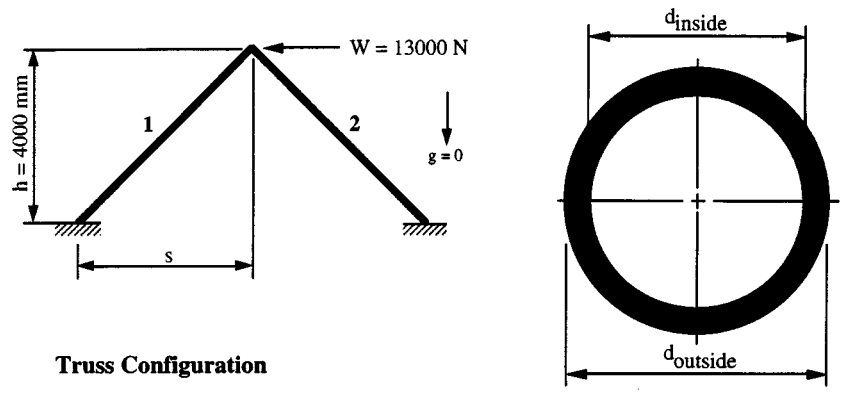

FIGURE 11.10.3 Definition of a simple two-member truss problem (gravity is assumed to be zero to simplify buckling calculations).

TABLE 11.10.1 Design Variables or Parameters to be Optimized in the Truss Problem

Design Variable	Limits
$d_{1(outside)}$	$0 < d_{1(outside)} < 100$ mm
$r_1 = d_{1(inside)}/d_{1(outside)}$	$0 < r_1 < 1$
$d_{2(outside)}$	$0 < d_{2(outside)} < 100$ mm
$r_2 = d_{2(inside)}/d_{2(outside)}$	$0 < r_2 < 1$
s	1000 mm < s < 3000 mm

In a continuous gradient-based formulation, the next step would be to model the relationships of interest as objective and constraint functions. Lagrange variables could then be introduced and the lagrangian would be subjected to the first- and second-order (constrained) optimality conditions to find a set of local optima. In addition to the upper and lower variable limits already listed, the other relationships of interest would include the normal stresses in members 1 and 2, the buckling stress in member 1, and the material cost as the objective function.

A genetic algorithm formulation does not use any derivatives. Instead, an objective function augmented with penalty terms for each potentially active constraint is used in an unconstrained optimization search. Wallace et al. (1995) formalize the notion of "design specifications" as a means to formulate such GA design optimization problems in a consistent and simplified way. The basic idea is that specifications indicate the probability that a particular performance level will be deemed acceptable. For the truss optimization the performance specifications considered are shown in Table 11.10.2. It is also possible to use other goal, objective, or preference formulations, such as the utility theory (Keeney and Raiffa, 1976).

The performance specifications on normal stress in the two members, $n_{\sigma 1}$ and $n_{\sigma 2}$, are modeled as safety factors. The specification distribution indicates that a safety factor for either member less than 1.5 is unacceptable (i.e., it will be accepted with a probability of zero, also see discussion below), and a safety factor greater than 2.0 is acceptable with certainty. To actually use this probabilistic specification, the design variables shown in Table 11.10.1 are decoded from a chromosome and used to compute values for $n_{\sigma 1}$ and $n_{\sigma 2}$, resulting in turn in two acceptance probabilities. A buckling safety factor for member 1 is treated in a similar manner (note that member 2 is always in tension). In addition to the upper and lower limits on r_1 and r_2, an additional performance specification is provided that indicates a strong preference for solid rod or thin-walled tube. This specification has, in effect, made the acceptable ranges of r_1 and r_2 discontinuous. Finally, the cost objective function is also provided to the problem as a probabilistic specification. If a full acceptance probability is achieved, the problem can be resolved with a lower material cost certainty point. In the solutions presented below, we assume that rod is 1/2 the price of pipe on a unit volume basis.

Once all individual acceptance probabilities are computed, a composite acceptance probability is used as the fitness function for the GA search. Intuitively, it seems as though the overall probability of acceptance is simply the product of the individual acceptance probabilities. Such a model does not work well in the GA-based search since a low score on a single characteristic will leave the overall design with a zero acceptance probability (in this case, the GA will consider "infeasible" designs with r_1 and/or r_2 between 0.2 and 0.7). The other characteristics of the designs could be very good and worthy of consideration in future generations. We therefore transform the multiplicative probability maximization into an additive information content minimization by taking the log of each probability term. The resulting objective is a generalized from of Suh's "Information Axiom" see Section 11.4.

$$I = \sum_{i=1}^{n} \log_2 \left(\frac{1}{p_i} \right) \tag{11.10.1}$$

where

n = number of design specifications or criteria
p_i = probability of being acceptable as defined by the i^{th} specification*
I = design information content in bits

Results for the solved truss problem are shown in Figure 11.10.4. Member 1 is under compression and thus is tubular (for buckling stiffness), while the tensile member 2 is made of less expensive rod stock. Convergence to a solution typically occurred in 80 generations requiring 2.5 sec on a Silicon Graphics

* For small values of p_i, a minimum nonzero value is used in Equation 11.10.1 to prevent division by zero.

TABLE 11.10.2 Performance Specifications and Distributions for the Truss Problem

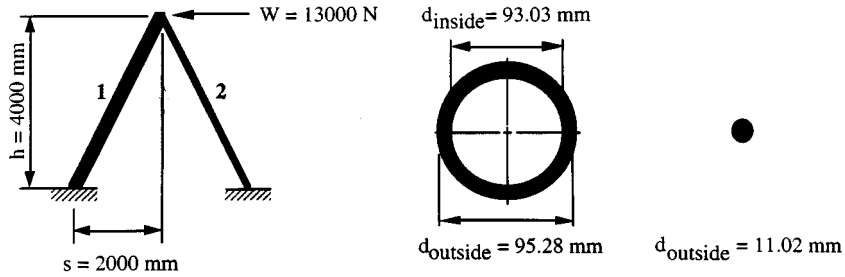

FIGURE 11.10.4 (a) Configuration of the optimized truss design.

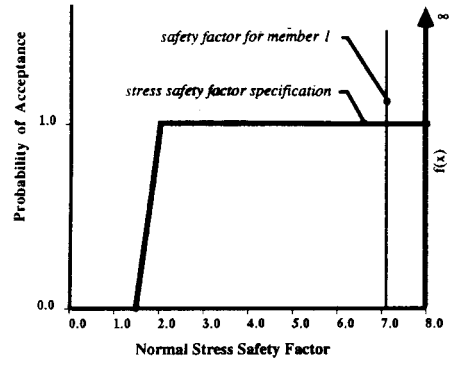
Indigo[2] Extreme[2]. This search involved the evaluation of 2400 candidate designs (30 per generation). The search space for this problem contains $\approx 1.1 \times 10^{12}$ points (five parameters at 8-bit resolution gives 2^{40} points).

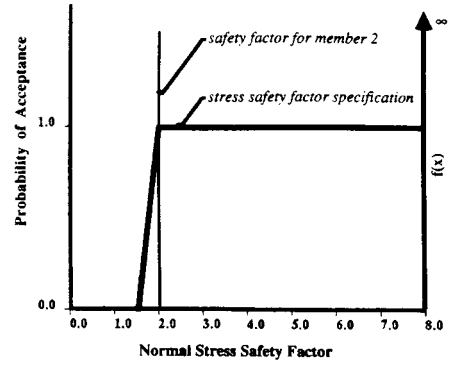
It must be noted that the search converged to this solution using rod stock for member 2 in only 17% of 60 consecutive optimizations. The more frequent solution shown in Figure 11.10.5 is nearly as good.

Topology Optimization. In this example, we will address planar stress/strain problems and the generation of optimal structural topologies. As shown in Figure 11.10.6, a design domain defines the allowable extents of any possible design. This domain is discretized into a rectangular grid, with each square element of the grid assigned a value of "material" or "void". Treating each grid element as a binary variable leads to a large combinatorial search space. The grid is used to create a finite element mesh for structural analysis. In our case, each material element contains four triangular finite elements made from the five nodes located at the four corners and the center of each material element. The genotype corresponding to this phenotype is a simple binary two-dimensional array chromosome, or a binary string, as described below.

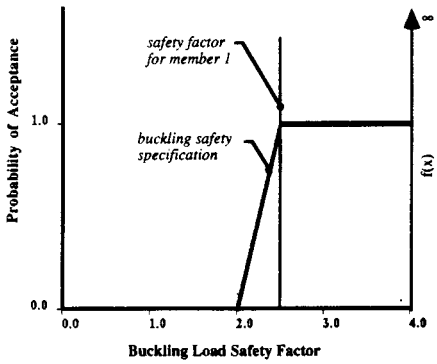
Phenotypically, certain material elements are required to always contain material, regardless of the bit value in the genome. We refer to these as material constraints. These are elements that serve as structural boundary conditions. In Figure 11.10.6, examples would be the highest and lowest elements bordering the wall, and the element that is used to apply the load. Thus, the genotype is not always a completely accurate representation of the actual structure.



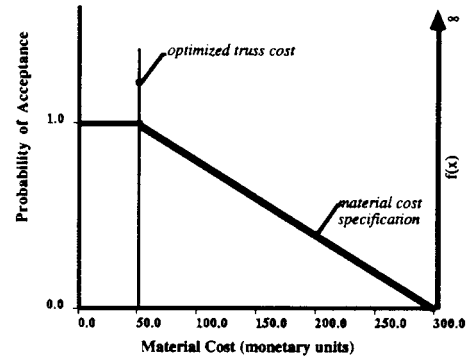
$n_{\sigma 1}$ = 7.09, $p_{acceptable}$= 1.0



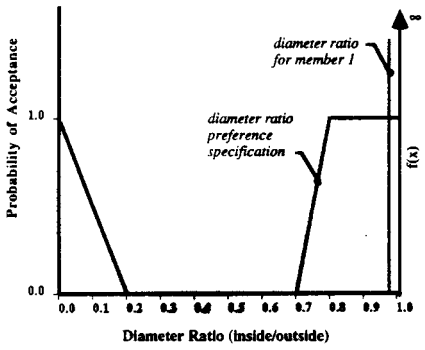
$n_{\sigma 2}$ = 2.03, $p_{acceptable}$= 1.0



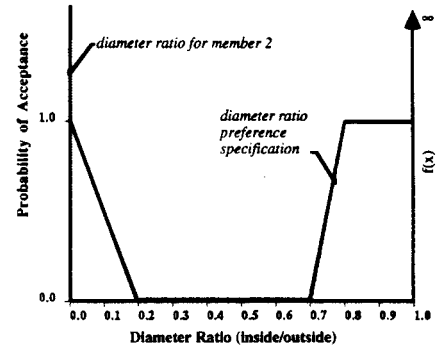
n_{B1} = 2.50, $p_{acceptable}$= 1.0



C = 51.02 units, p = .9958



r_1 = 0.9764, $p_{acceptable}$ = 1.0



r_2 = 0.0, $p_{acceptable}$ = 1.0

FIGURE 11.10.4 (b) Comparison of truss performance variables to design specifications.

The genotype can also differ from the phenotype because of connectivity analysis. Connectivity analysis requires that all elements that are included in the structural analysis be connected to other elements by at least one edge–edge connection, as opposed to only a corner connection. In addition, all elements considered connected must be linked to one of the material constraint elements by a path of edge connections. Any elements not so connected are removed from the mesh for the purposes of structural analysis: they are considered to have no stiffness and no mass. Since we are addressing planar problems, the rationale for connectivity analysis is that elements connected at corners cannot transfer

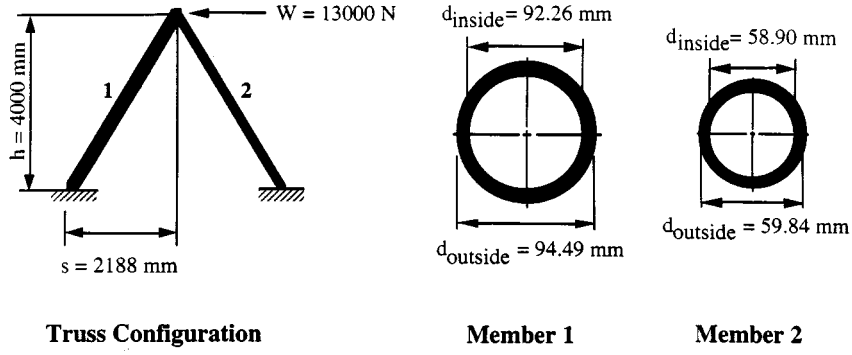


FIGURE 11.10.5 A result that did not find the better solution using cheaper rod stock for member 2. The cost is 56.73 units, giving $p_{acceptable}$ = 0.9728 (compared to 0.9958 for the solution using rod for member 2). $n_{\sigma 1}$ = 7.49, $n_{\sigma 2}$ = 2.01, $n_{\beta 1}$ = 2.50.

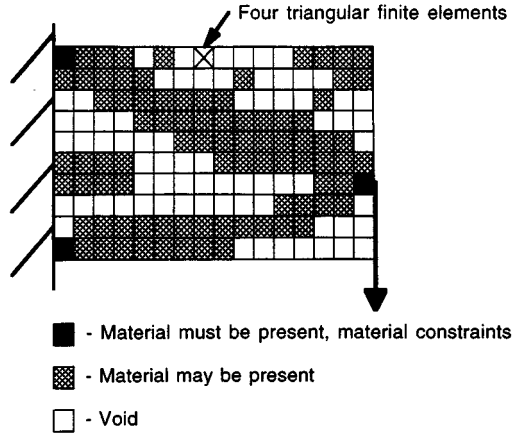

FIGURE 11.10.6 Typical design domain.

moments about those corners (since the finite element model treats corners as kinematic pin joints). It is less likely, therefore, that "disconnected" elements will contribute to enhanced structural performance. We have found that this is true empirically (see Chapman et al., 1993 for further discussion of this topic). Figure 11.10.7 shows the structure of Figure 11.10.6 after connectivity analysis. It is important to note that we do not penalize structures with more disconnected elements; we simply reward structures based upon the performance caused by their connected elements. This allows disconnected elements to in some sense be "recessive", in that crossover could cause them to combine with the (possibly disconnected) elements from another structure to yield a structure of connected elements of much improved performance.

As fitness, we are interested primarily in structural performance. In this study, this will be represented by two characteristics, mass and deflection. Generally, we wish the genetic algorithm to evolve structures that are both lightweight and deflect small amounts under a given load. The deflection, δ, will be measured with a finite element simulation and the mass m will be proportional to the number of connected material elements. These two characteristics can be used to create an unconstrained fitness, such as maximizing the following ratio:

$$\text{fitness} = \frac{1}{(\delta)(m)} \tag{11.10.2}$$

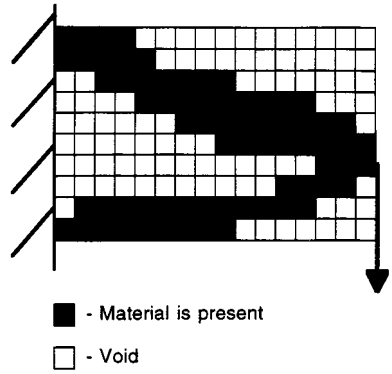

FIGURE 11.10.7 After connectivity analysis.

Alternatively, one of these characteristics can be optimized while treating the other as a constraint. Chapman and Jakiela (1995) provide some guidelines for using penalty functions for structural optimization that address many different characteristics (e.g., reducing the number of macroscopic holes in the topology).

In this example, we will use two different types of chromosomes to represent the material array. The first is a one-dimensional string chromosome made by concatenating the rows of the material array. The second is a two-dimensional binary array precisely matching the material array. For a two-dimensional array chromosome, a single-point crossover can be done as shown in Figure 11.10.8. A position is randomly selected along both dimensions, defining a point in the array. Complementary parts from both parents, diagonal about the point, contribute to the chromosomes of the children. Note that this approach can be extended to any dimension.

Parents:	1111111111 1111111111 1111111111 1111111111	0000000000 0000000000 0000000000 0000000000
Crossover:	111111 | 1111 111111 | 1111 111111 | 1111 111111 | 1111	000000 | 0000 000000 | 0000 000000 | 0000 000000 | 0000
Children:	1111110000 1111110000 0000001111 0000001111	0000001111 0000001111 1111110000 1111110000

FIGURE 11.10.8 One-point crossover on 2D arrays.

Using the binary string chromosome, Figure 11.10.9 shows results for three different material discretizations. The loading and material constraints were as described in Figure 11.10.6. All three cases display a uniformly distributed porosity with an overall shape arising implicitly from the topological optimization.

Hierarchial Shape Packing. Effective material utilization is important to virtually all industries. A specific problem in this area that can be modeled as a combinatorial optimization problem is the arrangement of planar shapes to be cut out from a piece of material so as to minimize scrap. This problem has great economic significance in the garment, sheet metal, shipbuilding, and other industries. A common instance involves a “blank” of stock material of fixed width, such as would result from a roll of material.

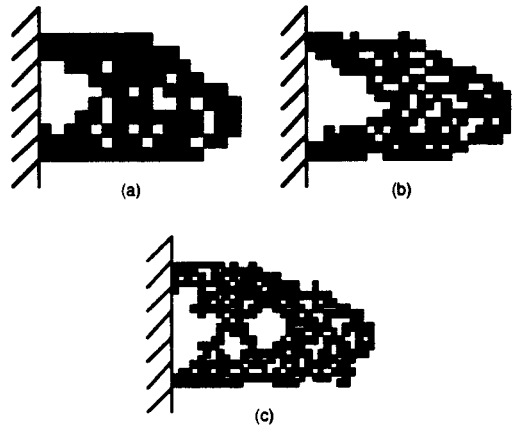

FIGURE 11.10.9 Results of (a) 10 × 16, (b) 15 × 24, and (c) 20 × 32 optimizations.

The part shapes must be arranged to minimize the length of material required from the roll. We have solved this problem with a two-level hierarchical genetic algorithm. A more complete description of this approach can be found in Dighe and Jakiela (1995a).

The approach of the lower level is shown in Figure 11.10.10. The blank of fixed width is considered analogous to a box into which the shapes will be packed. One by one, in a particular order, the shapes will be placed into the box so as to minimize the accrued height required. To pack a particular shape, a location and orientation is specified, as shown in Figure 11.10.10b, and the shape is "dropped" straight down until it contacts one of the previously packed shapes or the bottom of the box. The "dropping into a box" metaphor does not extend to include dynamic effects. Note, for example, that part D in Figure 11.10.10c would not rotate and slide to settle in a lower final position; it is in its final location for the values of x and θ chosen. Figure 11.10.10d shows a much better choice of parameters for x and θ. The lower level uses a genetic algorithm to optimize the values of x and θ and therefore is used each time a shape is packed.

The overall success of this packing strategy depends on the order in which the objects are placed. The higher-level GA searches the space of possible orders to find those that work well with the packing strategy of the lower-level GA. The chromosome representation for a packing order, and associated crossover and mutation operators are shown in Figure 11.10.11. The chromosome is simply a list of part labels, with the left-to-right order indicating the packing order. If we try to perform a single point crossover on these strings, Figure 11.10.11 shows that invalid offspring often result. Some labels are missing and others appear more than once. To remedy this problem, we use a simple order-based crossover as shown in Figure 11.10.11b. For positions to the left of the crossover point, each child receives the order from one of the parents. The order of the remaining parts is obtained from the order in which those remaining parts appear in the other parent's chromosome. Finally, mutation simply changes the location of a part label, usually by moving it to the left.

Note that this crossover operator tends to not disrupt the leftmost parts of the chromosomes. In particular, without mutation, the very leftmost position in any chromosome must have a label that was present in that position in the initial population. Hence, mutation is performed with a leftward bias.

Figure 11.10.12 shows some typical arrangements produced using this approach. Figures 11.10.12a and 11.10.12b show two configurations in the same optimization run. These ten objects were chosen such that their characteristic sizes varied by about a factor of 10. Figure 11.10.12 shows a jigsaw puzzle that we have used as a benchmark test for the packing system. Taking into account deliberate gaps between the parts, the density of the correct jigsaw arrangement is 0.92, not 1.00. Two arrangements from the same optimization run are shown in Figures 11.10.12d and 11.10.12e. It is clear that the simple "height-based" lower-level GA cannot match a human's visual processing and reasoning ability.

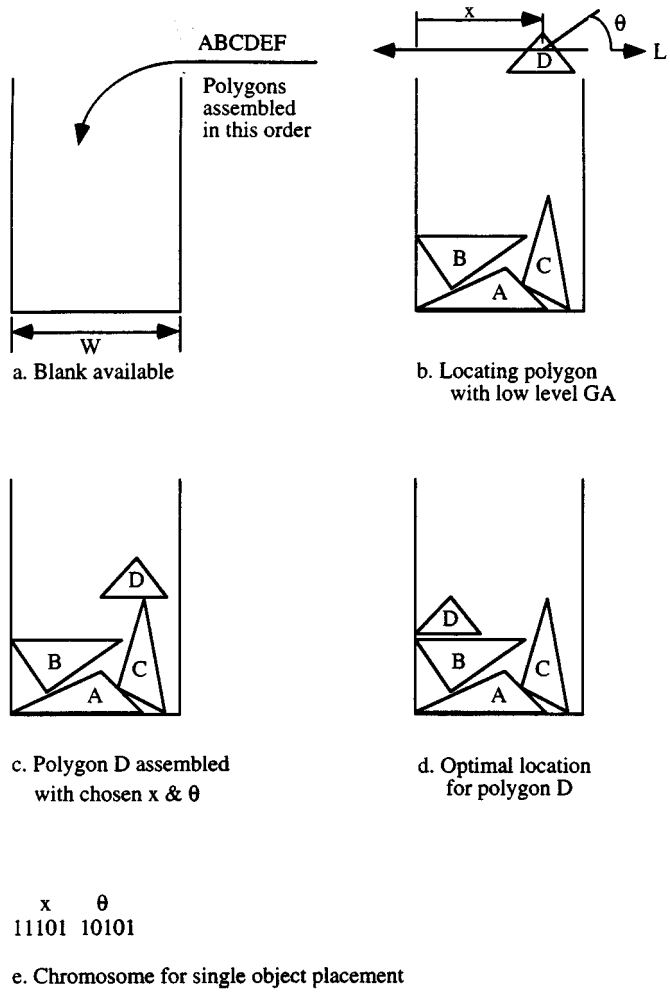

FIGURE 11.10.10 Lower-level GA for hierarchical shape packing.

Integrating a GA-based search with heuristics derived from observation of human experts is the subject of ongoing work in this area (see Dighe and Jakiela, 1995b).

Optimization in Multidisciplinary Design

Kemper Lewis, Farrokh Mistree, and J. R. Jagannatha Rao

Introduction

The design of complex systems is a difficult task of integrating disciplines, each with their own analysis, synthesis, and decision process. Optimizing such a system on a global scale is realistically impossible, but finding a solution that is "good enough" and robust is achievable. Several approaches to formulating and solving a multidisciplinary design problem have arisen in a rather ad hoc fashion since the inception of multidisciplinary design optimization (MDO). These approaches include single-level and multilevel formulations, hierarchical and nonhierarchical system decomposition methods, and numerous optimization and analysis processes and approaches at the system and subsystem levels. Designers are referred to as decision makes and objectives as goals or rewards. With only one decision maker, the problem becomes a scalar or vector optimization problem. But in MDO, many decision makers may exist, and each decision maker's strategy to optimize his/her rewards could depend on the strategies and decisions of other decision makers. The modeling of strategic behavior based on the actions of other individuals is known as a *game*. Therefore, the focus in this section is on problems characterized by

- Single decision makers who have multiple rewards
- Multiple decision makers who have multiple rewards

This focus in optimization theory is shown as the shaded region in Figure 11.10.13. Typical courses in optimization focus on the upper-left quadrant, namely, scalar optimization problems with one objective and one decision maker. In this section, the focus is on the other three quadrants as a means to expand the application of optimization theory to problems that frequently occur in engineering design.

Classification of MDO Formulations

Simultaneous and Nested Analysis and Design. With the advent of MDO and its various applications, a structure of problem approaches and formulations is necessary. In Cramer et al. (1994) and, more recently, Balling and Sobieski (1994) and Lewis and Mistree (1995), various classes and classifications of problem formulations are presented. Figure 11.10.14 is a generic representation of a coupled, three-discipline system.

Depending on the level of analysis, the modules in Figure 11.10.14 may refer to disciplines, components, or processes. It is the decomposition of the system, subsystem coupling and solution, and system synthesis that pose major research and application problems in MDO. The terms used in the figure, as well as other common terms, and are defined below.

s_1, s_2, s_3: disciplinary *state variables* which comprise the *state equations*
y_1, y_2, y_3: the *state equations*
r_1, r_2, r_3: *residuals* in the state equations
y_{12}, y_{13}, y_{21}, y_{23}, y_{31}, y_{32}: *coupling functions*, y_{ij} contains those functions computed in discipline i which are needed in discipline j

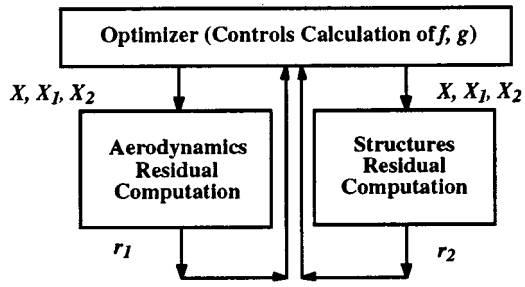

FIGURE 11.10.15 Single-SAND-SAND formulation.

$y^*_{12}, y^*_{13}, y^*_{21}, y^*_{23}, y^*_{31}, y^*_{32}$: *coupling variables*
x: *system design variables* needed by more than one discipline
x_1, x_2, x_3: *disciplinary design variables*
g_1, g_2, g_3: *design constraint functions*
f_1, f_2, f_3: *design objective functions*

The primary task at hand is summarized as follows: *Determine the values of the design, state, and coupling variables which satisfy the state equations, the coupling equalities, the design constraints, and the design objective functions.*

Based on this, six classifications for fundamental approaches to MDO problem formulation and solution are presented by Balling and Sobieski, which depend on three criteria:

1. System vs. multilevel decomposition
2. Simultaneous (SAND) vs. nested analysis and design (NAND) at the *system* level.
3. Simultaneous (SAND) vs. nested analysis and design (NAND) at the *subsystem* or *discipline* level.

At the discipline level, SAND implies that the disciplinary design and state variables are determined simultaneously by the optimizer, while NAND implies that the optimizer determines only the disciplinary design variables and requires determination of the state variables at each iteration. At the system level, SAND implies that the system design variables and coupling variables are determined simultaneously by the system optimizer, while NAND implies that the system optimizer determines only the system design variables and requires calls to a system analysis routine to determine the coupling variables at each iteration. The "optimizers" at the system level or discipline level could be gradient based or heuristic in nature, depending on the problem formulation. Further classifications can be generated if these approaches are combined or linked sequentially within one design problem.

Each approach has a three-part name consisting of the overall decomposition descriptor, the solution approach at the system level, and the solution approach at the subsystem level. The first part indicates whether the approach is a single-level or multilevel approach. The middle and last parts of the name indicate whether the SAND or NAND approach is used at the system and discipline levels, respectively.

Example

These terms are illustrated based on a simple example from aeroelastic MDO problem in Cramer et al. (1994). This aeroelastic problem involves two disciplines, aerodynamics and structures. This problem is extremely difficult, as the solution of either of these disciplines *alone* involves heavy analysis and computation. For simplicity, it is assumed that a *single-level* scheme is to be used. The first formulation choice is SAND or NAND at the system level. If a SAND formulation is used, the discipline-level formulation must be determined. These formulations are illustrated below.

Single-SAND-SAND. In this formulation, feasibility is *not* sought for the analysis problem in any sense until convergence in the solver is reached. The analysis "codes" for aerodynamics and structures in this formulation perform a simple function; they evaluate the *residuals* of the analysis equations, rather than solving some set of equations. This is illustrated in Figure 11.10.15. The *optimizer* controls the calculation of the objective functions, f, and the constraints, g, based on the residuals, r_i, from the disciplines. The optimizer sends system and disciplinary design variables, X and X_i, to the disciplinary analysis routines.

Single-SAND-NAND. In this formulation, feasibility *is* enforced for each individual discipline, while the optimizer drives the individual disciplines toward multidisciplinary feasibility and optimality by controlling the coupling functions between the disciplines. This is illustrated in Figure 11.10.16. The optimizer sends design and coupling variables, X and y^*_{ij}, to the disciplinary analysis routines, while these routines return coupling functions, y_{ij}, which are functions of the design variables and the disciplinary state variables, y_i.

Single-NAND-NAND. In this formulation, multidisciplinary feasibility is required at each iteration of the optimizer. Therefore, an aeroelastic analysis solver combines the information from the aerodynamics

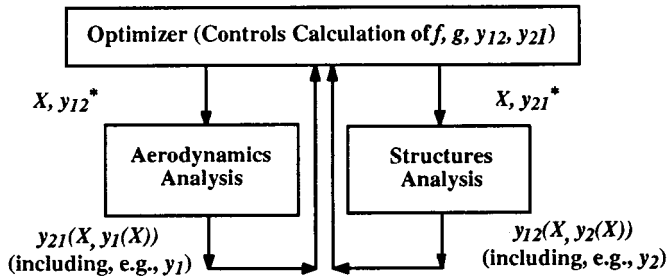

FIGURE 11.10.16 Single-SAND-NAND formulation.

and structures disciplines and ensures that the two disciplines are feasible concurrently. This is illustrated in Figure 11.10.17. The optimizer only controls the objective functions and constraints, while the coupling functions are handled by the aeroelastic analysis solver which becomes a "black box" from the perspective of the optimization code. In each discipline, an analysis code solves a set of equations. The resulting *state equations* are fed into the other disciplines. This process continues until convergence among the disciplines, and the optimizer is once again invoked.

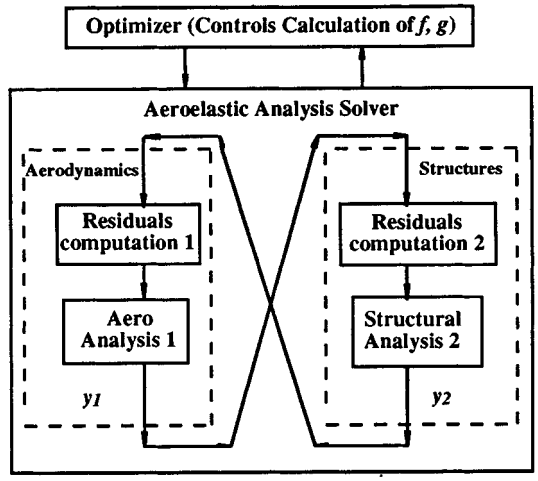

FIGURE 11.10.17 Single-NAND-NAND formulation.

Modeling Design Decisions: The Mathematical Programming Background

Decision-based design (DBD) is offered as a starting point for the creation of design methods that are based on the notion that the principal role of an engineer in the design of a product or process is to make decisions. Therefore, the process of design in its most basic sense is a series of decisions.

It is recognized that the implementation of DBD can take many forms; one implementation is the decision support problem (DSP) technique. Within the DSP technique there exist three types of decisions a designer can make: selection, compromise, or heuristic. In this section, the focus is on the compromise DSP, which is used to model multiobjective trade-offs in the solution of a mathematical model.

Compromise DSP. A compromise DSP is a hybrid formulation that incorporates concepts from both traditional mathematical programming and goal programming, and makes use of some new ones (Mistree et al., 1993). It is similar to goal programming in that the multiple objectives are formulated as system goals (involving both system and deviation variables) and the deviation function is solely a function of the goal deviation variables. This is in contrast to traditional mathematical programming where multiple objectives are modeled as a weighted function of the system variables only. The concept of system

constraints, however, is retained from the traditional constrained optimization formulation. Special emphasis is placed on the bounds on the system variables, unlike in traditional mathematical programming and goal programming. In effect the traditional formulation is a subset of the compromise DSP — an indication of the generality of the compromise formulation. The compromise DSP is stated in words as follows:

Given

An alternative that is to be improved through modification
Assumptions used to model the domain of interest
The system parameters
All other relevant information

n	Number of system variables
p + q	Number of system constraints
p	Equality constraints
q	Inequality constraints
m	Number of system goals
$g_i(X)$	System constraint function

$$g_i(\underline{X}) = C_i(\underline{X}) - D_i(\underline{X})$$

$f_k(d_i)$	Function of deviation variables to be minimized at priority level k for the preemptive case
W_i	Weight for the Archimedean case

Find

The values of the independent *system variables* (they describe the physical attributes of an artifact)

$$X_j \quad j = 1,\ldots, n$$

The values of the *deviation variables* (they indicate the extent to which the goals are achieved)

$$d_i^-, d_i^+ \quad i = 1,\ldots, m$$

Satisfy

The *system constraints* that must be satisfied for the solution to be feasible, there is no restriction placed on linearity or convexity

$$g_i(\underline{X}) = 0; \quad i = 1,\ldots, p$$

$$g_i(\underline{X}) \geq 0; \quad i = p+1,\ldots, p+q$$

The *system goals* that must achieve a specified target value as far as possible; there is no restriction placed on linearity or convexity

$$A_i(\underline{X}) + d_i^- - d_i^+ = G_i; \quad i = 1,\ldots, m$$

The lower and upper *bounds* on the system

$$X_j^{\min} \leq X_j \leq X_j^{\max}; \quad j = 1,\ldots, n$$

$$d_i^-, d_i \geq 0 \quad \text{and} \quad d_i^- \cdot d_i^+ = 0$$

Minimize

The *deviation function* which is a measure of the deviation of the system performance from that implied by the set of goals and their associated priority levels or relative weights:

Case a: Preemptive (lexicographic minimum)

$$Z = \left[f_1\left(d_i^-, d_i^+\right), \ldots, f_k\left(d_i^-, d_i^+\right) \right]$$

Case b: Archimedean

$$Z = \sum_{i=1}^{m} W_i\left(d_i^- + d_i^+\right); \qquad \sum W_i = 1; \quad W_i \geq 0$$

A graphical representation of a two-variable compromise DSP is shown in Figure 11.10.18. The difference between a system variable and a deviation variable is that the former represents a distance in the i^{th} dimension from the origin of the design space, whereas the latter has as its origin the surface of the system goal. The value of the i^{th} deviation variable is determined by the degree to which the i^{th} goal is achieved. It depends upon the value of $A_i(X)$ alone (Since G_i is fixed by the designer), which in turn is dependent upon the system variables X. The set of discrete variables can be continuous, Boolean, or a combination of types.

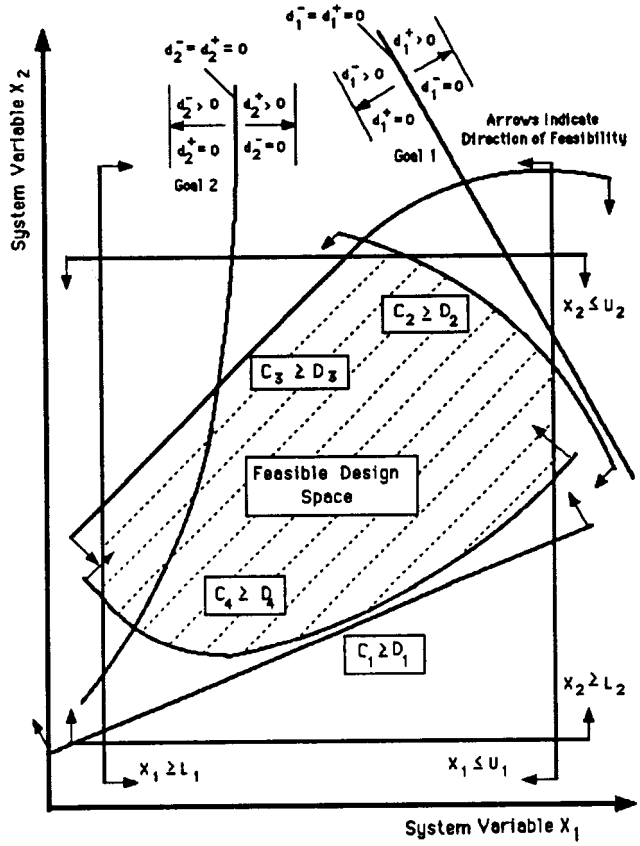

FIGURE 11.10.18 The compromise DSP.

The compromise DSP is fundamentally different from the traditional mathematical optimization model. This difference is depicted in Figure 11.10.19 where the optimization model on the left occurs when designer's aspirations can be met by the system achievement and therefore an optimum can be found. But when a designer's aspirations do not overlap with the actual achievements, a solution which is "good enough" or *satisficing*[*] must be found. This is depicted and modeled in the compromise DSP on the right of Figure 11.10.19. When the aspiration space overlaps with the feasible design space (center of Figure 11.10.19), the optimization model and compromise DSP are the same.

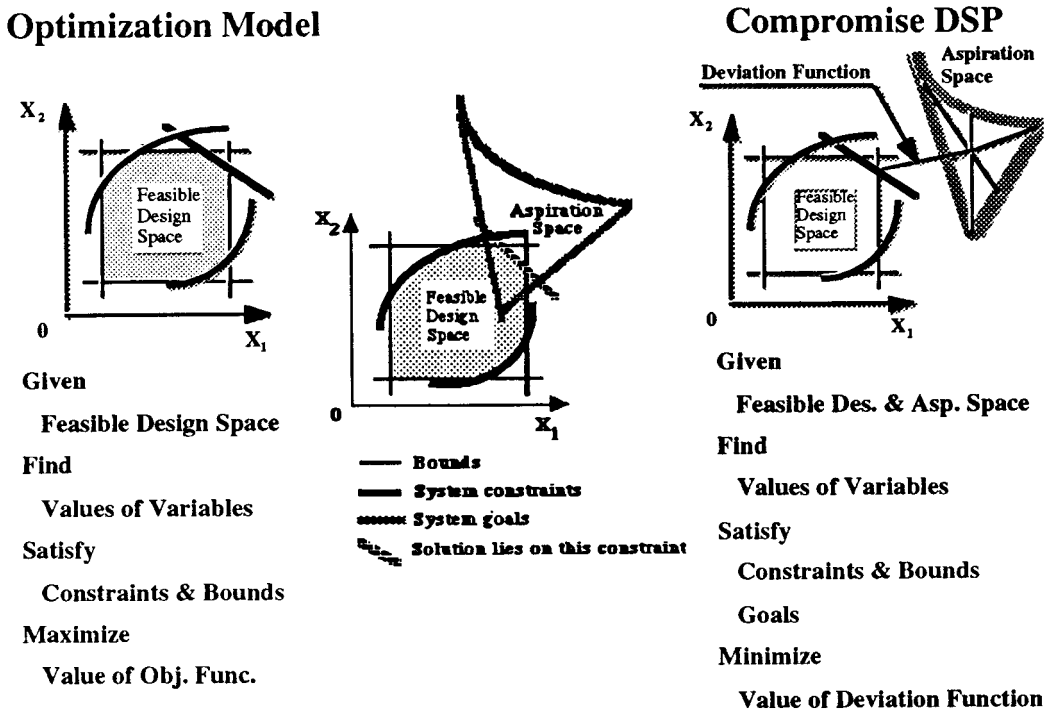

FIGURE 11.10.19 The optimizing and satisficing models.

Deviation Variables and Goals. In a **goal** one can distinguish the aspiration level, G_i, of the decision maker and the actual attainment, $A_i(X)$, of the goal. Three conditions need to be considered:

1. $A_i(X) \le G_i$; one wishes to achieve a value of $A_i(X)$ that is equal to or less than G_i.
2. $A_i(X) \ge G_i$; one wishes to achieve a value of $A_i(X)$ that is equal to or greater than G_i.
3. $A_i(X) = G_i$; one wishes to achieve a value of $A_i(X)$ equal to G_i.

Next, the concept of a **deviation variable** is introduced. Consider the third condition, namely, one would like the value of $A_i(X)$ to equal G_i. The deviation variable is defined as

$$d = G_i - A_i(\underline{X})$$

The deviation variable d can be negative or positive. In effect, a deviation variable represents the distance (deviation) between the aspiration level and the actual attainment of the goal. Considerable simplification

[*] Satisficing — not the "best", but "good enough" (the first use of this term, in the context of optimization, is attributed to Herbert Simon (Simon, 1982).

of the solution algorithm is affected if one can assert that all the variables in the problem being solved are positive. Hence, the deviation variable d is replaced by two variables:

$$d = d_i^- - d_i^+$$

where

$$d_i^- \cdot d_i^+ = 0 \quad \text{and} \quad d_i^-, d_i^+ \geq 0$$

The preceding ensures that the deviation variables never take on negative values. The product constraint ensures that one of the deviation variables will always be zero. The system goal becomes

$$A_i(\underline{X}) + d_i^- - d_i^+ = G_i; \quad i = 1, 2, \ldots, m \tag{11.10.3}$$

subject to

$$d_i^-, d_i^+ \geq 0 \quad \text{and} \quad d_i^- \cdot d_i^+ = 0 \tag{11.10.4}$$

If the problem is solved using an algorithm that provides a vertex solution as a matter of course, then the constraint is automatically satisfied making its inclusion in the formulation redundant. Since some algorithms use solution schemes which provide a vertex solution, it is assumed that this constraint is satisfied. For completeness this constraint is included in the mathematical forms of the compromise decision support problem given previously in this chapter and for brevity will be omitted from all subsequent formulations.

Note that a goal (Equation 11.10.3) is always expressed as an equality. When considering Equation (11.10.3), the following will be true:

if $A_i \leq G_i$ **then** $d_i^- > 0$ and $d_i^+ = 0$.
if $A_i \geq G_i$ **then** $d_i^- = 0$ and $d_i^+ \geq 0$.
if $A_i = G_i$ **then** $d_i^- = 0$ and $d_i^+ = 0$.

How are the three conditions listed using Equation (11.10.3)?

1. To satisfy $A_i(X) \leq G_i$, the positive deviation d_i^+ must be equal to zero. The negative deviation d_i^- will measure how far the performance of the actual design is from the goal.
2. To satisfy $A_i(X) \geq G_i$, the negative deviation d_i^- must be equal to zero. In this case, the degree of overachievement is indicated by the positive deviation d_i^+.
3. To satisfy $A_i(X) = G_i$, both deviations, d_i^- and d_i^+, must be zero.

At this point it is established what is to be minimized. In the next section means for minimization of the objective in goal programming are introduced.

The Lexicographic Minimum and the Deviation Function. The objective of a traditional single objective optimization problem requires the maximization or minimization of an objective function. The objective is a function of the problem variables. In a goal programming formulation, each of the objectives is converted into a goal (Equation 11.10.3) with its corresponding deviation variables. The resulting formulation is similar to a single objective optimization problem but with the following differences:

The objective is always to minimize a function.
The objective function is expressed using deviation variables only.

The objective in the goal programming formulation is called the achievement function. As indicated earlier the deviation variables are associated with goals and hence their range of values depend on the

goal itself. Goals are not equally important to a decision maker. Hence to effect a solution on the basis of preference, the goals may be rank-ordered into priority levels.

One should seek a solution which minimizes all unwanted deviations. There are various methods of measuring the effectiveness of the minimization of these unwanted deviations. The *lexicographic minimum* concept is a suitable approach, and it is defined as follows (see Ignizio, 1982; Ignizio, 1985).

Given an ordered array $\boldsymbol{f} = (f_1, f_2, \ldots, f_n)$ of nonnegative elements f_k, the solution given by $f^{(1)}$ is preferred to $f^{(2)}$ iff

$$f_k^{(1)} < f_k^{(2)}$$

and all higher-order elements (i.e., $f_1, \ldots, f_{k-1}$) are equal. If no other solution is preferred to $\boldsymbol{f}$, then $\boldsymbol{f}$ is the lexicographic minimum.

As an example, consider two solutions, $\boldsymbol{f}^{(r)}$ and $\boldsymbol{f}^{(s)}$, where

$$\boldsymbol{f}^{(r)} = (0,\ 10,\ 400,\ 56)$$

$$\boldsymbol{f}^{(s)} = (0,\ 11,\ 12,\ 20)$$

In this example, note that $\boldsymbol{f}^{(r)}$ is preferred to $\boldsymbol{f}^{(s)}$. The value 10 corresponding to $\boldsymbol{f}^{(r)}$ is smaller than the value 11 corresponding to $\boldsymbol{f}^{(s)}$. Once a preference is established, then all higher-order elements are assumed to be equivalent.

The Use of Coupled DSPs in Modeling and Solving Systems

Coupled compromise DSPs can be used to model multiobjective problems. These types of problems may involve the analysis and synthesis of problems from multiple disciplines, but in this section, the primary notion is *shared* design variable vectors. It is common in the design of complex systems, such as aircraft, for multiple design teams to include the same design variables in their design process. For example, consider the design of aircraft. The design variable, wing area, is used by the aerodynamics group to control the lift force. It is used by the structural group to control the structural framework of the wing. It is used by the propulsion group to control the amount of fuel needed. It seems advantageous to model systems this way, but this introduces an added level of complexity in a system model. Different disciplines are also dependent on the decisions made in other disciplines. Therefore, another focus is modeling the coupling of state variables between disciplines.

To begin the discussion, suppose that a designer (i.e., a decision maker) is investigating a typical engineering system such as a load-bearing structure, a high-speed mechanism, or an automotive transaxle. Assuming that this system is unambiguously described by a finite-dimensional variable vector $x \in \mathcal{R}^n$ (includes both the so-called "state" and "design" variables), then the general descriptive mathematical model can be characterized by a set of *parameters* p, which are fixed quantities over which the designer has no control, and the multifunction X, which represents the state equations and variational inequalities (derived from the natural laws such as the conservation principles) as well as the performance constraints for this system. Numerical approaches to such problems have been studied in Outrata (1990) and Outrata and Zowe (1995). If the only goal of the designer is to obtain a satisfying or a feasible design, then his/her task is simply to find a design x^o that satisfies the constraints and meets the goals as close as possible for a given p. On the other hand, if the designer wishes to find the design which minimizes the deviation between the goal achievement and aspiration with respect to several objective functions such as $f_i(x,p)$, i = 1, …, r, then the problem is to find a design x* that solves the following multiobjective formulation:

$$\underset{x \in X(p) \subset \Re^n}{\text{minimize}}\, d(x,p) = \left\{ d_1(x,p), \ldots, d_r(x,p) \right\} \tag{11.10.5}$$

where d_i represents the deviation from the objective f_i, to its target value, f_{iTV}. In other words, the problem is to minimize the deviation between what a designer wants and what a designer can achieve.

At this general level of discussion, one readily asserts that a model such as in Equation (11.10.5) is the typical starting point for much of the current education, research, and practice in mechanical systems modeling and applied optimization, and yet in specific design instances, this assertion should be boldly challenged. For example, since the designer only controls *x* and another foreign party controls *p*, how is *p* chosen? Can the designer assume that the foreign decision maker will always select the vector that is most advantageous to the design (as is tacitly assumed, it is argued later, by most justifications of existing engineering models)? If not, how should the designer respond to this conflict? A two-player strategic game has just been described (see, e.g., Von Neumann and Morgenstern, 1944; Aubin, 1979; Dresher, 1981) where one player controls *x* and the other player controls *p* and where *p* represents all decisions which are outside the scope of the designer. By the classical definition, a "game" consist of multiple decision makers or players (or designers, in this case) who each control a specified subset of system variables and who seek to minimize their own deviation functions subject to their individual constraints. To continue this argument further, consider a typical schedule of a product design and manufacture, as shown in Figure 11.10.20.

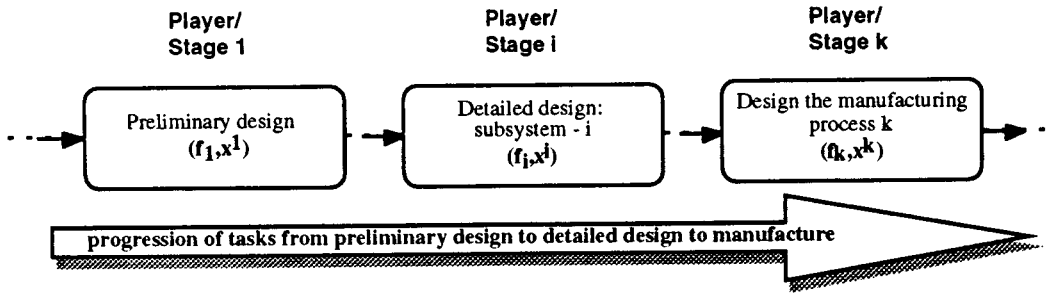

FIGURE 11.10.20 Different stages in a design time-line.

The decision makers at each of the several stages or stations in the time line are referred to as different players, even though they could be the same human designer. Each of the players controls and minimizes his own deviation function.

In the context where multiple decision makers collectively influence the final design, one must pose the following question: what mathematical formulation is appropriate for modeling the system in order to study the decisions made by *more than one player along the above time line?* Clearly, the conventional model of Equation (11.10.5) does not adequately represent the multiplayer scenario of the time line shown in Figure 11.10.20. This inadequacy is most acute when the players engage in strategic behavior which is anything other than total cooperation (e.g., dominance and noncooperation, among others). Thus, the major point of departure can be summarized as: (1) instead of formulating a single mathematical model at a single stage of the time line, as is done conventionally, these models represent one or more decision makers who determine the final design; and (2) each of the r decision makers has his own objective functions and one player's decision is influenced by the other. Thus, the final design could very well depend on whether the players compete, cooperate, or dominate one another — thus necessitating a study of the strategic interaction between the players. In short, a goal here is to model the design of Figure 11.10.20 as a *strategic game*, this figure perhaps being representative of a general engineering system design process at a high level of abstraction.

Mathematical modeling of such strategic behavior, where one decision maker's action depends on decisions by others, is well-established in wide-ranging applications from economics, business, and military (Aubin, 1979; Dresher, 1981; Fudenberg and Tirole, 1991; Mesterton-Gibbons, 1992). Such models are widely used in designing markets and auctions, and in predicting the outcome of encounters between competing companies or trading nations. As specific examples, consider automobile manufac-

turers who interact strategically in order to set prices and production schedules of cars; or the strategic behavior that occurs between drivers as they try to pass each other on a busy undivided highway.

12.1 Metals

Victor A. Greenhut

Introduction — Nature and Properties of Pure Metals

Metals achieve engineering importance because of their abundance, variety, and unique properties as conferred by metallic bonding. Twenty-four of the 26 most abundant elements in the Earth's crust are

0-8493-9418-X/98/$0.00+$.50

metals, with only two nonmetallic elements, oxygen and silicon, exceeding metals in frequency. The two most abundant metallic elements, iron (5.0%) and aluminum (8.1%), are also the most commonly used structural metals. Iron is the most-used metal, in part because it can be extracted from its frequently occurring, enriched ores with considerably less energy penalty than aluminum, but also because of the very wide range of mechanical properties its alloys can provide (as will be seen below). The next 15 elements in frequency, found at least in parts per thousand, include most common engineering metals and alloys: calcium (3.6%), magnesium (2.1%), titanium (0.63%), manganese (0.10), chromium (0.037%), zirconium (0.026%), nickel (0.020%), vanadium (0.017%), copper (0.010%), uranium (0.008%), tungsten (0.005%), zinc (0.004%), lead (0.002%), cobalt (0.001%), and beryllium (0.001%). The cost of metals is strongly affected by strategic abundance as well as secondary factors such as extraction/processing cost and perceived value. Plain carbon steels and cast irons, iron alloys with carbon, are usually most cost-effective for ordinary mechanical applications. These alloys increase in cost with alloying additions.

A variety of metal properties are unique among materials and of importance technologically. These properties are conferred by metallic bonding, in which the “extra” outer valence electrons are “shared” among all metal ion cores. This bonding is different from other types of solids in that the electrons are free to acquire energy, and the metallic ions are relatively mobile, and quite interchangeable with regard to their positions in the crystal lattice, the three-dimensional repeating arrangement of atoms in a solid. This section of the chapter will concentrate on the mechanical properties of metals, for which metallic bonding provides ductile deformation, i.e., shows substantial permanent shape change under mechanical load prior to fracture. The ductility of metals at low and moderate temperature makes them formable as solids and also confers safety (fracture toughness) in mechanical applications, in that under impact loading the metal will absorb energy rather than break catastrophically.

Metals are good conductors of heat and electricity because thermal and electrical energy can be transferred by the free electrons. These two properties tend to parallel each other. For example, the pure noble metals (e.g., copper, silver, gold, platinum) are among the best electrical and thermal conductors. As a broad generalization, metallic elements with an odd number of valence electrons tend to be better conductors than those with an even number. These behaviors can be seen in Table C.6A of the Appendix. Thermal conductivity and electrical resistivity (inverse conductivity) have a reciprocal relationship and follow the indicted trends. As metals are alloyed with other elements, are deformed, contain multiple phases, and contain crystalline imperfections, their electrical and thermal conductivity usually decreases significantly from that of the pure, perfect, unalloyed metal. The specific values of thermal conductivity and electrical resistivity for several common engineering alloys is given in Table C.6B of the Appendix. Electrical and thermal conductivities tend to decrease proportionately to each other with increasing temperature for a specific metal. These conductivities may be altered if heating introduces metallurgical change during annealing (see subsection on mechanical forming).

Metals are opaque to and reflective of light and most of the electromagnetic spectrum, because electromagnetic energy is transferred to the free electrons and immediately retransmitted. This gives most metals a characteristic reflective “metallic color” or sheen, which if the metal is very smooth yields a mirror surface. At very short wavelengths (high energies) of the electromagnetic spectrum, such as X rays, the radiant energy will penetrate the material. This is applied in radiographic analysis of metals for flaws such as cracks, casting porosity, and inclusions.

Metals are almost always crystalline solids with a regular repeating pattern of ions. A number of atomic-level defects occur in this periodic array. A large number of atomic sites are “vacancies” (point defects) not occupied by atoms (Figure 12.1.1). The number and mobility of vacant sites increase rapidly with temperature. The number and mobility of vacancies in metals are quite high compared with other materials because there are no charge balance or local electron bond considerations. This means that solid metal can undergo significant changes with only moderate thermal excitation as vacancy motion (diffusion) provides atom-by-atom reconstruction of the material. Vacancies allow solid metals to homogenize in a “soaking pit” after casting and permit dissimilar metals to diffusion bond at moderate temperatures and within short times. In the process, substitutional metallic atoms (ions) shown in Figure

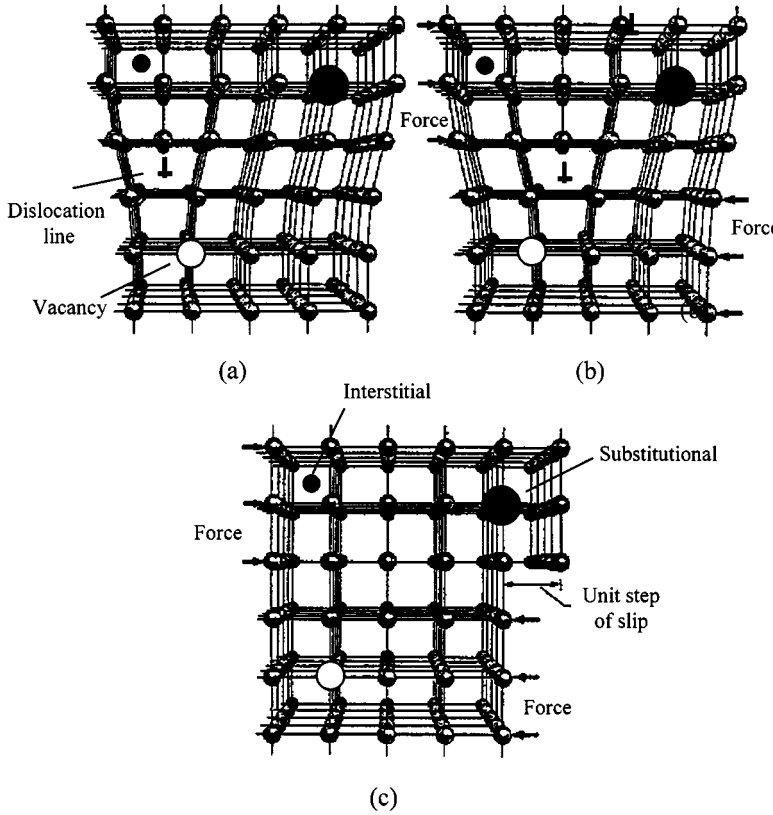

FIGURE 12.1.1 Point defects exist in the metal crystal structure: vacancies, substitutional atoms (ions), ions, and interstitial atoms (ions). A dislocation (⊥) line moves under an applied shear force until a surface step of plastic deformation is produced on the surface.

12.1.1 move via vacancy jumps while small interstitial atoms such as carbon (Figure 12.1.1) move from interstice to interstice. Vacancy mobility gives rise to major changes in mechanical properties during annealing (see subsection on mechanical forming) and is an important mechanism in creep deformation under load at elevated temperature (see subsection on corrosion and environmental effects).

At a slightly larger level, linear atomic packing defects known as dislocations, give rise to the ability of metallic materials to deform substantially under load. When a plane of atoms in the lattice ends, it gives rise to an edge "dislocation" such as that shown in Figure 12.1.1a. Such a dislocation can break and remake bonds relatively easily in a metal and thereby shift an atomic distance (Figure 12.1.1b). The process can continue until a surface step results. Many dislocations moving in this fashion can give rise to significant shape change in the material at moderate stresses. The onset of such massive dislocation motion in a metal is termed *yield* and occurs at the "yield stress" or "elastic limit" (see subsection on strength and deformation). Dislocations explain why the yield stress can be as low as about 100 Pa (10 psi) in a pure, pristine, single crystal of metal. Dislocations also explain how a fine-grained polycrystalline metal containing many microstructural features which interfere with dislocation motion may have a yield stress as great as 10 gPa (1000 ksi). Dislocations interact with each other in three dimensions and multiply. Therefore, dislocation motion can cause a major increase in dislocation density and yield stress, termed *cold work*. Vacancies can rearrange these dislocation tangles, restoring the metal to a condition closer to its original state, thereby lowering the yield stress. This can occur at moderate annealing temperatures (see subsection on mechanical forming).

The interaction of deformation, alloying elements, temperature, and time can cause a wide variety of microstructures in a solid metal down to near atomic levels with mechanical (and other) properties which

can vary over a very wide range. It is possible to manipulate the properties of a single metal composition over a very wide range in the solid state — a behavior which can be used to mechanically form a particular metal and then use it in a demanding load-bearing application. The use of minor alloying additions can provide a yet wider range of properties with appropriate thermal and mechanical treatment.

Casting

One of the important technological advantages of metals is their ability to incorporate a wide variety of secondary elements in a particular metal and thereby create alloys of the metal. Alloying can increase the strength of a metal by several orders of magnitude and permit the strength and ductility to be varied over a wide range by thermal and/or mechanical treatment, resulting in ease of mechanical forming or resistance to deformation.

Several metal phases may exist together in the solid as grains (crystals), or secondary phases may occur as smaller entities on grain (intercrystal) boundaries or within grains. Often the strengthening phase is submicroscopic and cannot be detected by optical metallography (reflection optical microscopy). The size and distribution of secondary phases is manipulated by thermomechanical (thermal and/or mechanical) treatment of the solid metal as well as the original casting procedure.

Casting methods include expendable mold casting (investment/precision, plaster mold, dry sand, and wet sand casting), permanent mold casting (ingot, permanent mold, centrifugal, and die casting), and continuous casting (direct chill and "splat" casting). These are listed in approximate order of cooling rate in Figure 12.1.2. As cooling rate increases, the grain (crystal) size tends to be smaller and the strength increases while compositional segregation decreases, providing more uniform properties. At the extremely high casting rates (10^5 to 10^6/sec) of continuous splat casting, it is possible to produce homogeneous metals not possible in terms of phase diagrams, and many metals have been produced in the amorphous state, yielding unusual metallic glasses. Ingot casting and continuous direct chill casting are primarily used to produce solid metal which will be extensively mechanically formed to final shape. The other casting methods are used to produce shapes near final dimensions, but to varying extends may receive extensive machining, forming, or finishing prior to use. For the latter group, grain refiners are frequently added to reduce solidification grain size. Metal tends to solidify directionally, with grains elongated in the direction of heat flow. This gives rise to directional mechanical properties which should be accounted for in design.

Comparison of Casting Methods

	Solidification Rate	Grain Size	Strength	Segregation
Expendable mold	Slow	Coarse	Low	Most
Investment	↓	↑	↓	↑
Plaster mold	↓	↑	↓	↑
Dry sand	↓	↑	↓	↑
Green sand	↓	↑	↓	↑
Reusable mold	↓	↑	↓	↑
Ingot	↓	↑	↓	↑
Permanent mold	↓	↑	↓	↑
Centrifugal	↓	↑	↓	↑
Die cast	↓	↑	↓	↑
Continuous — direct chill	↓	↑	↓	↑
Continuous — splat cast	Fast	Fine	High	Least

FIGURE 12.1.2 The effects of casting speed (solidification rate) are compared.

To obtain optimum properties and prevent flaws which may cause failure, the casting procedure must avoid or control compositional segregation, shrinkage cavities, porosity, improper texture (grain directionality), residual (internal) stresses, and flux/slag inclusions. This can be accomplished with good

casting practice. With the exception of investment (lost wax, precision) casting and to a lesser extent die casting, it is difficult to achieve very exacting tolerances and fine surface finish without postfinishing or forming of a casting.

Strength and Deformation, Fracture Toughness

Figure 12.1.3 shows a typical stress–strain diagram for a metal. The first portion is a linear, spring-type behavior, termed *elastic*, and attributable to stretching of atomic bonds. The slope of the curve is the "stiffness" (given for various metals in Table C.3 of the Appendix). The relative stiffness is low for metals as contrasted with ceramics because atomic bonding is less strong. Similarly, high-melting-point metals tend to be stiffer than those with weaker atomic bonds and lower melting behavior. The stiffness behavior is frequently given quantitatively for uniaxial loading by the simplified expressions of Hooke's law:

$$\varepsilon_x = \sigma_x / E \qquad \varepsilon_y = \varepsilon_z = -\upsilon \sigma_x / E \tag{12.1.1}$$

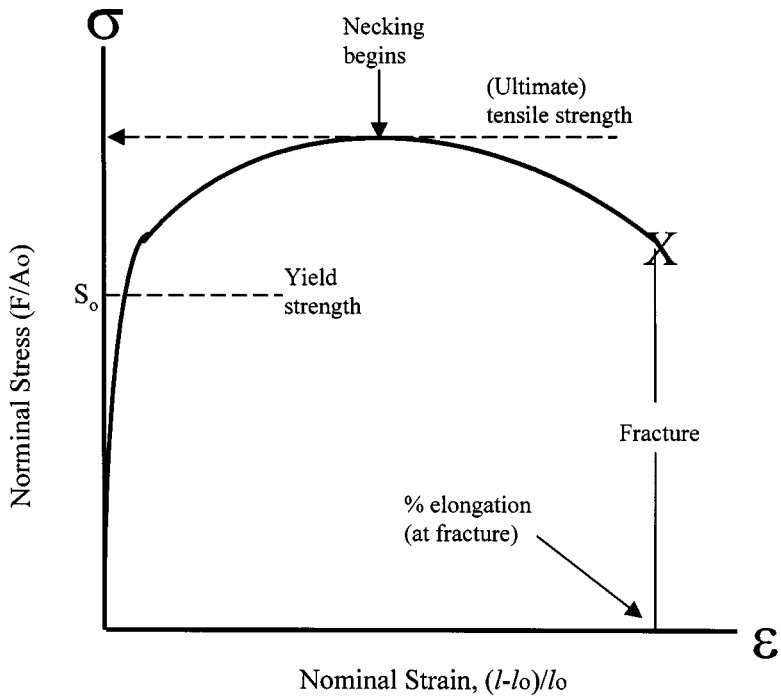

FIGURE 12.1.3 Typical engineering stress–strain curve for a metal.

Where σ_x is the stress (force per unit area, psi or Pa) in the *x* direction of applied unidirectional tensile load, ε_x is the strain (length per unit length or percent) in the same direction ε_y and ε_z are the contracting strains in the lateral directions, *E* is Young's modulus (the modulus of elasticity), and υ is Poisson's ratio. Values of the modulus of elasticity and Poisson's ratio are given in Table C.6A of the Appendix for pure metals and in C.6B for common engineering alloys. It may be noted that another property which depends on atomic bond strength is thermal expansion. As the elastic modulus (stiffness) increases with atomic bond strength, the coefficient of linear expansion tends to decrease, as seen in Table C.6.

The relationship of Equation (12.1.1) is for an isotropic material, but most engineering metals have some directionality of elastic properties and other structure-insensitive properties such as thermal expansion coefficient. The directionality results from directional elongation or preferred crystal orientation,

which result from both directional solidification and mechanical forming of metals. In most cases two elastic moduli and a Poisson's ratio are required to fully specify behavior. A principal modulus might be given in the rolling direction of sheet or plate with a secondary modulus in the transverse direction. A difference of 2 to 5% should ordinarily be expected, but some metals can show an elastic modulus difference as great as a factor of 2 in the principal directions of heavily formed material. Such directional differences should be accounted for when spring force or dimensional tolerance under load (or change of temperature) is critical in a design.

At a critical stress the metal begins to deform permanently, as seen as a break in the straight-line behavior in the stress-strain diagram of Figure 12.1.3. The stress for this onset is termed the yield stress or elastic limit. For engineering purposes it is usually taken at 0.2% plastic strain in order to provide a predictable, identifiable value. An extensive table of yield values and usual applications for commercial metals and alloys is given in Appendix C.5. In the case of steel a small yield drop allows for clear identification of the yield stress and this value is used. The onset of yield is a structure-sensitive property. It can vary over many orders of magnitude and depends on such factors as grain size and structure, phases present, degree of cold work, and secondary phases in grains or on grain boundaries as affected by the thermal and mechanical treatment of the alloy. The extension to failure, the ductility, and maximum in the stress–strain curve, the "ultimate stress" or "tensile strength" (see Appendix C.5) are also structure-sensitive properties. The strength and specific strength (strength-to-weight ratio) generally decrease with temperature.

The ductility usually decreases as the strength (yield or ultimate) increases for a particular metal. Reduction in the grain size of the metal will usually increase yield stress while decreasing ductility (Figure 12.1.4). Either yield or ultimate strength are used for engineering design with an appropriate safety factor, although the former may be more objective because it measures the onset of permanent deformation. Ductility after yield provides safety, in that, rather than abrupt, catastrophic failure, the metal deforms.

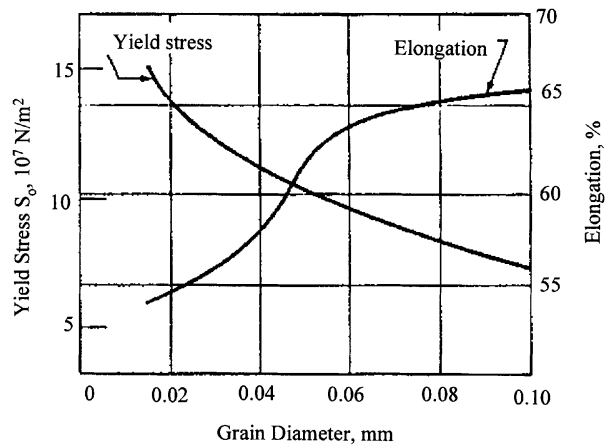

FIGURE 12.1.4 The effect of grain (crystal) size on yield stress and elongation to failure (ductility) for cartridge brass (Cu–30 Zn) in tension.

A different, independent measure is needed for impact loads — "toughness." This is often treated in design, materials selection, and flaw evaluation by extending Griffith's theory of critical flaw size in a brittle material:

$$\sigma_f = K_{1c} / \gamma c^{1/2} \tag{12.1.2}$$

where σ_f is the failure stress, K_{Ic} is a structure-sensitive materials property, the "fracture toughness" or "stress intensity factor" for a normal load, γ is a constant depending on orientation, and c is the depth of a long, narrow surface flaw or crack (or half that of an internal flaw). This is a separate design issue from that of strength. It is of particular importance when a metal shows limited ductility and catastrophic failure must be avoided. In some applications the growth of cracks, c is monitored to prevent catastrophic failure. Alternatively, as a performance test sufficient energy absorption as characteristic of a metal is determined when it is fractured in a Charpy or Izod impact test. Many metals will show a rapid decline in such energy absorption below a nil ductility temperature (NDT), which may establish a lowest use temperature for a particular metal in a particular state and for a particular application. Welds are often qualified by impact tests as well as strength testing. Care must be taken to apply the impact test appropriate to an application.

Hardness, the resistance of the near surface of a metal to penetration by an indentor, is also employed as a mechanical test. Increased hardness can often be correlated with an increase in yield and ultimate strengths. Typical hardness values for a large number of commercial metals and alloys are provided in Appendix C.5. A hardness indent is frequently done to "determine" the strength of a steel, using "equivalency" tables. Great caution must be taken in applying such tables because while hardness is an easy test to perform, it measures a complex and interactive set of properties, increasing with strength, elastic modulus, and work hardening rate. It is also an observation of surface properties which may not be characteristic of the bulk metal — particularly thick-gauge steel used in tension. Surface-hardening treatments can make the simplistic use of an "equivalency" table particularly dangerous. Application to nonferrous metals is also problematic. If a hardness tested part is to be put into service, the placement of hardness indents (surface flaws) can cause permanent failure.

A summary of important engineering metals can be found in Appendix C.5. This extensive table provides strength, hardness, and applications information for many commercial metals in varied heat treatments.

Mechanical Forming

Hot working is used when major shape change, cross-section reduction, or texture (directional) properties are desired. Cold working is preferred when close tolerances and fine surface finish are needed. The cold-worked form of a metal typically shows higher yield and tensile strength, as can be seen for several alloys listed in Appendix C.5. Rolling, forging, and extrusion are primarily done hot, while shape drawing, extrusion, deep drawing, stretching, spinning, bending, and high-velocity forming are more commonly performed cold. Hot rolling between parallel rollers is used to reduce ingots to plates, sheets, strips, and skelp, as well as structural shapes, rail, bar, round stock (including thick-walled pipe), and wire. Sheet metal and threads on round or wire stock may be rolled to shape cold. Closed die hot forging employs dies with the final part shape, while open die forging (including swaging and roll forging) uses less-shaped dies. Coining, embossing, and hobbing are cold-forging operations used to obtain precision, detailed surface relief or dimensions. Generally, extrusion and die drawing require careful control of die configuration and forming rate and, in the latter case, lubricant system. Impact extrusion, hydrostatic extrusion, and deep drawing (thin-walled aluminum cans) permit very large precise dimensional and cross-section changes to be made cold in a single pass. Stretching, spinning, bending are usually used to shape sheet or plate metal and the spring-back of the metal due to elastic modulus must be accounted for to obtain a precise shape.

Solute, Dispersion, and Precipitation Strengthening and Heat Treatment

Alloying additions can have profound consequences on the strength of metals. Major alloying additions can lead to multiphase materials which are stronger than single-phase materials. Such metal alloys may also give very fine grain size with further strengthening of material. Small alloying additions may also

substantially increase strength by solute strengthening as solid solution substitutional or interstitial atoms and or by particle strengthening as dispersion or precipitation hardening alloys.

Substitutional solute strengthening of copper by various atoms is shown in Figure 12.1.5. As the amount of an alloying element in solution increases, the strength increases as dislocations are held in place by the "foreign" atoms. The greater the ionic misfit (difference in size — Sn is a much larger ion than Ni), the greater the strengthening effect. The strength increase can be quite dramatic — as much as a 20-fold increase with a 1.5% addition to copper. Alternatively, a large addition of a very soluble element such as nickel can give major strengthening — monel, the Cu–70Ni alloy is more than four times stronger than pure copper (Figure 12.1.6). Interstitial solid solution carbon contributes to the strength of iron and is one contributor to strength in steels and cast irons. Solute strengthening can become ineffective in strengthening at elevated temperature relative to the absolute melting point of a metal as a result of rapid diffusion of substitutional and interstitial elements. The addition of more than one solute element can lead to synergistic strengthening effects, as this and other strengthening mechanisms can all contribute to the resistance of a metal to deformation.

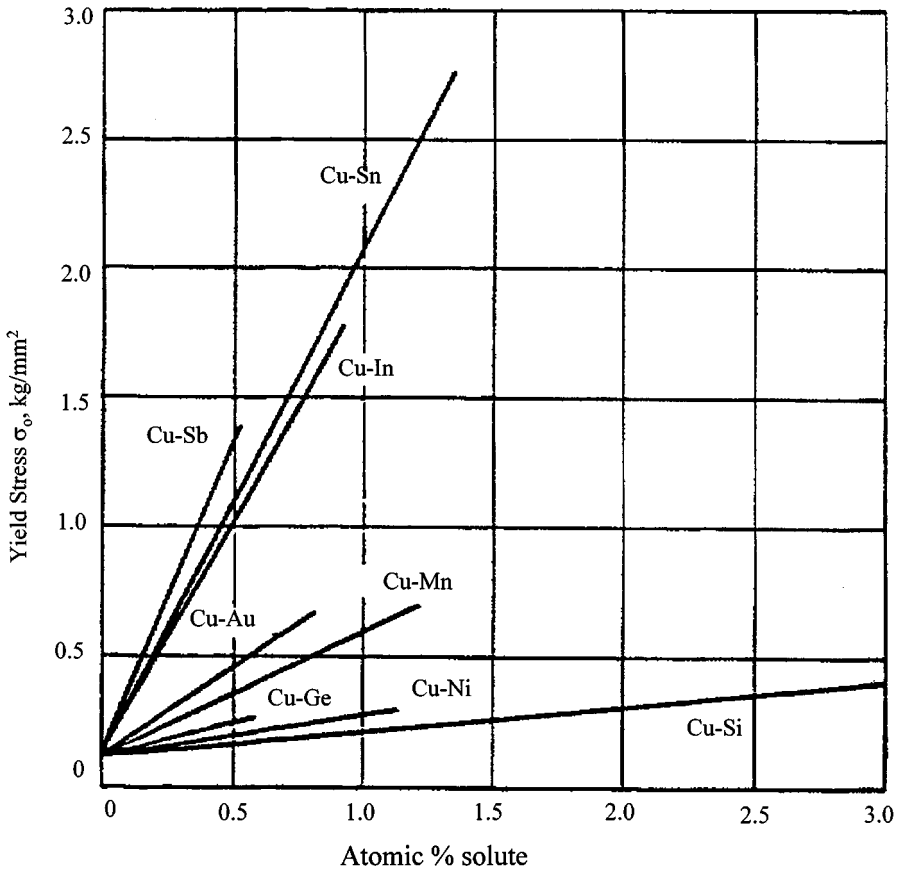

FIGURE 12.1.5 Effect of various substitutional atoms on the strength of copper. Note that as the ionic size of the substitutional atom becomes larger the strengthening effect becomes greater.

Ultrafine particles can also provide strengthening. A second phase is introduced at submicroscopic levels within each crystal grain of the metal. This may be done by a variety of phase-diagram reactions, the most common being precipitation. In this case the solid alloy is heated to a temperature at which the secondary elements used to produce fine second-phase particles dissolve in the solid metal — this is termed *solution heat treatment*. Then the metal is usually quenched (cooled rapidly) to an appropriate

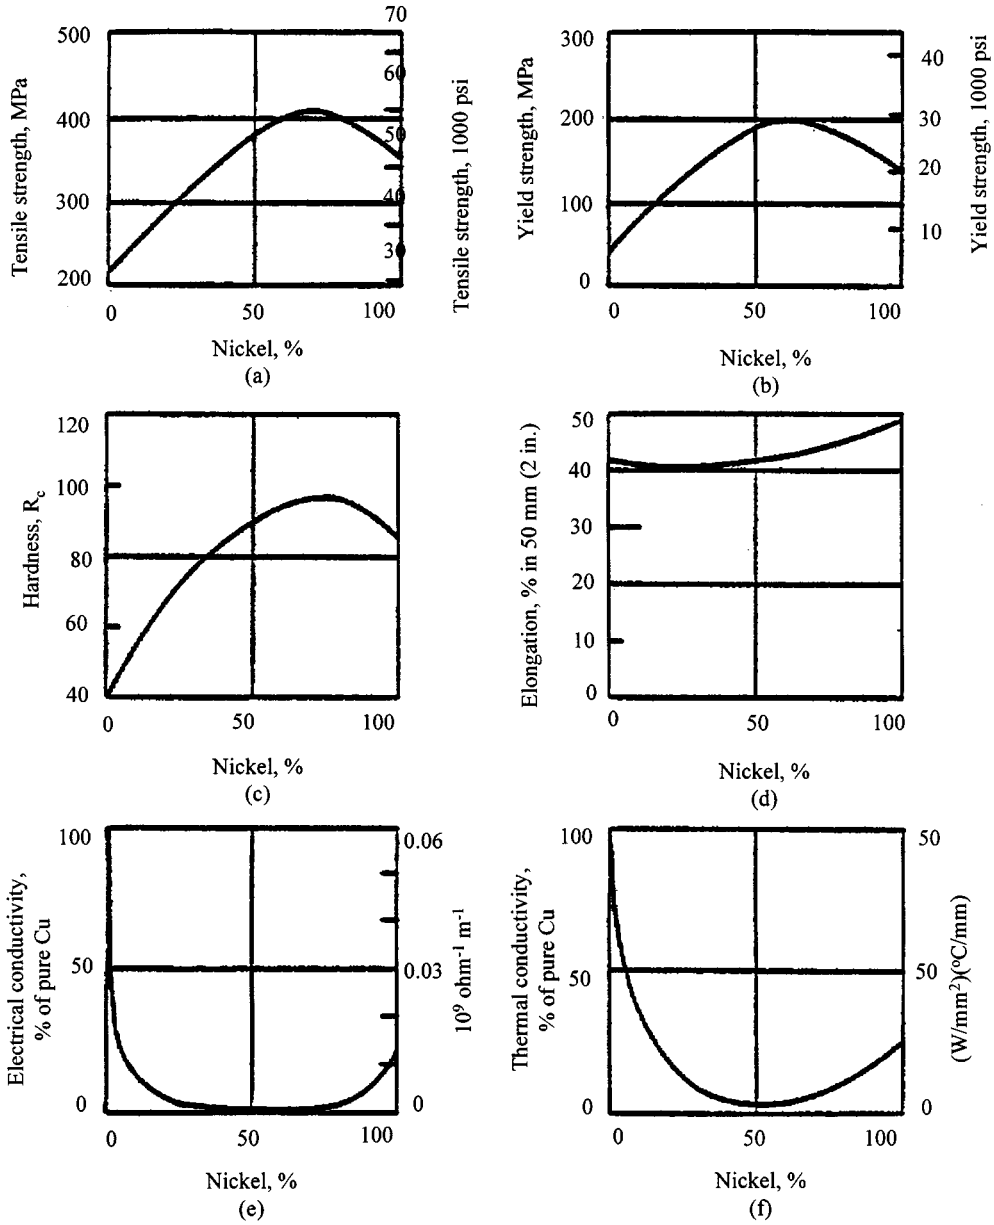

FIGURE 12.1.6 Variation in properties for copper–nickel random solid solution alloys. Note that over time at low temperature alloys (monel) may become nonrandom with significant strength increases.

temperature (e.g., room temperature or ice brine temperature) and subsequently held at an elevated temperature for a specified "aging" time during which particles precipitate and grow in size at near atomic levels throughout the solid metal. Temperature, time, alloy composition, and prior cold work affect the size and distribution of second-phase particles. The combination of treatments can be quite complex, and recently "thermomechanical treatments" combining temperature, time, and dynamic working have resulted in substantial property improvements. Heat treatment can be performed by the user, but it is difficult to achieve the optimum properties obtained by a sophisticated metallurgical mill. The heat treatment can manipulate structure and properties to obtain maximum strength or impact resistance. When metal is to be cold worked, a "softening treatment" can be employed which provides low yield

stress and high ductility. The difference between the "dead soft" and maximum strength conditions can be over an order of magnitude — a useful engineering property change.

Alternative surface diffusion methods such as nitriding and carburizing, which introduce particles for fracture and wear resistance, are presented in the subsection on metal surface treatments.

In the case of dispersion strengthening (hardening), the fine strengthening particles are a discontinuous second phase without atomic continuity with the matrix. The behavior of such particles is shown schematically in Figure 12.1.7a as a function of increasing aging time or aging temperature (fixed time) which result in larger, more widely spaced dispersed-phase particles. Under stress, dislocations must move around (bypass) such particles, so that yield strength decreases with increased aging. Long aging times may be used to decrease yield strength ("soften") of the metal for fabrication. A short aging time, would be used for maximum strength. The dispersed phase can also provide some enhancement of ductility. A dispersion-strengthened metal for which the dispersed phase is stable at elevated temperatures can provide both high-temperature strength and creep resistance (subsection on high-temperature effects). Surface diffusion treatments usually produce dispersion hardening.

Precipitation strengthening (hardening) employs particles which have at least some atomic continuity with the matrix metal. Thus, when the metal is deformed, dislocations can either bypass or pass through (cut) the particles. The resulting behavior is shown in Figure 12.1.7b. As aging time or temperature increases (particles grow larger and more widely spaced), the yield stress increases to a maximum and then decreases. The maximum is termed *critically aged*, and when this designation is part of an alloy treatment, precipitation strengthening may be assumed. For fabrication by cold working, the lower-strength, higher-ductility *underaged* condition is usually employed. There are different possible combinations of thermal and mechanical treatment which will provide a maximum critical aging treatment. Usually the best optimum for strength is given in handbooks and data sheets. However, improved treatments may be available, particularly of the combined thermomechanical type.

Strengthening of Steels and Steel Heat Treatment

Steels, perhaps the most important of all engineering metals, are alloys of iron and carbon usually containing about 0.02 to 1.0 $^{w}/_{o}$ carbon. The binary Fe–C phase diagram is important in describing this behavior and is shown in Figure 12.1.8. This diagram shows what phases and structures will occur in quasi equilibrium at various carbon contents and temperatures (under atmospheric pressure). Steel forming and heat treatment center on the transformation from austenite, γ phase, at elevated temperature to ferrite (α phase) plus cementite (iron carbide, Fe_3C) below 727°C (1340°F), the Ac_1 temperature, a eutectoid transformation. If there are no other intentional alloying elements, the steel is a "plain carbon" steel and has an AISI (American Iron and Steel Institute) designation 1002 to 10100. The first two characters indicate that it is a plain carbon steel, while the latter characters indicate the "points" of carbon.* Alloy steels, containing intentional alloying additions, also indicate the points of carbon by the last digits and together with the first digits provide a unique designation of alloy content. In the phase diagram (Figure 12.1.8) iron carbide (Fe_3C, cementite) is shown as the phase on the right. This is for all practical purposes correct, but the true thermodynamically stable phase is graphite (C) — relevant when the eutectic at 1148°C (2048°F) is used to produce cast irons (alloys greater than 2 $^{w}/_{o}$ C).

The solid-state eutectoid transformation is promoted by the magnetic effect in iron as nonmagnetic austenite transforms below the eutectoid (Ac_1) temperature to the two magnetic solid phases ferrite (iron with solid solution carbon) and cementite solid phase.** At the eutectoid composition, 0.77 $^{w}/_{o}$ carbon,

* Plain carbon steels contain about 0.2 $^{w}/_{o}$ Si, 0.5 $^{w}/_{o}$ Mn, 0.02 $^{w}/_{o}$ P, and 0.02 $^{w}/_{o}$ S.

** It should be noted that austenitic stainless steels (300 and precipitation hardening, PH, series designations), nonmagnetic alloys with considerable chromium and nickel content to provide corrosion resistance, do not ordinarily transform from austenite to the lower-temperature phases. They are not intentionally alloyed with carbon, are not magnetic, and do not show the phase transformation strengthening mechanisms of steels. The term *steel* is something of a misnomer for these alloys.

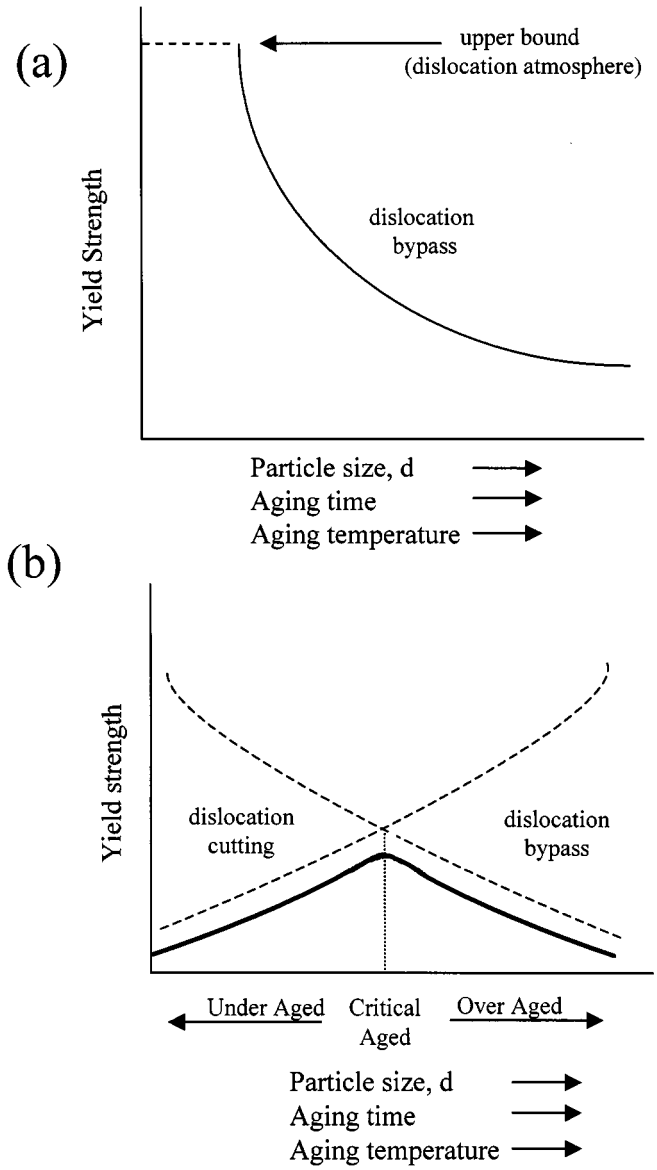

FIGURE 12.1.7 Effect of aging on dispersion- and precipitation-strengthened alloys for a fixed second–phase addition. (a) Dispersion strengthening: as aging time or temperature increases (dispersed phase particles larger and more separated), yield strength increases. A lower bound exists for near atomic size particles. (b) Precipitation hardening: two behaviors can occur giving a composite curve with a maximum at the critical aging time or temperature (optimum size and spacing of particles).

the two phases form as a fine alternating set of plates (lamellae) termed *pearlite* because of their pearllike appearance in a metallographic microscope. This two-phase structure of metal (ferrite) and carbide (cementite) provides strength (very slowly cooled — about 65 ksi, 14% tensile elongation), which increases as a more-rapid quenching yields a finer pearlite microstructure (to about 120 ksi). As strength increases, ductility and fracture toughness decrease. With yet more rapid quenching and more local atomic diffusion, the austenite transforms to bainite, a phase of alternating carbon and iron-rich atomic planes. This has yet higher strength (to about 140 ksi) and lower ductility. When the metal is quenched so rapidly that carbon diffusion is prevented, the austenite becomes unstable. Below a critical temperature,

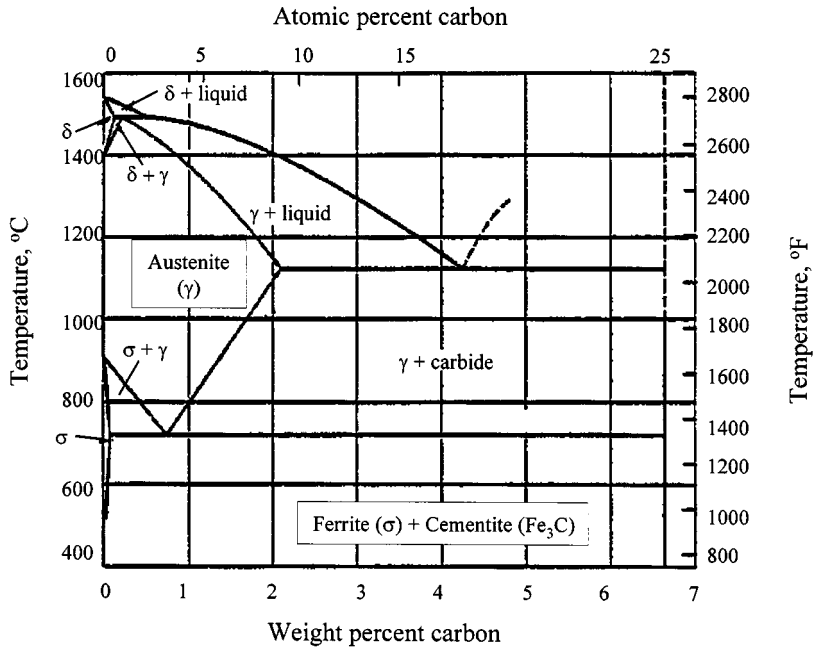

FIGURE 12.1.8 Iron–carbon phase diagram relevant for steel. The steel composition range is from about 0.02 to 1.00 $^{w}/_{o}$ carbon. Steel strengthening treatments require heating into the austenite region (above the Ac_3) and then quenching.

the martensitic start temperature (M_s), the metal transforms spontaneously by shear to martensite. Full transformation occurs below the martensite finish temperature (M_f). The formation of this hard phase introduces enormous microscopic deformation and residual stress. The strength is very much higher (about 300 ksi) but there is almost no ductility. This rapidly cooled material can spontaneously fail from "quench cracking," which results from residual stresses and the martensite acting as an internal flaw. To relieve stresses and provide some fracture toughness, martensitic steel is "tempered" at an intermediate temperature such as 500°C for about an hour to provide some ductility (about 7%) while sacrificing some strength (about 140 ksi). Tempering for shorter times or at lower temperatures can give intermediate properties. High-carbon steels are often used for cutting tools and forming dies because of their surface hardness and wear resistance. When a high-carbon steel (>0.7 $^{w}/_{o}$ C) requires fabrication at lower temperature, it may be held at a temperature just under the eutectoid for an extended time (e.g., for 1080 steel: 700°C, 1300°F — 100 hr) either after or without quenching to provide a soft condition (<60 ksi, 20% extension). A variety of different quenching temperatures, media, and procedures can be used to vary required combinations of the microstructures above and mechanical properties. The discussion above centered on eutectoid steel and holds for other high-carbon steels. Increasing carbon content favors the formation of martensite in steels, thereby providing increased strength, hardness, and wear resistance. However, such steels can be quite brittle.

At lower carbon content, "primary ferrite" forms (Figure 12.1.8) as the steel is quenched from above the boundary of austenitic (γ) region, the Ac_3. Subsequently, pearlite (ferrite and cementite), bainite, and/or martensite can form. Lower carbon content increases the amount of primary ferrite, a weaker/ductile phase, and decreases the tendency to form martensite, a stronger/brittle phase. The result is a more fracture tough, ductile ("safer") steel, but strength is lower. Such steels are also mechanically more forgiving if welded. Thus, a 1010 steel (0.10 $^{w}/_{o}$ C) might be used for applications where extreme "formability" and "weldability" are required, such as for car bodies and cans, while a 1020 steel (0.20 $^{w}/_{o}$ C) might be used for construction materials for which some increased strength is desired while

maintaining safety. A medium-carbon steel such as a 1040 would be used when a balance of strength and toughness (and ease of welding) is needed.

In order to quench (and temper) steels continuous cooling transformation (CCT) diagrams are used such as that in Figure 12.1.9 for a 1040, medium-carbon steel. The steel is quenched from above the Ac_3. Vertical lines indicate quenching rates as shown in the lower left inset of the diagram. The cooling rate for the center of a round bar of given diameter quenched in air, oil, and water is given below the diagram. Solid lines on the diagram indicate percent transformation (start, 10%, 50%, 90%, finish of transformation), and a dotted line separates the region where primary ferrite forms from that of transformation to pearlite. The lower diagram shows the indentation hardness to be expected, as this and other mechanical behavior can be predicted from the CCT curve. As an example, the center of a 15 mm ($\sim^1/_2$ in.) diameter bar quenched in air would be about 25% primary ferrite and 75% fine pearlite, with a Rockwell C hardness (HRC) of about 15. If quenched in oil, the bar center would be chiefly bainite with a small amount of martensite (HRC $\cong$ 25). The same bar quenched in water would be all martensite (HRC $\cong$ 55) before tempering. The transformation at other positions in the bar and for other engineering shapes (sheet, pipe, square rod, etc.) can be obtained from conversion curves.

It should be noted that layers in the steel closer to the quenched surface cool more quickly and are therefore displaced toward the left of the CCT diagram. There is a variation in structure and mechanical properties from the quenched surface to the center. One result is that the surface of the steel tends to be stronger, harder, and more wear resistant than the center. A steel beam undergoing bending has maximum strength at the near surface which undergoes the greatest stresses, while the center provides safety because of its relative fracture toughness and ductility. A thin knife edge cools quickly and can be resistant to deformation and wear, while the thick back prevents the blade from snapping in half when bent.

Many elements may be incorporated in steels to promote specific properties. Almost all common additions (other than cobalt) tend to promote strengthening by the formation of martensite (or bainite) instead of pearlite. When alloying additions tend to promote martensite throughout a thick section independent of cooling rate, the alloy is said to have *high hardenability.* Some elements such as chromium, molybdenum, and nickel also may help to provide high-temperature strength and environmental resistance. One class of alloys with relatively small alloying additions are termed *HSLA* steels (high strength, low alloy) and usually show somewhat superior mechanical properties to their plain carbon steel equivalents. As steel is alloyed, the relative cost increases substantially. A useful strategy in steel selection (and steels are usually the first engineering candidate on a cost basis) is to start by determining if a medium-carbon steel will do. If greater safety and formability are needed, a lower carbon content may be used (with slightly lower cost); alternatively, a higher-carbon steel would be chosen for greater strength and wear resistance. Heat treatment would be used to manipulate the properties. If plain carbon steels prove unsatisfactory, the HSLA steels would be the next candidate. For very demanding applications, environments, and long-term operations, specialty alloy steels would be selected insofar as they are cost-effective.

Fatigue

Fatigue is the repeated loading and unloading of metal due to direct load variation, eccentricity in a rotating shaft, or differential thermal expansion of a structure. Even substantially below the yield point (elastic limit) of a metal or alloy this repeated loading can lead to failure, usually measured in terms of the number of cycles (repeated load applications) to failure. Some studies have suggested that well over 80% of all mechanical failures of metal are attributable to fatigue.

High-stress, low-cycle fatigue usually occurs at stresses above the yield point and lifetimes are tens or hundreds of cycles (to about a thousand cycles). Failure occurs as a result of the accumulation of plastic deformation, that is, the area (energy) under the stress–strain curve (Figure 12.1.3). A simple lifetime predictive equation can be used to predict lifetime:

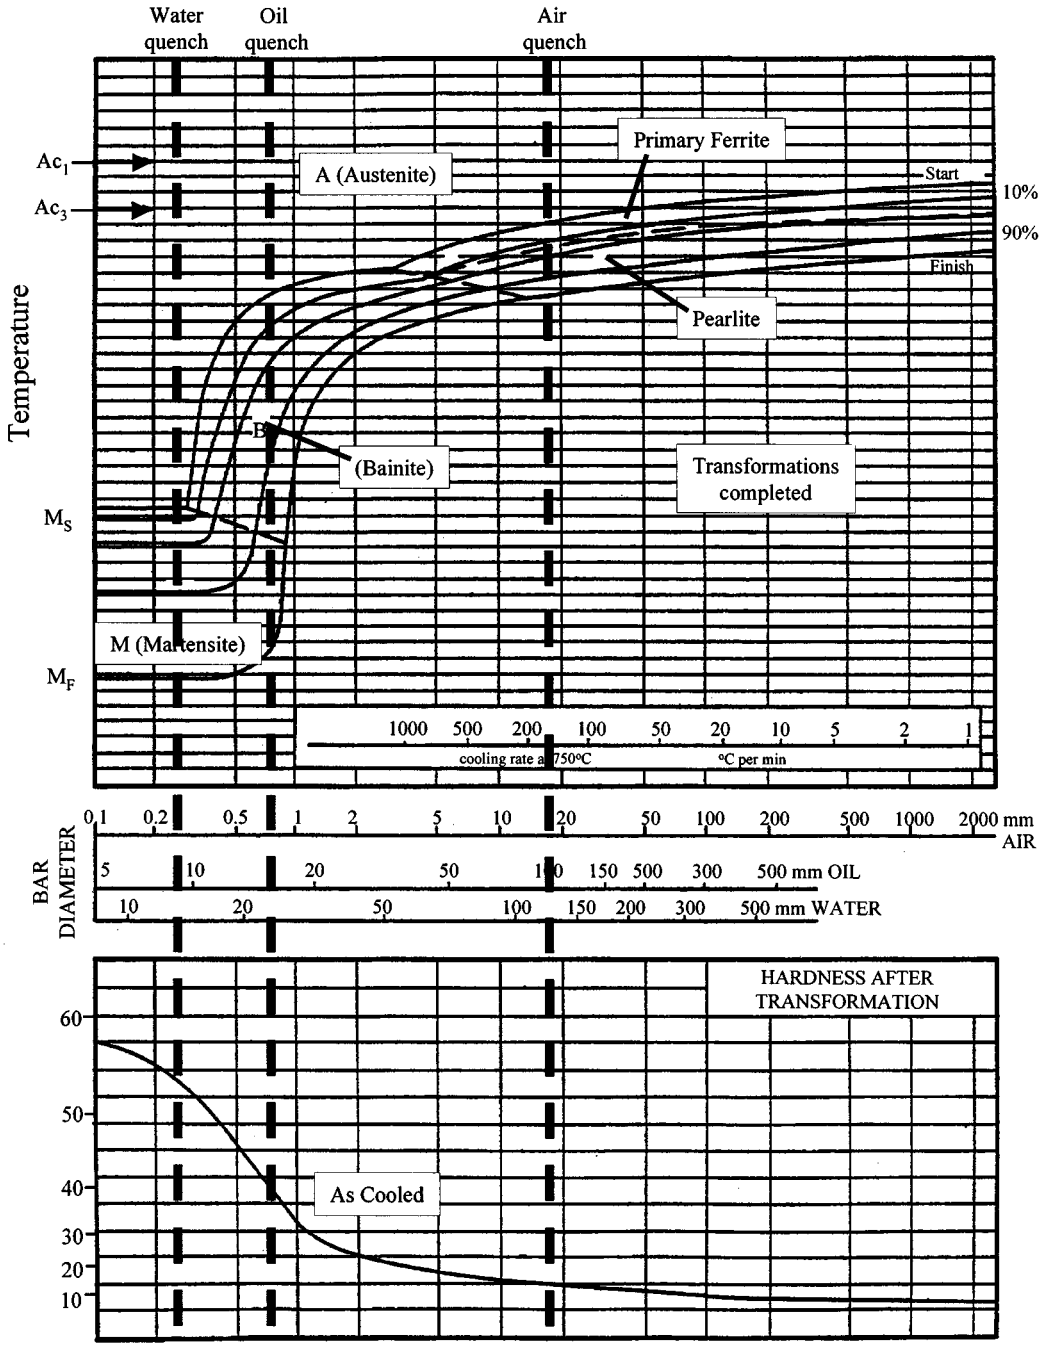

FIGURE 12.1.9 CCT diagram for 1040 steel. A 15-mm round bar air quenched from above the Ac_3 will be chiefly fine pearlite (ferrite and iron carbide, cementite) with about a quarter of the structure primary ferrite at the center. Quenching in oil will yield bainite with about 10% martensite. Water quenching will produce wholly martensite at the center. (After Atkins, M., *Atlas of Continuous Cooling Transformation Diagrams for Engineering Steels*, ASM International, Materials Park, OH, 1980.)

$$N \approx \left[\varepsilon_u / 2\varepsilon_{pf}\right]^2 \tag{12.1.3}$$

where N is the number of cycles to failure, ε_u is total strain from the stress–strain curve, and ε_{pf} is the plastic strain amplitude in each fatigue cycle.

More commonly, metals are used well below their yield point and fail after many, many cycles of repeated loading in low-stress, high-cycle fatigue. There is microscopic, local plastic deformation (cold working) and vacancy generation (recovery effects) during such cyclic loading which result in "fatigue hardening" (strengthening) of unworked metal and "fatigue softening" of unworked metal. Some have even found success relieving residual stressed with a vibratory anneal. Early in the fatigue process surface flaws or in some cases severe internal flaws begin to propagate. The fatigue crack propagates in areas of high stress a small, usually submicroscopic, distance with each tensile loading. The propagation on each cycle frequently leaves identifiable marking on the failure surface termed *fatigue striations* which mark the progress of the subcritical crack. When the crack becomes so large that the fracture toughness criterion is exceeded (Equation 12.1.2), catastrophic overload failure occurs. When the future fatigue loading can be predicted and the cyclic crack propagation rate is known, fatigue cracks can be inspected or monitored in different applications such as aircraft structures and pressure vessels to decommission or replace parts before fatigue failure. This must be done cautiously because a change to a more aggressive (corrosive, oxidative, elevated temperature) environment can increase the crack propagation rate. If a harmonic resonance occurs in the metal part, vibratory maxima can cause premature fatigue failure. Harmonics can change as fatigue cracks propagate. Harmonic vibration can be prevented with vibratory (dynamic) design concepts and/or direct monitoring.

Figure 12.1.10 shows typical metal *S–N* curves (stress vs. number of cycles to failure) for a high-strength aluminum and for a titanium alloy. Note that the convention is to make stress the vertical axis and to plot the number of cycles to failure on a logarithmic scale. For high-stress, low-cycle fatigue ($<10^3$ cycles) the curve is flat and linear, consistent with the model of Equation12.1.3. For high cycle fatigue the lifetime is a rapidly varying function of stress until very low stresses (long lifetimes occur). The actual fatigue life varies statistically about the mean value shown in approximate proportion to the number of cycles to failure. These curves are for testing in ambient air. Fatigue life would be longer in an inert environment and may be shortened drastically in an aggressive environment. Iron- and titanium-based alloys, such as the example shown, usually have an "endurance limit," a stress below which lifetime is ostensibly infinite. In air, at room temperature, the endurance limit is about half the tensile strength for most iron and titanium alloys. Other metals appear to show no stress below which they last indefinitely. Therefore, a "fatigue limit" is designated — usually the stress at which the fatigue life is 10^8 cycles. This may be a long lifetime or not depending on the frequency of loading and engineering lifetime. The fatigue limit is generally about 0.3 times the tensile strength for metals with strengths below about 100 ksi (700 MPa). The factor is somewhat poorer for higher-strength metals. It is apparent that on a relative strength basis, iron- and titanium-based alloys are fatigue-resistant metals when compared with others. Dispersion-strengthened alloys have been seen to provide some lifetime advantage in fatigue.

A number of mathematical relationships have been proposed to predict fatigue life, but none works with complete success and all require experimental data. Perhaps the most successful of the so-called fatigue "laws" are the "cumulative damage" laws. The simplest is Miner's law:

$$\sum i\left[n_i / N_i\right] = 1 \tag{12.1.4}$$

where n_i is the number of cycles applied and N_i is the number of cycles for failure at a particular stress level, σ_i. The conceptual basis is that the number of fatigue cycles at a stress level uses up its relative fraction of total fatigue lifetime and may be correlated to fatigue crack propagation (striation spacing). Modifications of this model account for the order and relative magnitude of loads. Several techniques

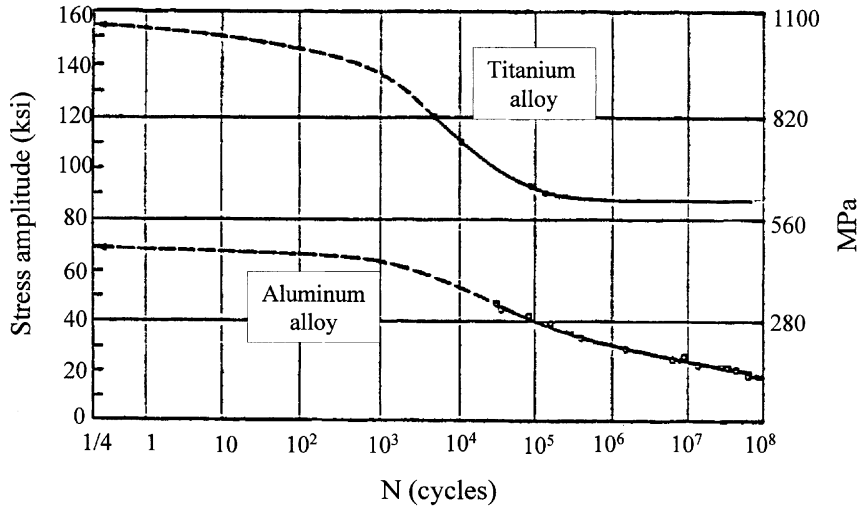

FIGURE 12.1.10 *S–N* (fatigue) curves for high-strength titanium (upper curve) and aluminum alloys. Note that titanium (and iron) alloys show an endurance limit, a stress below which the metal lasts indefinitely.

have met with partial success in increasing fatigue lifetime beyond that predicted by the cumulative damage models:

1. Coaxing — intermittent or continuous, superimposed vibration at very low stress,
2. Overstressing — intermittent or superimposed compressive loading,
3. Surface compression — intermittent shot peening or surface rolling,
4. Surface removal — chemical or mechanical surface polishing.

All but 1 are thought to close or eliminate fatigue cracks and surface damage. Coaxing has been said to introduce more of the vacancy-related recovery effects associated with fatigue.

High-Temperature Effects — Creep and Stress Rupture

Elevated temperature can cause a significant loss of strength and elastic modulus, so that a metal part may fail as a result of overheat even at loads which appear small at room temperature. High temperature is a relative matter and is usually judged as a fraction of the melting point measured on the absolute temperature scale. Thus, even moderate temperature excursions can be important for low-melting-point metals and alloys. As indicated in several sections above, many alloying and cold work strengthening methods depend upon heat treatment; an alloy can undergo metallurgical change due to overheat or to long-term holds at moderate temperatures and thereby alter properties significantly. Thus, the thermal stability of the microstructure should be determined. For example, metallographic replica techniques have been developed for determining in the field if microstructure has coarsened, making the metal weak.

Creep deformation is the continued deformation of a metal under load at elevated temperature, usually at a design stress well below the yield point. While measurable creep can occur at low temperatures over very long times or at very high (compressive) loads, creep usually becomes of engineering importance above about two thirds the melting point (absolute) of an alloy. Thus, both lead, which creeps at room temperature, and tungsten, which creeps in an incandescent light bulb at white heat, require a mechanical support or creep-resistant alloying additions. Figure 12.1.11 shows a schematic creep curve plotting creep strain* vs. time, *t*, at a particular tensile load and temperature. After the immediate elastic

* If a constant extension is applied to an object, the force it generates will decline over time due to creep. This is called *stress relaxation* and can be treated in a similar way.

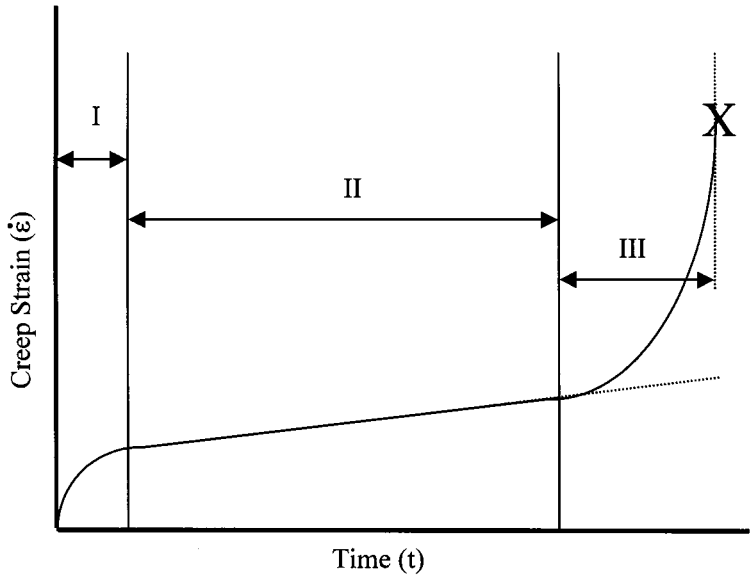

FIGURE 12.1.11 Schematic creep curve showing transient creep (I), steady-state creep (II), and tertiary creep (III). Note that the slope of the straight-line portion is the steady-state creep rate (minimum creep rate).

strain (t = 0), "transient creep" occurs in Region I. At elevated temperature this usually follows a $t^{1/3}$ behavior (Andrade creep). The majority of the curve has a straight-line behavior (Region II) in which the extension with time is constant. The slope of this part of the curve is termed the *steady-state strain rate* or *minimum creep rate*. It is used to calculate the creep extension which could cause functional failure when dimensional tolerances are exceeded. A simplified predictive model is

$$\varepsilon' = A\sigma^m e^{-h/kT} \tag{12.1.5}$$

where ε' is the minimum creep rate, A is a constant, σ is the applied stress, m is the stress dependence exponent (often 4 to 8), h is the activation enthalpy for creep, and T the absolute temperature.

In Region III the creep rate accelerates as the metal necks down severely in a local area, thereby increasing the local stress. The steady-state rate would continue (dotted line) if the load were adjusted to give constant load at the minimum cross section. Since loads do not readjust to compensate for necking in real applications, a final accelerated stage can be experienced. For example, a blowout can occur in late creep of a pressurized high-temperature piping system. The time to failure is termed the *stress rupture lifetime*. Predictive models are developed from Equation (12.1.5) to provide lifetime information.

Lowering use temperature or applied stress decreases susceptibility to creep deformation and increases stress rupture lifetime. Frequently, a moderate temperature decrease is most effective in this regard. Higher-melting-point metals are more creep resistant, so that the refractory metals tungsten and molybdenum can be used but require an inert atmosphere or protective coating to prevent rapid oxidation. In air or other active atmosphere, niobium-, nickel-, titanium-, and iron-based alloys may be used for creep resistance. Dispersion hardening, particularly with a high-temperature stable phase, such as an oxide, nitride, or carbide, can confer a degree of creep resistance.

Corrosion and Environmental Effects

Corrosion usually involves the slow removal of metal due to chemical and/or electrochemical reaction with an environment. Most metallic corrosion involves a galvanic, that is, electrochemical, component and localized attack in the form of pitting, attack in crevices, grain boundary attack, selective leaching

of one phase, and exfoliation (attack parallel to the surface causing layers to peel away). Uniform corrosion is less common and also less of a concern as long as the rate of material removal is gradual and predictable.

Galvanic corrosion requires a medium, usually liquid (water), often containing a specific agent which promotes corrosion, a potential difference, and a complete electrical circuit, as well as an anode and a cathode. The anode will be the attacked, corroded, portion of the system. One cause for potential corrosion is dissimilar metals. For example, the galvanic series in seawater shows magnesium alloys as most anodic followed by zinc, aluminum, iron, nickel, brass, and copper alloys which are progressively more cathodic. When coupled electrically, the more-anodic metal would be corroded and the more cathodic would promote corrosion. One way of preventing corrosion is to isolate with insulator material the metal parts electrically so that a circuit is interrupted. The surfaces can be isolated from the corroding medium with paint, protective metal, conversion coatings, or a corrosion inhibitor additive to the liquid. In this situation it is more important to coat the cathode (noncorroding metal) since it impresses corrosion on the anodic metal dependent on exposed area. When in doubt, all parts should be painted repeatedly to prevent pinholes. Other possibilities include cathodic protection with an impressed electrical counterpotential or use of a sacrificial anode which is attacked instead of the metal components. Some metals such as stainless steels and aluminum alloys provide protection via an oxide coating, a *passive film*, which will form under specific, controlled electrochemical conditions providing *anodic protection.*

Another source for an anode and cathode can be the solution itself. Differences in temperature, ion concentration, oxygen content, and pH can all lead to a potential difference which results in corrosion. Often corrosion occurs far more rapidly for a specific range of solution concentration — indeed, sometimes dilution may accelerate corrosive attack. An oxygen deficiency cell under dirt or in a crevice frequently causes attack at the resulting anode. Potential differences can also exist in the metal itself: between different phases, inclusions, or grain chemistries; between grains and grain boundaries; between surface films and metal; and between different grain orientations. Selective leaching such as dezincification of high-zinc brasses (Cu–Zn) is an example for composition differences, while exfoliation corrosion of aluminum alloys and sensitized stainless steel are examples of grain boundary attack. Cold-worked metal tends to be anodic to annealed material so that a heavily formed part of a metal part may corrode preferentially.

Another important environmental cause of failure is stress corrosion cracking (SCC). A combination of applied or residual tensile stress and environmental attack results in progressive slow crack propagation over a period of time. Eventually, the crack becomes critical in size (Equation 12.1.2) and catastrophic failure occurs. There need be no evidence of corrosion for SCC to occur. When the loading is of a cyclic nature the effect is termed *corrosion fatigue*. To prevent these long-term crack propagation effects the environment and/or the source of tensile load may be removed. Considerable effort has been made to identify an ion concentration below which stress corrosion cracking will not occur (e.g., Cl for austenitic stainless steels), but there may be no level for complete immunity, merely a practical maximum permissible level.

Hydrogen embrittlement and hydrogen cracking can occur in the presence of stress and a hydrogen source. Embrittlement results when hydrogen diffuses into the metal and/or acts on the crack tip altering the fracture toughness. Hydrogen cracking may be regarded as a special case of stress corrosion cracking. Either environmental effect can lead to catastrophic failure. The source of hydrogen can be an acid solution, hydrogen evolved during corrosion, electrochemical treatment (plating, electropolishing), or hydrocarbons. Often isolation from the hydrogen source is difficult because hydrogen diffuses quickly through most materials and barrier coatings. Glass coating has met with some success.

Metal Surface Treatments

A number of treatments are employed to strengthen the surface of steels and make them more resistant to failure or wear. Some of the techniques may also be applied to selected nonferrous alloys. Flame, induction, and laser hardening provide intense heat to the outer surface of a medium- or high-carbon

(hardenable) steel bringing it into the austenitic region, above Ac_3 (see subsection on fatigue). The bulk of the metal is not heated so that the surface can then be quenched rapidly forming hardening phases and a compressive surface stress. This provides strength and wear resistance. Another surface-hardening technique is carburizing. This can also be used on steels with lower carbon content. The metal is exposed to a controlled balance of carbon monoxide and carbon dioxide or is packed in graphite. At elevated temperature (usually above the Ac_3) carbon diffuses into the surface, converting it to a high-carbon steel. The steel is then either quenched directly from the carburizing temperature or reaustenitized and quenched. The result is similar to flame hardening, but higher hardness and surface compression can be accomplished compared with flame hardening. The center of the piece, with much lower carbon content, can provide fracture toughness, ductility, and safety. Nitriding exposes steel containing appropriate alloying elements (chromium, aluminum, vanadium, …) to monatomic nitrogen in the form of cracked ammonia, cyanide, or high-energy dissociated nitrogen gas. This is done below the eutectoid (lower transformation) temperature. Dispersed-phase nitrides are formed as nitrogen diffuses into the surface which harden the surface without a need for further heat treatment. The effects of both carburizing and nitriding can be introduced by carbonitriding above the transformation temperature and quenching or nitrocarburizing below the transformation to austenite.

12.2 Polymers

James D. Idol and Richard L. Lehman

Introduction

Polymers constitute a wide range of materials which are derived at least in part from organic, usually petroleum-based, raw materials; they consist of repeating molecular units and have special properties obtained by engineering the form of the molecular structures. The term *polymer* is derived from Greek roots and means "having many parts," a term which aptly describes the infinite number of compounds which can be synthesized from a relatively limited number of monomer units. The term *plastic* is often used in describing polymers, although this term is not in current usage since it is a general descriptive which refers to the forming rheology of many polymers but is too general to accurately describe this group of materials.

Polymers are used as engineering materials in the neat form, i.e., as the pure material, or in combination with a large diversity of additives, both organic and inorganic. These additives may be, among others, plasticizers which reduce the rigidity or brittleness of the material, fillers which increase strength and load deflection behavior under load, or stabilizers which protect the polymer against ultraviolet radiation.

The following discussion will separate polymers into two groups, thermoplastic and thermosetting, based on the distinctly different thermal processing behavior of these two broad classes of polymers. Thermoplastic polymers soften when heated and can be reshaped, the new shape being retained on cooling. The process can be repeated many times by alternate heating and cooling with minimal degradation of the polymer structure. Thermosetting polymers (or thermosets) cannot be softened and reshaped by heating. They are plastic and moldable at some state of processing, but finally set to a rigid solid and cannot be resoftened. Thermosets are generally stronger and stiffer than thermoplastic.

Table 12.2.1 of this section gives an overview of the physical properties of the most commonly used industrial polymers. Table 12.2.2 provides an overview of properties such as chemical resistance, ease of machining, and compressive strength for thermoplastic and thermosetting plastics, while Table 12.2.3 is a selection guide for polymers by application. A detailed summary of polymer properties, including electrical properties, thermal properties, optical properties, and fabrication, is presented in Table 12.2.4.

Thermoplastic Polymers

Acetal and Polyacetal

These combine very high strength, good temperature and abrasion resistance, exceptional dimensional stability, and low coefficient of thermal expansion. They compete with nylon (but with many better properties) and with metal die castings (but are lighter). Chemical resistance is good except for strong acids. Typical applications are water-pump parts, pipe fittings, washing machines, car instrument housings, bearings, and gears.

Acrylics (Methylmethacrylate, PMMA)

These are noted for their optical clarity and are available as sheet, rod, tubings, etc., as Perspex (U.K.) and Plexiglas (U.S., Germany, etc.). They are hard and brittle and quite resistant to discoloring and, especially, weathering. Applications include outdoor display signs, optical lenses and prisms, transparent coverings, drafting instruments, reflectors, control knobs, baths, and washbasins. They are available in a wide range of transparent and opaque colors.

Acrylonitrile-Butadiene-Styrene (ABS)

This combination of three monomers gives a family of materials which are strong, stiff, and abrasion resistant with notable impact-resistance properties and ease of processing. The many applications include

TABLE 12.2.1 Physical Properties of Polymers

Properties of Plastics	ρ (kg m^{-3})	Tensile Strength (N mm^{-2})	Elongation (%)	*E* (GN m^{-2})	BHN	Machinability
Thermoplastics						
PVC rigid	1330	48	200	3.4	20	Excellent

Phenol formaldehye (Bakelite)	G	G	F	F
Polyester (glass-fiber filled)	E	G	G	F
Silicone (asbestos filled)	O	G	F	F

Note: O = outstanding, E = excellent, G = good, F = fair, P = poor.

[a] Tensile strength (typical): E = 55 Nmm^{-2}; P = 21 Nmm^{-2}.

[b] Compressive strength (typical): E = 210 Nmm^{-2}; P = Nmm^{-2}.

pipes, refrigerator liners, car-instrument surrounds, radiator grills, telephones, boat shells, and radio and television parts. Available in medium, high, and very high impact grades.

Cellulosics

"Cellulose nitrate" is inflammable and has poor performance in heat and sunlight. Its uses are therefore limited. Cellulose acetate has good strength, stiffness, and hardness and can be made self-extinguishing. Glass-filled grades are made. Cellulose acetate-butyrate (CAB) has superior impact strength, dimensional stability, and service temperature range and can be weather stabilized. Cellulose proprionate (CP) is similar to CAB, but has better dimensional stability and can have higher strength and stiffness. Ethyl cellulose has better low-temperature strength and lower density than the others. Processing of cellulose

TABLE 12.2.3 Selection Guide for Polymers by Application

Application or Service	Properties Required	Suitable Plastics
Chemical and thermal equipment	Resistance to temperature extremes and to wide range of chemicals; minimum moisture absorption; fair to good strength	Fluorocarbons, chlorinated polyether, polyvinylidene fluoride, polypropylene, high-density polyethylene, and epoxy glass
Heavily stressed mechanical components	High-tensile plus high-impact strength; good fatigue resistance and stability at elevated temperatures; machinable or moldable to close tolerance	Nylons, TFE-filled acetals, polycarbonates, and fabric-filled phenolics
Electrostructural parts	Excellent electrical resistance in low to medium frequencies; high-strength and -impact properties; good fatigue and heat resistance; good dimensional stability at elevated temperatures	Allylics, alkyds, aminos, epoxies, phenolics, polycarbonates, polyesters, polyphenylene oxides, and silicones
Low-friction applications	Low coefficient of friction, even when nonlubricated; high resistance to abrasion, fair to good form stability and heat and corrosion resistance	Fluorocarbons (TFE and FEP), filled fluorocarbons (TFE), TFE fabrics, nylons, acetals, TFE-filled acetals, and high-density polyethylenes
Light-transmission components, glazing	Good light transmission in transparent or translucent colors; good to excellent formability and moldability; shatter resistance; fair to good tensile strength	Acrylics, polystyrenes, cellulose acetates, cellulose butyrates, ionomers, rigid vinyls, polycarbonates, and medium-impact styrenes
Housings, containers, ducts	Good to excellent impact strength and stiffness; good formability and moldability; moderate cost; good environmental resistance; fair to good tensile strength and dimensional stability	ABS, high-impact styrene, polypropylene, high-density polyethylene, cellulose acetate butyrate, modified acrylics, polyester–glass and epoxy–glass combinations

plastics is by injection molding and vacuum forming. Applications include all types of moldings, electrical insulation, and toys.

Ethylene-Vinyl Acetate (EVA)

This material gives tough flexible moldings and extrusions suitable for a wide temperature range. The material may be stiffened by the use of fillers and is also specially formulated for adhesives. Applications include all types of moldings, disposable liners, shower curtains, gloves, inflatables, gaskets, and medical tubing. The material is competitive with polyvinyl chloride (PVC), polyethene, and synthetic rubbers, and is also used for adhesives and wax blends.

Fluorocarbons

This class of polymers, characterized by fluorine substitution, has outstanding chemical, thermal, and electrical properties and is characterized by the following four main classes of structures.

Polytetrafluoroethylene (PTFE), known commercially as Teflon or Fluon, is the best-known material and resists all known chemicals, weather, and heat, has an extremely low coefficient of friction, and is "non-stick." These materials are inert with good electrical properties. They are nontoxic, nonflammable, and have a working temperature range of –270 to 260°C. They may be glass filled for increased strength and rigidity. They do not melt and they must be formed by sintering of powders. Applications include chemical, mechanical, and electrical components, bearings (plain or filled with glass and/or bronze), tubing, and vessels for "aggressive" chemicals.

Fluoroethylenepropylene (FEP), unlike PTFE, can be processed on conventional molding machines and extruded, but thermal and chemical resistance properties are not quite as good.

Ethylenetetrafluoroethylene (ETFE) possess properties similar to but not as good as those of PTFE. However, the material exhibits a thermoplastic character similar to that of polyethylene which gives it a very desirable molding behavior.

TABLE 12.2.4 Properties of Polymers

Chemical class	Cellulose acetate	Cellulose acetate	Cellulose acetate butyrate	Cellulose acetate butyrate	Nylon	Polycarbonates	Polyethylene	Polyethylene

Perfluoroalkoxy (PFA) is the fourth group of fluorinated polymers. These materials have the same excellent properties as PTFE, but the compound is melt processible and, therefore, suitable for linings for pumps, valves, pipes, and pipe fittings.

Ionomers

These thermoplastics are based on ethylene and have high melt strength, which makes them suitable for deep forming, blowing, and other similar forming processes. They are used for packaging, bottles, moldings for small components, tool handles, and trim. They have a high acceptance of fillers.

Polymethylpentene

Polymethylpentene (TPX) is a high-clarity resin with excellent chemical and electrical properties and the lowest density of all thermoplastics. It has the best resistance of all transparent plastics to distortion at high temperature — it compares well with acrylic for optical use, but has only 70% of its density. It is used for light covers, medical and chemical ware, high-frequency electrical insulation, cables, microwave oven parts, and radar components. It can withstand soft soldering temperatures.

Polyethylene Terephthalate

Polyethylene terephthalate (PETP) and modified versions thereof have high strength, rigidity, chemical and abrasion resistance, impact resistance in oriented form, and a low coefficient of friction. It is attacked by acetic acid and concentrated nitric and sulfuric acids. It is used for bearings, tire reinforcement, bottles, automotive parts, gears, and cams.

Polyamides (Nylons)

The polyamides are a family of thermoplastics, e.g., Nylon 6, Nylon 66, and Nylon 610, which are among the toughest engineering plastics with high vibration-damping capacity, abrasion resistance, inherent lubricity, and high load capacity for high-speed bearings. They have a low coefficient of friction and good flexibility. Pigment-stabilized types are not affected by ultraviolet radiation and chemical resistance is good. Unfilled nylon is prone to swelling due to moisture absorption. Nylon bearings may be filled with powdered molybdenum disulfide or graphite. Applications include bearings, electrical insulators, gears, wheels, screw fasteners, cams, latches, fuel lines, and rotary seals.

Polyethylene

Low-density polyethylene (orinally called *polythene*) is used for films, coatings, pipes, domestic moldings, cable sheathing, and electrical insulation. High-density polyethylene is used for larger moldings and is available in the form of sheet, tube, etc. Polyethylene is limited as an engineering material because of its low strength and hardness. It is attacked by many oxidizing chemical agents and some hydrocarbon solvents.

Polyketone, Aliphatic

Aliphatic polyketones are relatively strong, tough, ductile polymeric resins derived from equal proportions of ethylene and carbon monoxide with an additional few percent of higher olefin for property and processibility adjustment. Their physical, thermal, and mechanical properties are similar to polyamides and polyacetals. Mechanical properties are characterized by preservation of high levels of stiffness, toughness, and strength over a broad temperature range. Resistance to hydrolysis, swelling, and permeation provides broad chemical resistance. Relatively new in commercial supply, they find application in gears, machine components, and similar engineering applications. Tribological performance is very good, and in particular they have a low coefficient of friction and a low wear factor against steel. The electrical properties of the neat polyketone are typical of those of polar, semicrystalline thermoplastics.

Polyethersulfone

Polyethersulfone is a high-temperature engineering plastic — useful up to 180°C in general and some grades have continuous operating ratings as high as 200°C. It is resistant to most chemicals and may

be extruded or injection molded to close tolerances. The properties are similar to those of nylons. Applications are as a replacement for glass for medical needs and food handling, circuit boards, general electrical components, and car parts requiring good mechanical properties and dimensional stability.

Polystyrene

This polymer is not very useful as an engineering material because of brittleness in unmodified forms, but it is well known for its use in toys, electrical insulation, refrigerator linings, packaging, and numerous commercial articles. It is available in unmodified form as a clear transparent resin and also in clear and opaque colors. High-impact forms are achieved by compounding with butadiene or other rubbery resins and heat-resistant forms are achieved by the use of fillers. Polystyrene can be stabilized against ultraviolet radiation and also can be made in expanded form for thermal insulation and filler products. It is attacked by many chemicals, notably aromatic hydrocarbon solvents, and by ultraviolet light.

Polysulfone

Polysulfone has properties similar to nylon, but these properties are retained up to 180°C compared with 120°C for nylon, which greatly expands the range of applications. Its optical clarity is good and its moisture absorption lower than that of nylon. Applications are as a replacement for glass for medical needs and chemistry equipment, circuit boards, and many electrical components.

Polyvinyl Chloride

This is one of the most widely used of all plastics. With the resin mixed with stabilizers, lubricants, fillers, pigments, and plasticizers, a wide range of properties is possible from flexible to hard types, in transparent, opaque, and colored forms. It is tough, strong, with good resistance to chemicals, good low-temperature characteristics and flame-retardant properties. PVC does not retain good mechanical performance above 80°C. It is used for electrical conduit and trunking, junction boxes, rainwater pipes and gutters, decorative profile extrusions, tanks, guards, ducts, etc.

Polycarbonate

Polycarbonate is an extremely tough thermoplastic with outstanding strength, dimensional stability, and electrical properties, high heat distortion temperature and low-temperature resistance (down to –100°C). It is available in transparent optical, translucent, and opaque grades (many colors). Polycarbonates have only fair resistance to chemicals as evidenced by the stress cracking caused by many solvents. The weathering tendencies can be stabilized against ultraviolet radiation by the use of proper additives. Polycarbonate compounds are used for injection moldings and extrusions for glazing panels, helmets, face shields, dashboards, window cranks, and gears. Polycarbonate is an important engineering plastic.

Polypropylene

Polypropylene is a low-density, hard, stiff, creep-resistant plastic with good resistance to chemicals, good wear resistance, low water absorption, and is relatively low cost. Polypropylene can be spun into filaments, converted into weaves, injection molded, and is commonly produced in a large variety of forms. Glass-filled polypropylene is widely used for its enhanced mechanical properties. It is used for food and chemical containers, domestic appliances, furniture, car parts, twine, toys, tubing, cable sheath, and bristles.

Polyphenylene Sulfide

Polyphenylene sulfide is a high-temperature plastic useful up to 260°C. Ambient temperature properties are similar or superior to those of nylon. It has good chemical resistance and is suitable for structural components subject to heat. Glass filler improves strength and enables very high heat resistance to 300°C. Uses are similar to those of nylon, but for higher temperatures.

Polyphenylene Oxide

This is a rigid engineering plastic similar to polysulfone in uses. It can be injection molded and has mechanical properties similar to those for nylon. It is used for automotive parts, domestic appliances, and parts requiring good dimensional stability. Frequently, the commercially available product is blended (or "alloyed") with polystyrene which acts as a cost-effective extender.

Thermosetting Polymers

Alkyds

There are two main groups of alkyds: diallyphthalate (DAP) and diallylisopthalate (DIAP). These have good dimensional stability and heat resistance (service temperature 170°C; intermittent use 260°C), excellent electrical properties, good resistance to oils, fats, and most solvents, but limited resistance to strong acids and alkalis. The mechanical properties are improved by filling with glass or minerals. The main uses are for electrical components and encapsulation. A wide range of colors and fast-curing grades are available.

Amino Resins

These are based on formaldehyde reacted with urea or melamine and are formulated as coatings and adhesives for laminates, impregnated paper textiles, and molding powders. The resins are usually compounded with fillers of cellulose, wood flour, and/or other extenders. As composites with open-weave fabric, they are used for building panels. Uses also include domestic electrical appliances and electric light fittings; the melamine type is used for tableware. The strength is high enough for use in stressed components, but the material is brittle. Electrical, thermal, and self-extinguishing properties are good.

Epoxies

Epoxy resins are used extensively across industry as engineering polymers and as adhesives. They can be cold cured without pressure using a "hardener" or may be heat cured. Inert fillers, plasticizers, flexibilizers, and extenders give a wide range of properties from soft flexible to rigid solid materials. Bonding to nearly all materials, e.g., wood, metal, glass, is excellent as are the mechanical, electrical, and chemical properties. Epoxies are used in all branches of engineering, including large castings, electrical parts, circuit boards, potting, glass and carbon fiber structures, flooring, protective coatings, and adhesives. Importantly, they exhibit little or no shrinkage on cure.

Phenolics (Phenol Formaldehyde, PF)

PF, the original "Bakelite," is usually filled with 50 to 70% wood flour for molded nonstressed or lightly stressed parts. Other fillers are mica for electrical parts, asbestos for heat resistance, glass fiber for strength and electrical properties, nylon, and graphite. Phenolics represent one of the best polymers for low-creep applications. Moldings have good strength, good gloss, and good temperature range (150°C wood filled; intermittent use 220°C), but are rather brittle. Applications include electrical circuit board, gears, cams, and car brake linings (when filled with asbestos, glass, metal powder, etc.). The cost is low and the compressive strength very high.

Polyester

Polyester resins can be cured at room temperature with a hardener or alone at 70 to 150°C. It is used unfilled as a coating, for potting, encapsulation, linings, thread locking, castings, and industrial moldings. It is used mostly for glass-reinforced-plastic (GRP) moldings.

Polyimides

Polyimides are noted for their unusually high resistance to oxidation and service temperatures up to 250°C (400°C for intermittent use). The low coefficient of friction and high resistance to abrasion make them ideal for nonlubricated hearings. Graphite or molybdenum disulfide filling improves these properties. They are used for high-density insulating tape. Polyimides have high strength, low moisture absorption, and resist most chemicals, except strong alkalis and ammonia solutions.

Silicones

These may be cold or heat cured and are used for high-temperature laminates and electrical parts resistant to heat (heat distortion temperature 450°C). Unfilled and filled types are used for special-duty moldings. Organosilicones are used for surface coatings and as a superior adhesive between organic and nonorganic materials.

Laminated Polymer Structures

A wide range of composite structures are prepared from polymer resins combined with fibers. The reader is referred to Section 12.6 for a more extensive discussion of polymer composites. Laminated polymer structures consist of layers of fibrous material impregnated with and bonded together usually by a thermosetting resin to produce sheets, bars, rods, tubes, etc. The laminate may be "decorative" or "industrial," the latter being of load-bearing mechanical or electrical grade.

Phenolics

Phenolic plastics can be reinforced with paper, cotton fabric, asbestos paper fabric or felt, synthetic fabric, or wood flour. They are used for general-purpose mechanical and electrical parts. They have good mechanical and electrical properties.

Epoxies

These are used for high-performance mechanical and electrical duties. Fillers used are paper, cotton fabric, and glass fiber.

Tufnol

"Tufnol" is the trade name for a large range of sheet, rod, and tube materials using phenolic resin with paper and asbestos fabric and epoxy resin with glass or fabric.

Polyester

This is normally used with glass fabric (the cheapest) filler. The mechanical and electrical properties are inferior to those of epoxy. It can be rendered in self-colors.

Melamine

Fillers used for melamine are paper, cotton fabric, asbestos paper fabric, and glass fabric. Melamines have a hard, nonscratch surface, superior electrical properties, and can be rendered in self-colors. They are used for insulators, especially in wet and dirty conditions, and for decorative and industrial laminates.

Silicone

Silicone is used with asbestos paper and fabric and glass fabric fillers for high-temperature applications (250°C; intermittent use 300°C). It has excellent electrical but inferior mechanical properties.

Polyimide

Polyimide is most often used with glass fabric as filler. Polyimides have superior thermal and electrical properties with a service temperature similar to that for silicones but with two to three times the strength and flexibility.

Foam and Cellular Polymers

Thermoplastics

Polyurethane Foams. The "flexible" type is the one most used. It is "open cell" and used for upholstery, underlays, thermal and vibration insulation, and buoyancy. It can be generated *in situ*. The rigid type has "closed cells" and is used for sandwich construction, insulation, etc. Molded components may be made from rigid and semirigid types.

Expanded Polystyrene. This material is produced only in rigid form with closed cells. It can be formed *in situ*. The density is extremely low, as is the cost. Chemical resistance is low and the service temperature is only 70°C. It is used for packaging, thermal and acoustic insulation, and buoyancy applications.

Cellular Polyvinyl Chlorides. The low-density type is closed cell and flexible. It is used for sandwich structures, thermal insulation, gaskets, trim, to provide buoyancy, and for insulating clothing. The moderate- to high-density open-cell type is similar to latex rubber and is used as synthetic leather cloth. The rigid closed-cell type is used for structural parts, sandwich construction, thermal insulation, and buoyancy. Rigid open-cell PVC (microporous PVC) is used for filters and battery separators. In general, cellular PVC has high strength, good flame resistance, and is easy to work.

Polyethylene Foams. The flexible type is closed cell and has low density with good chemical resistance and color availability, but is a poor heat insulator and is costly. The flexible foams are used for vibration damping, packaging, and gaskets. The rigid type has high density and is used for filters and cable insulation. A structural type has a solid skin and a foam core.

Ethylene Vinyl Acetates. These are microcellular foams similar to microcellular rubber foam, but are much lighter with better chemical resistance and color possibilities.

Other Types. Other types of thermoplastics include cellular acetate, which is used as a core material in constructions; expanded acrylics, which have good physical properties, thermal insulation, and chemical resistance; expanded nylon (and expanded ABS), which are low-density, solid-skin constructions; expanded PVA, which has similar properties to expanded polystyrene; and expanded polypropylene, which gives high-density foams.

Thermosets

Phenolics. These can be formed *in situ*. They have good rigidity, thermal insulation, and high service temperature, but are brittle.

Urea Formaldehyde (UF) Foam. This is readily formed *in situ* and has good thermal insulation. It has open pores and is used for cavity-wall filling.

Expanded Epoxies. These have limited use because of their high cost. They give a uniform texture and good dimensional stability and are used for composite forms, e.g., with polystyrene beads.

Silicon Foams. These are rigid and brittle with a high service temperature (300°C; 400°C intermittent use). Their use is limited to high-temperature-resistant sandwich constructions. The flexible closed-cell type is costly but will operate up to 200°C and is used for high-temperature seals and gaskets.

Elastomers

Cellular Rubbers. There are three types: *sponge*, solid rubber blown to give an open-cell structure, *foam*, a liquid rubber expanded to form open or closed cells which is stiffer than sponge; and *expanded*, a solid rubber blown with mainly closed cells, also it is stiffer than sponge. Uses include gaskets, seals, thermal insulation, cushioning, shock absorption, sound and vibration damping, buoyancy, and sandwich constructions.

Elastomers

Elastomers, or rubbers, are essentially amorphous polymers with linear chain molecules with some cross-linking, which ensures elasticity and the return of the material to its original shape when a load is removed. They are characterized by large strains (typically 100%) under stress. The synthetic rubber styrene butadiene is the most-used elastomer, with natural rubber a close second. The following describes the commonly used elastomers and gives some applications and properties.

Natural Rubbers (Polyisoprene, NR)

These elastomers have high strength, flexibility, and resilience, but have poor resistance to fuels, oils, flame, and sunlight aging. They are more costly than synthetic rubbers, which often replace them. "Soft-rubber" contains 1 to 4% sulfur as a vulcanizer. Wear resistance is increased by inclusion of fillers such as carbon black, silicon dioxide, clay, and wood flour. "Hard rubber" may contain up to 25% sulfur. Applications include vehicle tires and tubes, seals, antivibration mountings, hoses, and belts. Full vulcanization of 45% produces ebonite. Shore hardness: 30 to 90. Temperature range: –55 to 82°C.

Synthetic Rubbers

Styrene Butadiene Rubbers (SBR, GRS, BUNAS). These are similar to natural rubbers in application, but are usually inferior in mechanical properties, although cheaper. They are used in car brake hydraulic systems and for hoses, belts, gaskets, and antivibration mountings. Shore hardness: 40 to 80. Temperature range: –50 to 82°C.

Butadiene Rubbers (Polynutadiene, BR). These are used as substitutes for natural rubber, but are generally inferior. They have similar applications as natural rubber. Shore hardness: 40 to 90. Temperature range: –100 to 93°C.

Butyl Rubbers (Isobutylene Isoprene, GR 1). These are extremely resistant to water, silicon fluids and grease, and gas permeation. They are used for puncture-proof tires, inner tubes, and vacuum seals. Shore hardness: 40 to 90. Temperature range: –45 to 150°C.

Nitrile Rubbers (Butadiene Acrylonitrile, BUNA, N.NBR). These have good physical properties and good resistance to fuels, oils, solvents, water, silicon fluids, and abrasion. They are used for O rings and other seals, petrol hoses, fuel-pump diaphragms, gaskets, and oil-resistant shoe soles. Shore hardness: 40 to 95. Temperature range: –55 to 82°C.

Neoprene Rubbers (Polychloroprene, Chloroprene). These are some of the best general-purpose synthetic rubbers. They have excellent resistance to weather aging, moderate resistance to oils, and good resistance to refrigerants and mild acids. Shore hardness: 40 to 95. Temperature range: –40 to 115°C.

Chlorosulfonated Polyethylene Rubbers (CSM). These have poor mechanical properties but good resistance to acids and heat with complete resistance to ozone. They are used in chemical plants, tank linings, and high-voltage insulation. Shore hardness: 45 to 100. Temperature range: –100 to 93°C.

Ethylene Propylene Rubbers (EP, FPM). These specialized rubbers are especially resistant to weather aging heat, many solvents, steam, hot water, dilute acids and alkalis, and ketones, but not petrol or mineral oils. They are used for conveyor belts, limited automotive applications, silicone fluid systems, and electrical insulation. Shore hardness: 40 to 90. Temperature hardness: –50 to 177°C.

Fluorocarbon Rubbers. These comprise a wide range of rubbers with excellent resistance to chemical attack, heat, acids, fuels, oils, aromatic compounds, etc. They have a high service temperature. They are particularly suitable for vacuum applications. Shore hardness: 60 to 90. Temperature hardness: –23 to 260°C.

Isoprenes (Polyisoprene, IR). These are chemically the same as natural rubber but are more costly. The properties and applications are similar to those of natural rubber. Shore hardness: 40 to 80. Temperature hardness: –50 to 82°C.

Polyacrylic Rubbers (ACM, ABR). This is a group of rubbers with properties midway between nitrile and fluorocarbon rubbers with excellent resistance to mineral oils, hypoid oils, and greases and good resistance to hot air and aging. The mechanical strength is low. They are often used for spark plug seals and transmission seals. Shore hardness: 40 to 90. Temperature hardness: –30 to 177°C.

Polysulfide Rubbers. These have poor physical properties and heat resistance, but good resistance to oils, solvents, and weathering and are impermeable to gases and moisture. They are used for caulking and sealing compounds and as a casting material. Shore hardness: 40 to 85. Temperature hardness: –50 to 121°C.

Polyurethane Rubbers. These have exceptional strength and tear and abrasion resistance (the best of all rubbers), low-temperature flexibility, and good resistance to fuels, hydrocarbons, ozone, and weather. Resistance to solutions of acids and alkalis, hot water, steam, glycol, and ketones is poor. They are used for wear-resistant applications such as floor coverings. Shore hardness: 35 to 100. Temperature hardness: –53 to 115°C.

Silicone Rubbers (SI). These have exceptionally high service-temperature ranges, but the mechanical properties and chemical resistance are poor. They cannot be used in applications which expose them to fuels, light mineral oils, or high-pressure steam. They are used for high- and low-temperature seals, high-temperature rotary seals, cable insulation, hydraulic seals, and aircraft door and canopy seals. Shore hardness: 30 to 90. Temperature hardness: –116 to 315°C (380°C for intermittent use).

Fluorosilicone Rubbers. These are similar to silicone rubbers but have better oil resistance and a lower temperature range. Shore hardness: 40 to 80. Temperature hardness: –64 to 204°C.

12.3 Adhesives

Richard L. Lehman

Introduction

Adhesives are substances capable of holding materials together in a useful manner by surface attachment. The principal attribute of adhesives is their ability to form strong bonds with surfaces of a wide range of materials and to retain bond strength under expected use conditions. Although most adhesives do not have excellent bulk properties and it is therefore important to keep adhesive films thin, some materials such as epoxies have bulk properties which qualify them as engineering materials and thus can be used in multifunctional applications.

Advantages and Limitations of Use

The principal advantages of adhesives are their ability to bond similar to dissimilar materials of different thickness; to enable the fabrication of complex shapes not feasible by other fastening means; to smooth external joint surfaces; to permit economic and rapid assembly; to distribute stresses uniformly over joined interfaces, to provide weight reduction in critical structures via the elimination of fasteners; to dampen vibrations; to prevent or reduce galvanic corrosion; and to provide thermal and electrical insulation.

The limitations of adhesives depend on the specific adhesive and application and may include the necessity of surface preparation, long curing times, service-temperature limitations, loss of properties during service, toxicity of flammability during assembly or use, and the tendency of many adhesives to creep under sustained load.

Classes of Adhesives

Thermoplastic adhesives are a general class of adhesives based upon long-chained polymeric structure, and are capable of being softened by the application of heat with subsequent hardening upon cooling (hot-melt adhesives). The softening process if reversible for numerous cycles, which facilitates assembly and disassembly of structures. Thermosetting adhesives are a general class of adhesives based upon cross-linked polymeric structures which develop strong bonds that cannot be reversibly broken once they are formed. Thus, the thermoset adhesives are incapable of being softened once solidified.

Thermoplastic and thermosetting adhesives are cured, a process often referred to as setting, by polymerization or solidification, by heat, catalysis, chemical reaction, free-radical activity, radiation, evaporation of solvent, or another process as governed by the chemical nature of the particular adhesive.

Elastomers are a special class of thermoplastic adhesive possessing the common quality of substantial flexibility or elasticity. Refer to Section 12.2 on polymers.

Anaerobic adhesives are a special class of thermoplastic adhesive, the polyacrylates, that set only in the absence of air (oxygen). The two basic types are (1) machinery — possessing shear strength only and (2) structural — possessing both tensile and shear strength.

Pressure-sensitive adhesives are permanently and aggressively tacky solids which form immediate bonds when two parts are brought together under pressure. They are available as films and tapes as well as hot-melt systems.

Performance of Adhesives

To obtain optimum mechanical performance of an adhesive, it is critical to select the proper compound for the target application. Table 12.3.1 illustrates compatibility of adhesives and five broad classes of common materials. Generally, for good adhesive bonds the chemistry of the adhesive must match or be

TABLE 12.3.1 Relative Performance of Adhesive Resins

Adhesive Resin	Adherence To:					Resistance			
	Paper	Wood	Metal	Ceramics	Rubbers	Water	Solvents	Alkali	Acids

TABLE 12.3.2 High-Performance Engineering and Machine Part Adhesives

Thread locking	• Anaerobic acrylic
Hub mounting	• Anaerobic acrylic — compatible materials or flow migration unimportant
	• Modified acrylic — large gaps or migration must be avoided
	• Epoxy — maximum strength at high temperatures
Bearing mounting	• Anaerobic acrylic — compatible materials necessary and flow into bearing area to be prevented
	• Modified acrylic — for lowest cost
Structural joining	• Epoxies and modified epoxies — for maximum strength (highest cost)
	• Acrylics — anaerobic or modified cyanacrylates
Gasketing	• Silicones — primarily anaerobic

similar to the surface energy, polarity, and/or chemistry of the material being bonded. The elastic modulus of the adhesive should not be greater than the bonded material.

Adhesives are used in two classes of application, those requiring only shear strength and those requiring structural properties, often tensile and shear strength. Table 12.3.2 provides a quick reference for some typical applications. A much more detailed summary and classification of adhesives is given in Table 12.3.3.

Table 12.3.3 presents a sample of a number of adhesives (with practical information) that are available from various sources. The table is adapted from the rather extensive one found in J. Shields, *Adhesives Handbook*, CRC Press, Boca Raton, FL, 1970. For other extensive lists of trade sources, the reader is

TABLE 12.3.3 Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
			Animal		
Animal (hide)	Melted at 70–75°C; sets on cooling	<70	Paper, wood, textiles	Woodworking, carpet materials, paper, bookbinding	May be thinned with water
Animal (hide) + plasticizers	Applied as a melt at 60°C	<60	Paper, cellulosic materials	Bookbinding, stationery applications	Cures to permanent flexible film
Fish glue	1 hr at 20°C	<60	Wood, chipboard, paper	General-purpose for porous materials	Rapid setting; good flexibility, moderate resistance to water; high tack
Casein	Cold setting after 20 min standing period on mixing	<50	Timber with moisture content	Laminated timber arches and beams, plybox beams, and engineering timber work	Full bond strength developed after seasoning period of 48 hr
Casein + 60% latex	Cold setting after 20 min standing period on mixing	<60	Aluminum, wood, phenolic formaldehyde (rigid, leather, rubber)	Bonding of dissimilar materials to give flexible, water-resistant bond	Flexible
			Vegetable		
Dextrine	Air drying		Paper, cardboard, leather, wood, pottery	General-purpose glue for absorbent materials	Medium drying period of 2–3 hr
Dextrine–starch blend	Applied above 15°C air drying	<48	Cellulosic materials, cardboard, paper	Labeling, carton sealing, spiral-tube winding	Fast setting; may be diluted with water
Gum arabic	Cold setting	<50	Paper, cardboard	Stationery uses	Fast drying
			Mineral		
Silicate	8 hr at 20°C	10–430	Asbestos, magnesia	Lagging asbestos cloth on high-temperature insulation	Unsuitable where moisture; not recommended for glass or painted surfaces

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Silicate with china-clay filler	Dried at 80°C before exposure to heat	–180–1500	Asbestos, ceramics, brickwork, glass, silver, aluminum, steel (mild)–steel	General purpose cement for bonding refractory materials and metals; furnace repairs and gastight jointing of pipe work; heat-insulating materials	Resistant to oil, gasoline, and weak acids
Sodium silicate	Dried at 20–80°C before exposure to heat	0–850	Aluminum (foil), paper, wood–wood	Fabrication of corrugated fiber board; wood bonding, metal foil to paper lamination	Suitable for glass-to-stone bonding
Aluminum phosphate + silica filler	Dried $^1/_2$ hr at 20°C, then $^1/_2$ hr at 70°C + $^1/_2$ hr at 100°C + 1 hr at 200°C + 1 hr at 250°C; repeat for two overcoatings and finally cure at 1 hr at 350°C	<750	Steels (low-alloy), iron, brass, titanium, copper, aluminum	Strain-gauge attachment to heat-resistant metals; heater-element bonding	Particularly suited to heat-resistant steels where surface oxidation of metal at high temperatures is less detrimental to adhesion
Bitumen/latex emulsion	Dried in air to a tacky state	0–66	Cork, polystyrene (foam), polyvinyl chloride, concrete, asbestos	Lightweight thermal-insulation boards, and preformed sections to porous and nonporous surfaces; building applications	Not recommended for constructions operated below 0°C
			Elastomers		
Natural rubber	Air dried 20 min at 20°C and heat-cured 5 min at 140°C	<60	Rubber (styrene butadiene), rubber (latex), aluminum, cardboard, leather, cotton	Vulcanizing cement for rubber bonding to textiles and rubbers	May be thinned with toluene
Natural rubber in hydrocarbon solvent	Air dried 10 min at 20°C and heat-cured for 20 min at 150°C	<100	Hair (keratin), bristle, polyamide fiber	Brush-setting cement for natural- and synthetic-fiber materials	Resistant to solvents employed in oil, paint and varnish industries, can be nailed without splitting
Rubber latex	Air drying within 15 min	<60	Canvas, paper, fabrics, cellulosic materials	Bonding textiles, papers packaging materials; carpet bonding	Resistant to heat; should be protected from frosts, oils

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Chlorinated rubber in hydrocarbon solvents	Air dried 10 min at 20°C and contact bonded	–20–60	Polyvinyl chloride, acrylonitrile butadiene styrene, polystyrene, rubber, wood	General-purpose contact adhesive	Resistant to aging, water, oils, petroleum
Styrene–butadene rubber lattices	Air drying	–20–60	Polystyrene (foam), wood, hardboard, asbestos, brickwood	Bonding polystyrene foams to porous surface	—
Neoprene/nitrile rubbers in (?)	Dried 30 min in air and bonded under pressure; tacky	–20–60	Wood, linoleum, leather, paper, metals, nitrile rubbers, glass, fabrics	Cement for bonding synthetic rubbers to metals, woods, fabrics	May be thinned with ketones
Acrylonitrile rubber + phenolic resin	Primer air dried 60 min at 20°C, film cured 60 min at 175°C under pressure; pressure released on cooling at 50°C	–40–130	Aluminum (alloy)–aluminum to DTD 746	Metal bonding for structural applications at elevated temperatures	Subject to creep at 150°C for sustained loading
Polysulfide rubber in ketone solvent and catalyst	3 days at 25°C	–50–130, withstands higher temperatures for short periods	Metals	Sealant for fuel tanks and pressurized cabins in aircraft, where good weatherproof and waterproof properties are required	Resistant to gasoline, oil, hydraulic fluids, ester lubricants; moderate resistance to acids and alkalis
Silicone rubber	24 hr at 20°C (20% R.H.); full cure in 5 days	–65–260	Aluminum, titanium, steel (stainless), glass, cork, silicone rubber, cured rubber–aluminum, cured rubber–titanium, cured rubber–steel (stainless), aluminum–aluminum (2024 Alclad), cork–cork (phenolic bonded)	General-purpose bonding and scaling applications; adhesive/sealant for situations where material is expected to support considerable suspended weight; high-pressure exposure conditions	Resistant to weathering and moisture
Reclaim rubber	Contact bonded when tacky	<50	Fabric, leather, wood, glass, metals (primed)	General industrial adhesive for rubber, fabric, leather, porous materials	May be thinned with toluene
Polychloroprene	Air dried 10–20 min at 20°C	<60	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Modified polyurethane	3 hr at 18°C to 16 hr at –15°C	–80–110	Concrete, plaster, ceramics, glass, hardboards, wood, polyurethane (foam), phenol formaldehyde (foam), polystyrene (foam), copper, lead, steel, aluminum	Bonding to rigid and semirigid panels to irregular wall surfaces, wall cladding and floor laying; building industry applications	Foam remains flexible on aging even at elevated temperatures; will withstand a 12% movement
			Thermoplastic		
Nitrocellulose in ester solvent	Heat set 1 hr at 60°C after wet bonding	60	Paper, leather, textiles, silicon carbide, metals	Labeling, general bonding of inorganic materials including metals	Good resistance to mineral oils
Modified methyl cellulose	Dries in air	<50	Vinyl-coated paper, polystyrene foam	Heavy-duty adhesive; decorating paper and plastics	Contains fungicide to prevent biodeterioration
Ethylene vinyl acetate copolymer + resins	Film transfer at 70–80°C followed by bonding at 150–160°C	60, or 1 hr at 90	Cotton (duck)–cotton, resin rubber–leather, melamine laminate–plywood, steel (mild)–steel, acrylic (sheet) acrylic	Metals, laminated plastics, and textiles; fabrication of leather goods; lamination work	Good electrical insulation
Polyvinyl acetate	Rapid setting	<60	Paper, cardboard	Carton sealing in packaging industry	Resistant to water
Synthetic polymer blend	Applied as a melt at 177°C	<70	Paper, cardboard, polythene (coated materials)	Carton and paperbag sealing; packaging	—
Polychloroprene/resin blend in solvent	Air dried 10 min at 20°C and cured 4 days at 20°C to 7 hr at 75°C	<70	Chlorosulfonated polythene, polychloroprene fabrics, polyamide fabrics, leather, wood, textiles	Bonding synthetic rubbers and porous materials; primer for polyamide-coated fabrics such as nylon, terylene	—
Polychloroprene	Air dried 10–20 min at 20°C	—	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance
Saturated polyester + isocyanate catalyst in ethyl acetate	Solvent evaporation and press cured at 40–80°C when tacky	—	Cellulose, cellulose acetate, polyolefins (treated film), polyvinyl chloride (rigid), paper, aluminum (foil), copper (foil)	Lamination of plastic films to themselves and metal foils for packaging industry, printed circuits	Resistant to heat, moisture, and many solvents

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Cyanoacrylate (anaerobic)	15 sec to 10 min at 20°C substrate dependent	Melts at 165	Steel–steel, steel–aluminum, aluminum–aluminum, butyl rubber–phenolic	Rapid assembly of metal, glass, plastics, rubber components	Anaerobic adhesive. Curing action is based on the rapid polymerization of the monomer under the influence of basic catalysts; absorbed outer layer on most surfaces suffices to initiate polymerization and brings about bonding
Polyacrylate resin (anaerobic)	3 min at 120°C to 45 min at 65°C or 7 days at 20°C	–55–95	Aluminum–aluminum	Assembly requirements requiring high resistance to impact or shock loading; metals, glass and thermosetting plastics	Anaerobic adhesive
			Thermosetting		
Urea formaldehyde	9 hr at 10°C to 1 hr at 21°C after mixing powder with water (22%)	<90	Wood, phenolic laminate	Wood gluing and bonding on plastic laminates to wood; plywood, chipboard manufacture; boat building and timber engineering	Excess glue may be removed with soapy water
Phenolic formaldehyde + catalyst PX-12	Cold acting	<100	Wood	Timber and similar porous materials for outdoor-exposure conditions; shop fascia panels	Good resistance to weathering and biodeterioration
Resorcinol formaldehyde + catalyst RXS-8	Cured at 16–80°C under pressure	<100	Wood, asbestos, aluminum, phenolic laminate, polystyrene (foam), polyvinyl chloride, polyamide (rigid)	Constructional laminates for marine craft; building and timber applications; aluminum–plywood bonding; laminated plastics	Recommended for severe outdoor-exposure conditions
Epoxy resin + catalyst	24–48 hr at 20°C to 20 min at 120°C	100	Steel, glass, polyester–glass fiber composite, aluminum–aluminum	General-purpose structural adhesive	—

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Epoxy resin + catalyst	8 hr at 24°C to 2 hr at 66°C to 45 min at 121°C	65	Steel, copper, zinc, silicon carbide, wood, masonry, polyester–glass fiber composite, aluminum–aluminum	Bonding of metals, glass, ceramics, and plastic composites	Cures to strong, durable bond
Epoxy + steel filler (80% w/w)	1–2 hr at 21°C	120	Iron, steel, aluminum, wood, concrete, ceramics, aluminum–aluminum	Industrial maintenance repairs; metallic tanks, pipes, valves, engine castings, castings	Good resistance to chemicals, oils, water
Epoxy + amine catalyst (ancamine LT)	2–7 days at 20°C for 33% w/w catalyst content	–5–60	Concrete stonework	Repair of concrete roads and stone surfaces	Excellent pigment-wetting properties; effective underwater and suited to applications under adverse wet or cold conditions
Epoxy resin (modified)	4–5 hr at 149°C to 20 min at 230°C to 7 min at 280°C	150	Aluminum, steel, ceramics	One-part structural adhesive for high-temperature applications	Good gap-filling properties for poorly fitting joints; resistant to weather, galvanic action
Epoxy	45 sec at 20°C	—	Gem stones, glass, steel, aluminum–aluminum	Rapid assembly of electronic components, instrument parts, printed circuits; stone setting in jewelry and as an alternative to soldering	—
Epoxy resin in solvent + catalyst	8 hr at 52°C to $^1/_2$ hr at 121°C	–270–371	Aluminum and magnesium alloys for elevated-temperature service	Strain gauges for cryogenic and elevated-temperature use; micromeasurement strain gauges	Cured material resists outgassing in high vacuum
Epoxy polyamide	8 hr at 20°C to 15 min at 100°C	100	Copper, lead, concrete, glass, wood, fiberglass, steel–steel aluminum–aluminum	Metals, ceramics, and plastics bonding; building and civil engineering applications	Resists water, acids, oils, greases

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Epoxy/polysulfide	24 hr at 20°C to 3 hr at 60°C to 20 min at 100°C	<120	Asbestos (rigid), ceramics, glass–fiber composites, carbon, polytetrafluoroethylene (treated), polyester (film), polystyrene (treated), rubber (treated), copper (treated), tungsten carbide, magnesium alloys, aluminum–aluminum, steel (stainless)–steel	Cold-setting adhesive especially suitable for bonding materials with differing expansion properties	Cures to flexible material; resistant to water, petroleum, alkalis, and mild acids
Phenol furfural + acid catalyst	2 days at 21°C	90–140	Alumina, carbon (graphite)	Formulation of chemically resistant cements; bedding and joining chemically resistant ceramic tiles	Extremely resistant to abrasion and heat
			Pressure-sensitive		
	Heated by air drying for several hours or 15–30 min at 210°F	—	Teflon–Teflon, Teflon–metal	—	Good resistance to acids and alkalis; excellent electrical properties
			Miscellaneous		
Ceramic-based	Dried for 1/2 hr at 77°C and cured 1/2 hr at 200°C + 1 hr at 250°C; postcured, 1 hr at 350°C	816	Metals	Strain gauges, temperature sensors for elevated-temperature work	—

12.4 Wood

Daniel J. Strange

Definition

Wood is the structural component of a tree. It is composed of dead cells which were originally formed near the cambium (just beneath the bark). As the tree grows, the cambium moves outward, leaving the dead cells behind to serve as structure.

The two broad classifications for types of wood and softwoods and hardwoods. Softwoods come from conifers while hardwoods come from deciduous trees, and as the name implies softwoods are generally softer and hence weaker and with lower elastic modulus than hardwoods, although this generalization is not universally true.

The wood closest to the bark is called sapwood, and this layer extends about an inch into the tree. Although most of the cells in this layer are dead, this is the layer which transports moisture to the rest of the tree by capillary action. Beneath the sapwood layer is the heartwood, which is almost totally inactive except to provide structural support.

Composition

Wood is a fibrous cellular material with the cell walls composed primarily of cellulose, hemicellulose, and lignin. Cellulose is a linear polymer of glucose units and is the single most common organic chemical in nature. It accounts for roughly 40 to 50% of the wood by weight. Hemicellulose is a modified form of cellulose comprising approximately 30% of the cell wall whose structure can vary depending upon the exact type of wood. Lignin is a complex three-dimensional phenolic polymer which composes 20 to 30% of the structure of the wood. The rest of the weight of the wood is composed primarily of extraneous extractive substances which reside within the cellular structure and affect properties such as specific gravity, moisture absorption, and durability.

Variations in the compositions, structures, and volumes of these four components can have dramatic effects on the properties of the wood. These properties are relatively constant within a species, although growing conditions can have a significant influence.

Mechanical Properties

The properties of wood can vary substantially depending upon moisture content. “Green” wood, wood taken directly from a living tree with associated high moisture level, is significantly weaker (lower Young’s modulus, tensile strength, and compressive strength) than oven-dried wood. Typical ratios of dry to green wood strength properties vary from 1.2 to 1.8.

The failure modes of wood are more complex than one might expect. Because wood is essentially a composite material, it does not follow Hooke’s law at high stresses but instead exhibits viscoelastic behavior. Figure 12.4.1 shows typical stress–strain curves for wood in tension and compression. At very high stresses, creep can occur. Wood is strongest in tension parallel to the grain, on the order of 100 MPa for a typical softwood. Perpendicular to the grain this value drops to about 4 MPa. In compression the strength values are approximately half the tension values, due to the collapse of the cellular structure and buckling of the wood fibers.

There are three principal shear failure modes in wood, six if one distinguishes between the radial and tangential directions. These modes are shear perpendicular to grain, shear parallel to grain, and rolling shear. Rolling shear occurs when the failure plane is parallel to the grain but the sliding direction is perpendicular to the grain, hence the fibers “roll” over each other. Wood is strongest when the shear is perpendicular to the grain, and weakest in rolling shear.

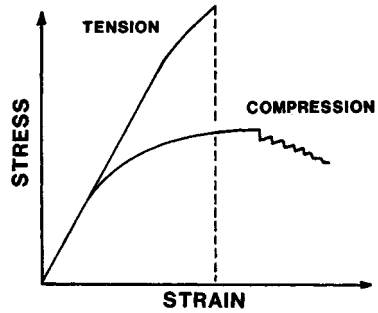

FIGURE 12.4.1 Stress–strain behavior of wood in tension and compression. Stress–strain curves for wood in tension and compression parallel to grain. Signs of stress and strain have been ignored so that both may be plotted together. Note particularly the difference in strength and in the extent of the nonlinear deformation prior to maximum stress.

Decay Resistance

Totally dry wood does not decay. Furthermore, wood kept completely submerged will not decay significantly. Wood decays most rapidly in warm, humid, low-altitude areas. Some species of wood are more decay resistant than others as a result of the presence of extractives. White oak, walnut, cherry, cedar, and yew are examples of highly decay-resistant woods. Pines, willows, elms, beeches, and spruces are examples of low decay-resistant woods.

Composites

By gluing wood plies, chips, fibers, or pulp together a composite material can be formed which has more isotropic and homogenous properties than regular timber. In addition, this technique creates a strong and durable product out of wood unsuitable for timber. In general, wood composites homogenize the extreme anisotropy of timber into a nearly isotropic material whose properties are an average of the properties in each direction of the original timber. Table 12.4.1 classifies the various wood composites based upon the constitutive particle and the binder.

The most common wood composite is paper. Paper is made from pulped and chemically treated cellulose fibers, which is then rolled into sheets, pressed, and dried. There is no glue involved, as the microfibrils of the cellulose interlock and form hydrogen bonds. Fiberboard is similar to paper, only thicker (by an arbitrary value, typically 0.012 in.) and with larger fiber bundles. *Hardboard* simply refers to a high-density fiberboard.

Wood chips and/or sawdust pressed and glued together is referred to as *particleboard*. Typically, the chips range in size from 10 to 300 mm long and are in the form of flakes or fibers. Particleboard is effectively isotropic, easily machineable, and inexpensive. It is often used in furniture and for floor underlayment. When larger wood chips are used the product is referred to as *flakeboard*.

Plywood is created by layering plies of radial-cut wood. Typically, the plies are oriented at 90° to each other, which results in a strong material when the stress in parallel or perpendicular to the grain of the face plies, but a lesser strength at any other angle. Some design strength specifications of plywood are given in Table 12.4.2. Plywood makes efficient use of timber due to its radial cut, minimizes the effects of imperfections, resists warping, and can be formed into large sheets. Plywood is also less expensive than clear lumber.

The reader is referred to Table C.14 in the Appendix for an overview of the physical properties and uses of American woods. The table also contains recommendations for appropriate applications. Table E.1 in the Appendix gives nominal sizes for lumber and timber, as well as allowable stresses in tension and compression and moduli of elasticity of various kinds of woods.

12.5 Portland Cement Concrete

Steven H. Kosmatka

Introduction

Portland cement concrete is a simple material in appearance with a very complex internal nature. In contrast to its internal complexity, versatility, durability, and economy of concrete have made it the most-used construction material in the world. This can be seen in the variety of structures it is used in, from highways and bridges to buildings and dams.

Concrete is a mixture of portland cement, water, and aggregates, with or without admixtures. The portland cement and water form a paste that hardens as a result of a chemical reaction between the cement and water. The paste acts as a glue, binding the aggregates (sand and gravel or crushed stone) into a solid rocklike mass. The quality of the paste and the aggregates dictate the engineering properties of this construction material. Paste qualities are directly related to the amount of water used in relation to the amount of cement. The less water that is used, the better the quality of the concrete. Reduced water content results in improved strength and durability and in reduced permeability and shrinkage. As the fine and coarse aggregates make up 60 to 75% of the total volume of the concrete (Figure 12.5.1), their selection is important. The aggregates must have adequate strength and resistance to exposure conditions and must be durable.

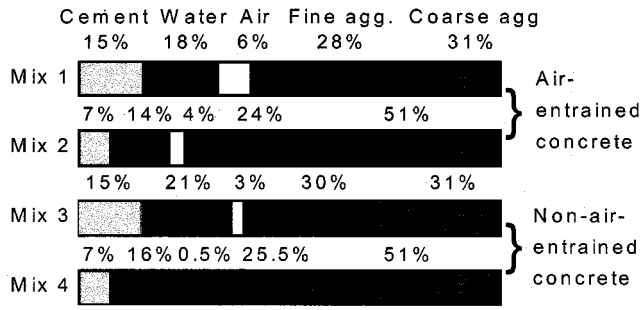

FIGURE 12.5.1 Range of proportions of materials used in concrete. (From *Design and Control of Concrete Mixtures*, EB001, Portland Cement Association, Skokie, IL, 1992. With permission.)

Fresh Concrete Properties

Freshly mixed concrete should be in a semifluid state capable of being molded by hand or mechanical means. All the particles of sand and coarse aggregate are encased and held in suspension. The ingredients should not segregate or separate during transport or handling. After the concrete hardens, it becomes a homogeneous mixture of all the components. Concrete of plastic consistency should not crumble, but flow sluggishly without segregation.

Concrete must be consolidated to form a homogeneous mass without the presence of large voids to achieve the desired strength and durability of the construction material. Internal and external vibration of concrete using vibrators allows stiff, slow-slump mixtures to be properly densified. The use of mechanical vibration provides an economical, practical method to quickly consolidate concrete without detrimentally affecting its properties.

Hardened Concrete Properties

Strength

Concrete gains strength by the reaction between cement and water — called hydration. Portland cement is primarily a calcium silicate cement. The calcium silicate combines with water and forms calcium

silicate hydrate, which is responsible for the primary engineering properties of concrete, such as setting, hardening, strength, and dimensional stability. The compressive strength of concrete increases with age as long as an appropriate moisture content and temperature are available. This is illustrated in Figure 12.5.2. Compressive strength is usually specified at the age of 28 days; however, depending on the project, ages of 3 and 7 days can also be specified. For general-use concrete, a 28-day compressive strength between 20 and 40 MPa (3000 and 6000 psi) is used. 28 MPa (4000 psi) is most common. Higher-strength concrete, 50 to 140 MPa (7000 to 20,000 psi), is used in special applications to minimize structural dimensions, increase abrasion resistance and durability, and minimize creep (long-term deformation).

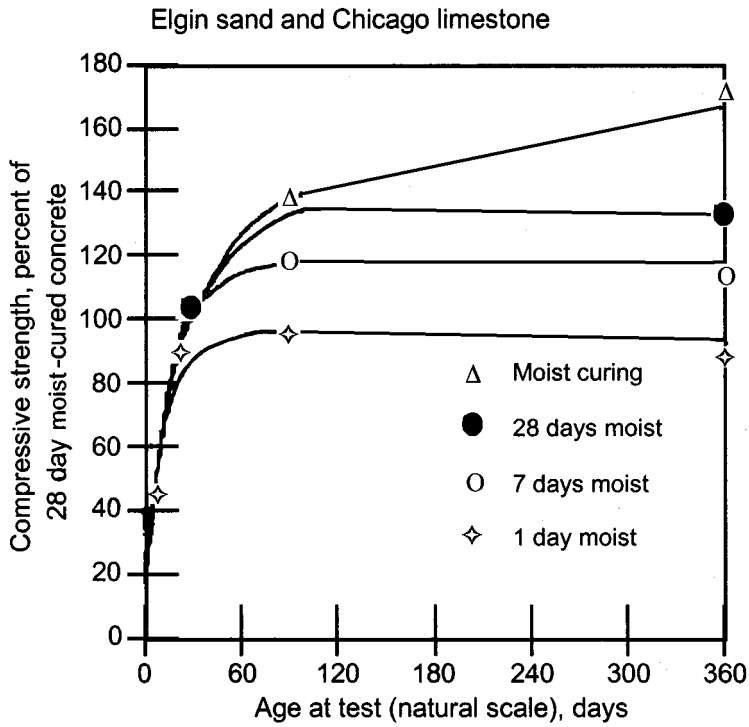

FIGURE 12.5.2 Concrete strength increases with age as long as moisture and a favorable temperature are present.

Increase in strength with age continues as long as any unhydrated cement is still present, the relative humidity in the concrete is approximately 80% or higher, and the concrete temperature is favorable. In order to maintain this increase in strength, concrete must be properly cured. Curing means that not only will a favorable temperature be present, but also moisture loss will not be permitted or extra water will be provided at the surface.

The compressive strength of concrete is directly related to the water/cement ratio. A decrease in water/cement ratio results in higher strength. Concrete achieves about 70 to 75% of its 28-day strength in 7 days. Although concrete is very strong in compression, it is weak in tensile strength. Tensile strength is about 8 to 12% of the compressive strength. Flexural strength is 0.7 to 0.8 times (for English units 5 to 7.5 times) the square root of the compressive strength. Shear strength is about 20% of the compressive strength. Modulus of elasticity ranges from 14,000 to 41,000 MPa and can be estimated as 5000 times the square root of the compressive strength (2 to 6 million psi or 57,000 times the square root of the compressive strength in English units). Refer to Tables 12.5.1, 12.5.2, and 12.5.3.

TABLE 12.5.1 Typical Properties of Normal-Strength Portland Cement Concrete

Compressive strength	20–40 MPa (3000–6000 psi)
Flexural strength	3–5 MPa (400–700 psi)
Tensile strength	2–5 MPa (300–700 psi)
Modulus of elasticity	14,000–41,000 MPa (2–6 million psi)
Permeability	1×10^{-10} cm/sec
Coefficient of thermal expansion	10^{-5}/°C (5.5×10^{-6}/°F)
Drying shrinkage	$4–8 \times 10^{-4}$
Drying shrinkage of reinforced concrete	$2–3 \times 10^{-4}$
Poisson's ratio	0.20–0.21
Shear strain	6000–17,000 MPa (1–3 million psi)
Density	2240–2400 kg/m^3 (140–150 lb/ft^3)

Density

Normal-weight concrete has a density of 2240 to 2400 kg/m^3 (140 to 150 lb/ft^3). The density of concrete varies with the relative density of the aggregate, the amount of air present in the paste, and the amount of water and cement in the mixture.

Permeability

Concrete permeability is a function of the permeability of the paste and aggregate and the interface between them. Decreased permeability improves the resistance of concrete to saturation, sulfate attack, chemical attack, and chloride penetration. Paste permeability has the greatest influence on concrete permeability. Paste permeability is directly related to the water/cement ratio and the degree of hydration or length of moist curing. A low water cement ratio and an adequate moist-curing period result in concrete with low permeability (Figure 12.5.3). The water permeability of mature, good-quality concrete, is approximately 1×10^{-10} cm/sec.

Abrasion Resistance

Abrasion resistance is directly related to the compressive strength of the concrete. The type of aggregate and the surface finish also have a strong influence on abrasion resistance. A hard aggregate, such as a granite, would provide more abrasion resistance than a soft limestone aggregate.

Volume Change and Crack Control

Concrete changes slightly in volume for various reasons. Understanding the nature of these changes is useful in planning concrete work and preventing cracks from forming. If concrete is free to move, normal volume changes would have very little consequence; but since concrete in service is usually restrained by foundations, subgrades, reinforcement, or connecting elements, significant stresses can develop. As the concrete shrinks, tensile stresses develop that can exceed the tensile strength of the concrete, resulting in crack formation.

The primary factors affecting volume change are temperature and moisture changes. Concrete expands slightly as temperature rises and contracts as temperature falls. The average value for the coefficient of thermal expansion of concrete is about 1.0×10^{-5}/°C (5.5×10^{-6}/°F). This amounts to a length change of 5 mm for a 10-m length (0.66 in. for 100 ft) of concrete subjected to a rise or fall of 50°C (100°F). The thermal coefficient of expansion for steel is about 1.2×10^{-5} per degree Celsius (6.5×10^{-6}/°F), comparable to that of concrete. The coefficient for reinforced concrete can be assumed as 1.1×10^{-5}/°C (6×10^{-6}/°F).

Concrete expands slightly with a gain in moisture and contracts with a loss in moisture. The drying-shrinkage of concrete specimens ranges from 4 to 8×10^{-4} when exposed to air at a 50% relative humidity. Concrete with a unit shrinkage of 5.5×10^{-4} shortens about the same amount as a thermal contraction caused by a decrease in temperature of 55°C (100°F). The shrinkage of reinforced concrete is less than that for plain concrete because of restraint offered by the reinforcement. Reinforced concrete structures with normal amounts of reinforcement have a drying-shrinkage in the range of 2 to 3×10^{-4}.

The amount of shrinkage is directly related to the amount of water in the concrete. Higher water content results in higher shrinkage. Specimen size also has an effect. Larger specimens shrink less than small specimens.

Drying-shrinkage is an inherent and unavoidable property of concrete; therefore, properly positioned reinforcing steel is used to reduce crack widths or joints are used to predetermine or control the location of cracks. Shrinkage control joints should be spaced about 25 to 30 times the thickness of a concrete slab on ground.

Deformation and Creep

Concrete will deform a small amount when a load is placed on it. When concrete is loaded, the deformation caused by the load can be divided into two parts: a deformation that occurs immediately, such as elastic strain, and a time-dependent deformation that begins immediately but continues at a decreasing rate for as long as the concrete is loaded (Figure 12.5.4). This latter deformation is called creep. The amount of creep is dependent on the magnitude of the stress, the age and strength of the concrete when the stress is applied, and the length of time the concrete is stressed. Creep is of little concern for normal concrete pavements, bridges, and small buildings; however, creep should be considered in design for very tall buildings or very long bridges.

Concrete Ingredients

Portland Cements

Portland cements are hydraulic cements; that is, they set and harden by reacting with water. This reaction, called hydration, combines water and cement to form a stonelike mass. Portland cement was invented in 1824 by an English mason, Joseph Aspdin, who named his product portland cement because it produced a concrete that was of the same color as natural stone on the Isle of Portland in the English Channel.

Portland cement is produced by combining appropriate proportions of lime, iron, silica, and alumina and heating them. These raw ingredients are fed into a kiln that heats the ingredients to temperatures of 1450 to 1650°C (2600 to 3000°F) and changes the raw materials chemically into cement clinker. The clinker is cooled and then pulverized. During this operation a small amount of gypsum is added to control the setting of the cement. The finished pulverized product is portland cement. Portland cement is essentially a calcium silicate cement.

The American Society for Testing and Materials (ASTM) Standard C 150, Specification for Portland Cement, provides for the following types of portland cement:

Type I	General portland cement
Type II	Moderate-sulfate-resistant cement
Type III	High-early-strength cement
Type IV	Low–heat-of-hydration cement
Type V	High-sulfate-resistant cement

Types I, II, and III may also be designated as being air entraining. Type I portland cement is a general cement suitable for all uses where special properties of other cements are not required. It is commonly used in pavements, building, bridges, and precast concrete products.

Type II portland cement is used where precaution against moderate sulfate attack is important where sulfate concentrations in groundwater or soil are higher than normal, but not severe. Type II cement can also be specified to generate less heat than Type I cement. This moderate heat of hydration requirement is helpful when placing massive structures, such as piers, heavy abutments, and retaining walls. Type II cement may be specified when water-soluble sulfate in soil is between 0.1 and 0.2%, or when the sulfate content in water is between 150 and 1500 ppm. Types I and II are the most common cements available.

Type III portland cement provides strength at an early age. It is chemically similar to Type I cement except that the particles have been ground finer to increase the rate of hydration. It is commonly used in fast-track paving or when the concrete structure must be put into service as soon as possible, such as in bridge deck repair.

Type IV portland cement is used where the rate and amount of heat generated from hydration must be minimized. This low heat of hydration cement is intended for large, massive structures, such as gravity dams. Type IV cement is rarely available.

Type V portland cement is used in concrete exposed to very severe sulfate exposures. Type V cement would be used when concrete is exposed to soil with a water-soluble sulfate content of 0.2% and higher or to water with over 1500 ppm of sulfate. The high sulfate resistance of Type V cement is attributed to its low tricalcium aluminate content.

Blended Hydraulic Cements

Blended hydraulic cements are produced by intimately blending two or more types of cementitious material. Primary blending materials are portland cement, ground granulated blast-furnace slag, fly ash, natural pozzolans, and silica fume. These cements are commonly used in the same manner as portland cements. Blended hydraulic cements conform to the requirements of ASTM C 595 or C 1157. ASTM C 5195 cements are as follows: Type IS — portland blast-furnace slag cement, Type IP and Type P — portland–pozzolan cement, Type S — slag cement, Type I (PM) — pozzolan-modified portland cement, and Type I (SM) — slag-modified portland cement. The most common blended cements available are Types IP and IS.

ASTM C 1157 blended hydraulic cements include the following: Type GU — blended hydraulic cement for general construction, Type HE — high-early-strength cement, Type MS — moderate-sulfate-resistant cement, Type HS — high-sulfate-resistant cement, Type MH — moderate-heat-of-hydration cement, and Type LH — low-heat-of-hydration cement.

Supplementary Cementing Materials (Mineral Admixtures)

Supplementary cementing materials, also called mineral admixtures, are sometimes added to concrete mixtures. They contribute to the properties of hardened concrete through hydraulic or pozzolanic activity. Typical examples are natural pozzolans, fly ash, ground granulated blast-furnace slag, and silica fume. These materials react chemically with calcium hydroxide released from the hydration of portland cement to form cement compounds.

Below is a summary of the specifications and classes of supplementary cementing materials:

1. Ground granulated iron blast-furnace slag—ASTM C 989

   Grade 80 — Slags with a low activity index
   Grade 100 — Slags with a moderate activity index
   Grade 120 — Slags with a high activity index
2. Fly ash and natural pozzolans — ASTM C 618
3. Class N — Raw or calcined natural pozzolans including diatomaceous earth, opaline cherts, shales, tuffs, volcanic ashes, and some calcined clays and shales
4. Class F — Fly ash with pozzolanic properties
5. Class C — Fly ash with pozzolanic and cementitious properties
6. Silica fume — ASTM C 1240

Mixing Water for Concrete

Almost any natural water that is drinkable can be used as mixing water for making concrete. However, some waters that are not fit for drinking may be suitable for concrete. Reference 1 provides guidance concerning the use of waters containing alkali carbonates, chlorides, sulfates, acids, oils, and other materials, and provides guidance as to allowable levels of contamination.

Aggregates for Concrete

The importance of using the right type and quality of aggregates cannot be overemphasized since the fine coarse aggregates occupy between 60 to 75% of the concrete volume and strongly influence the freshly mixed and hardened properties, mix proportions, and economy of the concrete. Fine aggregates consist of natural sand or crushed rock with particles smaller than 5 mm (0.2 in). Coarse aggregates

consist of a combination of gravel or crushed aggregate with particles predominately larger than 5 mm (0.2 in.) and generally between 10 and 13 mm ($^3/_8$ and $^1/_2$ in.). The most common coarse aggregate size is 19 and 25 mm ($^3/_4$ and 1 in.) aggregate.

Normal weight aggregates should meet the requirements of ASTM C 33. This specification limits the amounts of harmful substances and states the requirements for aggregate characteristics, such as grading. The grading and maximum size of the aggregate affect the relative aggregate proportions as well as cement and water requirements, workability, pumpability, economy, shrinkage, and durability of the concrete.

Chemical Admixtures for Concrete

Admixtures are ingredients in concrete other than portland cement, water, and aggregates that are added to the mixture immediately before or during mixing. Common chemical admixtures include air-entraining, water-reducing, retarding, accelerating, and superplasticizing admixtures. The major reasons for using admixtures are to reduce the cost of concrete construction, achieve certain properties in concrete more effectively than by other means, or to ensure the quality of concrete during the states of mixing, transporting, placing, or curing in adverse weather conditions. Refer to Table 12.5.4.

Air-entraining admixtures are used purposely to entrain microscopic air bubbles in concrete. Air entrainment will dramatically improve the durability of concrete exposed to moisture during freezing and thawing. Air-entraining admixtures are commonly used to provide between 5 and 8% air content in concrete.

Water-reducing admixtures are used to reduce the quantity of mixing water required to produce concrete of a certain slump, reduce water/cement ratio, reduce cement content, or increase slump. Typical water-reducing admixtures reduce the water content by approximately 5 to 10%. High-range water reducers (superplasticizers) reduce the water content by approximately 12 to 30% and they can produce a highly fluid concrete.

Retarding admixtures are used to retard the rate of setting of concrete. An accelerating admixture is used to accelerate strength development of concrete at an early age.

Proportioning Normal Concrete Mixtures

The objective in proportioning concrete mixtures is to determine the most economical and practical combination of readily available materials to produce a concrete that will satisfy the performance requirements under particular conditions of use. To fulfill these objectives a properly proportioned concrete mix should possess these qualities: (1) acceptable workability of freshly mixed concrete, (2) durability, strength, and uniform appearance of hardened concrete, and (3) economy. Only with proper selection of materials and mixture characteristics can the above qualities be obtained in concrete production.

The key to designing a concrete mixture is to be fully aware of the relationship between the water/cement ratio and its effect on strength and durability. The specified compressive strength at 28 days and durability concerns dictate the water/cement ratio established for a concrete mixture. The water/cement ratio is simply the weight of water divided by the weight of cement. If pozzolans or slags are used, it would include their weights and would be referred to as the water/cementitious material ratio. The water/cement ratio can be established by a known relationship to strength or by durability requirements. For example, a concrete structure may require only 20 MPa (3000 psi) compressive strength, which would relate to a water/cement ratio of about 0.6; however, if the concrete is exposed to deicers, the maximum water/cement ratio should be 0.45 (Table 12.5.5). For corrosion protection or reinforced concrete exposed to deicers, the maximum water/cement ratio should be 0.40. When designing concrete mixtures, remember that where durability is concerned, water/cement ratio should be as low as practical. Entrained air must be used in all concrete that will be exposed to freezing and thawing and

TABLE 12.5.4 Concrete Admixtures by Classification

Type of Admixture	Desired Effect	Material
Accelerators (ASTM C 494, Type C)	Accelerate setting and early-strength development	Calcium chloride (ASTM D 98) Triethanolamine, sodium thiocyanate, calcium formate, calcium nitrite, calcium nitrate
Air detrainers	Decrease air content	Tributyl phosphate, dibutyl phthalate, octyl alcohol, water-insoluble esters of carbonic and boric acid, silicones
Air-entrained admixtures (ASTM C 260)	Improve durability in environments of freeze-thaw, deicers, sulfate, and alkali reactivity Improve workability	Salts of wood resins (Vinsol resin) Some synethic detergents Salts of sulfonated lignin Salts of petroleum acids Salts of proteinaceous material Fatty and resinous acids and their salts Alkylbenzene sulfonates Salts of sulfonated hydrocarbons
Alkali-reactivity reducers	Reduce alkali-reactivity expansion	Natural pozzolans, fly ash, silica fume, blast-furnace slag, salts of lithium and barium
Bonding admixtures	Increase bond strength	Rubber, polyvinyl chloride, polyvinyl acetate, acrylics, butadiene-styrene copolymers
Coloring agents	Colored concrete	Modified carbon black, iron oxide, phthalocyanine, umber, chromium oxide, titanium oxide, cobalt blue (ASTM C 979)
Corrosion inhibitors	Reduce steel corrosion activity in a chloride environment	Calcium nitrite, sodium nitrite, sodium benzoate, certain phosphates or fluorosilicates, fluoroaluminates
Dampproofing admixtures	Retard moisture penetration into dry concrete	Soaps of calcium or ammonium stearate or eleate Butyl stearate Petroleum products
Finely divided mineral admixtures		
Cementitious	Hydraulic properties Partial cement replacement	Ground granulated blast-furnace slag (ASTM C 989) Natural cement Hydraulic hydrated lime (ASTM C 141)
Pozzolans	Pozzolanic activity Improve workability, plasticity, sulfate resistance; reduce alkali reactivity, permeability, heat of hydration Partial cement replacement Filler	Diatomaceous earth, opaline cherts, clays, shales, volcanic tufts, pumicites (ASTM C 618, Class N); fly ash (ASTM C 618, Classes F and C), silica fume
Pozzolanic and cementitious	Same as cementitious and pozzolan categories	High calcium fly ash (ASTM C 618, Class C) Ground granulated blast-furnace slag (ASTM C 989)
Nominally inert	Improve workability Filler	Marble, dolomite, quartz, granite
Fungicides, germicides, and insecticides	Inhibit or control bacterial and fungal growth	Polyhalogenated phenols Dieldrin emulsions Copper compounds
Gas formers	Cause expansion before setting	Aluminum powder Resin soap and vegetables or animal glue Saponin Hydrolized protein
Grouting agents	Adjust grout properties for specific applications	See Air-entraining admixtures, Accelerators, Retarders, Workability agents
Permeability reducers	Decrease permeability	Silica fume (ASTM C 1240) Fly ash (ASTM C 618) Ground slag (ASTM C 989) Natural pozzolans (ASTM C 618)

TABLE 12.5.4 Concrete Admixtures by Classification (continued)

Type of Admixture	Desired Effect	Material
		Water reducers
		Latex
Pumping aids	Imnprove pumpability	Organic and synthetic polymers
		Organic flocculents
		Organic emulsions of paraffin, coal tar, asphalt, acrylics
		Bentonite and pyrogenic silicas
		Natural pozzolans (ASTM C 618, Class N)
		Fly ash (ASTM C 618, Classes F and C)
		Hydrated lime (ASTM C 141)
Retarders (ASTM C 494, Type B)	Retard setting time	Lignin
		Borax
		Sugars
		Tartaric acid and salts
Superplasticizers[a] (ASTM C 1017, Type 1)	Flowing concrete	Sulfonated melamine formaldehyde condensates
	Reduce water/cement ratio	Sulfonated napthalene formaldehyde condensates
		Ligonsulfonates
Superplasticizer[a] and retarder (ASTM C 1017, Type 2)	Flowing concrete with retarded set Reduce water	See Superplasticizers and also Water reducers
Water reducer (ASTM C 494, Type A)	Reduce water demand at least 5%	Lignosulfonates
		Hydroxylated carboxylic acids
		Carbohydrates
		(Also tend to retard set so accelerator is often added)
Water reducer and accelerator (ASTM C 494, Type E)	Reduce water (minimum 5%) and accelerate set	See Water reducer, Type A (Accelerator is added)
Water reducer and retarder (ASTM C 494, Type D)	Reduce water (minimum 5%) and retard	See Water reducer, Type A
Water reducer — high range (ASTM C 494, Type F)	Reduce water demand (miniumum 12%)	See Superplasticizers
Water reducer — high range — and retarder (ASTM C 494, Type G)	Reduce water demand (miniumum 12%) and retard set	See Superplasticizers and also Water reducers
Workability agents	Improve workability	Air-entraining admixtures
		Finely divided admixtures, except silica fume
		Water reducers

[a] Superplasticizers are also referred to as high-range water reducers or plasticizers. These admixtures often meet both ASTM C 494 and C 1017 specifications simultaneously.

the presence of deicing chemicals. A typical air content for concrete would range from 5 to 8%. Reference 1 provides step-by-step procedures for proportioning concrete. Refer to Tables 12.5.6, 12.5.7, and 12.5.8.

Mixing, Transporting, and Placing Concrete

All concrete should be mixed thoroughly until it is uniform in appearance with all ingredients evenly distributed. If concrete has been adequately mixed, samples taken from different portions of a batch will have essentially the same unit weight, air content, slump, and strength. Concrete is sometimes mixed at a job site at a stationary mixer or paving mixer, and other times it is mixed in central mixers at ready-mix plants (ASTM C 94). Once concrete is transported to a job site it is then conveyed by a variety of methods including belt conveyors, buckets, shoots, cranes, pumps, wheelbarrows, and other equipment.

TABLE 12.5.5 Relationships Between Water Cement Ratio and Compressive Strength of Concrete

Compressive Strength at 28 days, MPa (psi)	Water-Portland Cement Ratio, by Mass	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
40 (5800)	0.42	—
35 (5100)	0.47	0.39
30 (4400)	0.54	0.45
25 (3600)	0.61	0.52
20 (2900)	0.69	0.60
15 (2200)	0.79	0.70

Note: Strength is based on 150 × 300-mm cylinders moist cured 28 days at 23 ± 2°C. Relationship assumes maximum size of aggregate about 25 mm.
Adapted from *Design and Control of Concrete Mixtures,* EBDD1, Portland Cement Association, Skokie, IL, 1992. With permission.

Concrete should be conveyed in a manner in which the concrete is not allowed to dry out, be delayed, or allowed to segregate before it is placed.

Curing

All concrete must be properly cured. Curing is the maintenance of a satisfactory moisture content and temperature in concrete during some definite time period immediately following placing and finishing so that the desired properties of strength and durability may develop. Concrete should be moist cured for 7 days at a temperature between 10 and 27°C (50 and 80°F). Common methods of curing include ponding, spraying, or fogging; use of wet covers, impervious paper, plastic sheets, and membrane-forming curing compounds; or a combination of these.

Durability

Freeze-Thaw and Deicer Scaling Resistance

As water freezes in wet concrete, it expands 9%, producing hydraulic pressures in the cement paste and aggregate. Accumulated effects of successive freeze-thaw cycles and disruption of the paste and aggregate eventually cause significant expansion and extensive deterioration of the concrete. The deterioration is visible in the form of cracking, scaling, and crumbling.

The resistance of hardened concrete to freezing and thawing in a moist condition, with or without the presence of deicers, is significantly improved by the use of entrained air. Air entrainment prevents frost damage and scaling and is required for all concretes exposed to freezing and thawing or deicer chemicals. An air content of between 5 and 8% should be specified. Air-entrained concrete should be composed of durable materials and have a low water/cement ratio (maximum 0.45), a minimum cement content of 335 kg/m^3 (564 lb/yd^3) or move, proper finishing after bleed water has evaporated from the surface, adequate drainage, a minimum of 7-days moist curing at or above 10°C (50°F), a minimum compressive strength of 28 MPa (4000 psi), and a minimum 30-day drying period after moist curing. Sealers may also be applied to provide additional protection against the effects of freezing and thawing and deicers. However, a sealer should not be necessary for properly proportioned and placed concrete.

Sulfate-Resistant Concrete

Excessive amounts of sulfates in soil or water can, over 5 to 30 years, attack and destroy concrete that is not properly designed. Sulfates attack concrete by reacting with hydrated compounds in the hardened cement paste. Due to crystallization growth, these expansive reactions can induce sufficient pressure to

disrupt the cement paste, resulting in cracking and disintegration of the concrete. The first defense against sulfate attack is to use a low water/cement ratio (0.45 or preferably less), and to select a Type II or V cement (see the section on cement).

Corrosion Protection

Concrete protects embedded steel from corrosion through its highly alkaline nature. The high-pH environment (usually greater than 12.5) causes a passive and noncorroding protective oxide film to form on steel. However, carbonation or the presence of chloride ions from deicers or seawater can destroy or penetrate the film, causing rusting of the reinforcing steel. In addition to using a water/cement ratio of 0.40 or less, the following protective strategies can be used individually or in combination to reduce the risk of corrosion:

1. Cover thickness of 90 mm (3.5 in.) or more of concrete over top, reinforcing steel of compression zones. [*Note:* Excessive cover in tension zones exacerbates surface crack width.]
2. Low-slump dense concrete overlay
3. Latex-modified concrete overlay
4. Interlayer membrane/asphaltic concrete systems
5. Epoxy-coated reinforcing steel
6. Corrosion-inhibiting admixtures in concrete
7. Sealers with or without overlay
8. Silica-fume or other pozzolans that significantly reduce concrete permeability
9. Low water/cement ratio (<0.35) superplasticized concrete
10. Cathodic protection
11. Polymer concrete overlay

12. Galvanized reinforcing steel
13. Polymer impregnation
14. Lateral and longitudinal prestressing for crack control
15. Blended cements containing silica fume or other pozzolans to reduce permeability

Alkali–Silica Reaction

Most aggregates are chemically stable in hydraulic cement concrete, without deleterious interaction with other concrete ingredients. However, this is not the case for aggregates containing certain siliceous substances that react with soluble alkalis in concrete. Alkali–silica reactivity (ASR) is an expansive reaction between reactive forms of silica in aggregate and alkali hydroxides in concrete. Very reactive aggregates can induce cracks within a year, whereas slowly reactive aggregates can take over 20 years to induce noticeable cracks. ASR is best controlled through the use of fly ash, slag, silica fume, natural pozzolans, or blended hydraulic cement. With proper care in analyzing aggregates and selecting appropriate concrete ingredients, ASR can be effectively minimized using available materials. Reference 2 provides guidance on ASR.

12.6 Composites

Introduction

Victor A. Greenhut

A composite material is a macroscopic, physical combination of two or more materials in which one material usually provides reinforcement. Composites have been developed where no single, quasi-continuous material will provide the required properties. In most composites one phase (material) is continuous and is termed the *matrix*, while the second, usually discontinuous phase, is termed the *reinforcement*, in some cases *filler* is applied when the reinforcement is not a quasi-continuous fiber. Matrix-filler nomenclature is one method of categorization. This yields the categories *metal matrix* (MMC), *polymer (plastic) matrix* (PMC), and *ceramic matrix* (CMC) composites — the major subdivisions of this section. Other categories are given the shape and configuration of the reinforcing phase. The reinforcement is usually a ceramic and/or glass. If it is similar in all dimensions, it is a *particulate-reinforced* composite; if needle-shaped single crystals, it is *whisker-reinforced*; if cut continuous filament, *chopped fiber-reinforced*; and if continuous fiber, *fiber composite*. For fiber composites configuration gives a further category. If fibers are aligned in one direction, it is a *uniaxial fiber composite*; if arranged in layers, it is a *laminar composite*; if a three-dimensional arrangement, it is a *3D weave composite*. Laminates and 3D weaves can be further divided by the weave used for the fiber.

Composites are not new materials. Perhaps the first important engineering structural composite was the Biblical straw-reinforced, sun-dried mud brick — adobe. Laminated structures such as bows have been used since prehistoric times. In the early 1900s doped fabric was employed in early aircraft surfaces. Reinforced phenolics were developed in the 1930s and glass-reinforced plastics in the 1940s. More recently, emphasis turned to reinforcements, with graphitic and boron-based fibers developed in the 1960s. High-performance aramids, such as Kevlar™, were developed in the 1970s. This and the previous decade have seen new developments in both fiber and matrix with lightweight aerospace MMCs and high-temperature CMCs showing major advances.

This section will concentrate on advanced composites in which major structural performance is achieved, but it should be noted that the largest tonnage and dollar value of composites is driven by the cost of materials. Polymers are reinforced with glass particulate or chipped fiber because it lowers the price per pound of a plastic, hence the term *filler* for reinforcement material. The structural properties are also improved, as PMCs show increased stiffness (resistance to bending) and strength (resistance to failure). These and other properties will receive the emphasis in this section. In MMCs high hardness, maintenance of hardness at elevated temperature, and precise tolerance are often lead properties, although stiffness and strength are important. The metal matrix confers some ductility so that the catastrophic failure of a solely ceramic material is avoided. In CMCs the reinforcement is chiefly incorporated to prevent catastrophic failure to introduce a more predictable failure stress (increased reliability), and to a lesser extent to increase strength. Particulate-reinforced plastics and fiberglass (glass fiber–reinforced plastic) have become commonplace engineering materials, as have ceramic-reinforced metal matrices (cemented carbides and cermets). Reinforcement with graphite and other advanced technology fibers has emerged for aerospace applications, biomedical use, and high-performance/high-cost consumer products such as sporting goods. Fiber-reinforced MMCs and ceramic–ceramic composites have developed greatly, but are still quite limited in application to very advanced technologies which can bear relatively high costs.

An important consideration for composite production is the bond between the matrix and the reinforcement. For MMCs and PMCs load must be transferred (Figure 12.6.1) to the relatively high-strength, high-elastic-modulus ceramic or glass in order to maximize the mechanical performance. For best transfer there must be no relative sliding or interface failure, so the strain at the matrix-to-reinforcement area can be maximum and equal ($\varepsilon_{matrix} = \varepsilon_{reinforcement} = \varepsilon_{m,c}$). This means that the reinforcement bears the major portion of the load, σ_c, while the weaker matrix bears a lower load, σ_m, because it has lower modulus.

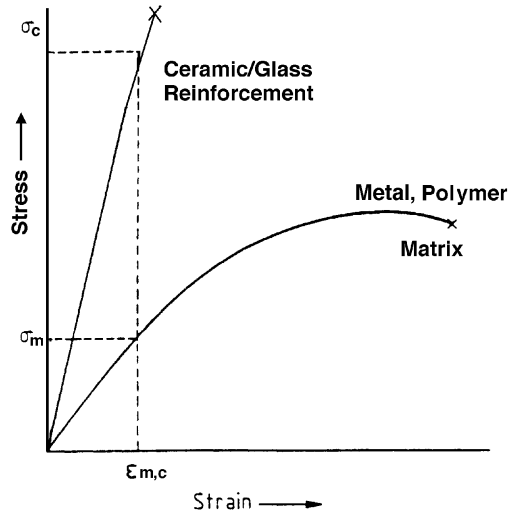

FIGURE 12.6.1 In a composite with good bonding between high-modulus ceramic and low-modulus metal or polymer matrix the interfacial strain must be the same. Thus, the high-strength ceramic fiber bears most of the load (stress).

To accomplish load transfer the bond interface must be engineered because metal and polymers do not show intrinsic bonding to ceramic reinforcement. A *coupling agent*, often a xylene, is applied to the ceramic or glass to promote bonding to a polymer. For metals, a metal matrix often has to be selected because it will wet and bond to the selected ceramic when molten or sintering during fabrication. Commonly, a controlled "forming gas" atmosphere must be used to produce MMCs composites so that a strong metal-to-ceramic bond is made.

The situation is somewhat different for ceramic–ceramic composites. These materials usually bond strongly to each other during fabrication. However, unlike the PMCs and MMc a less perfect bond is required. This is because local failure is required between matrix and reinforcement to introduce toughness or noncatastrophic fracture. This will be discussed further in the section on CMCs.

Polymer Matrix Composites

Weiping Wang, R. Allan Ridilla, and Mathew B. Buczek

Introduction

PMCs are used extensively as commodity and specialty engineering materials and constitute the largest class of composite materials on a dollar basis. The enormous success of PMCs arises from the wide range of properties which can be obtained and the low cost of low-end materials, such as fiberglass-reinforced polyester. Furthermore, the combination of high-strength/high-stiffness fibers in commodity polymer matrices offers an outstanding example of the composite principle — taking the best properties of both materials. The result is a strong, tough, stiff material which, depending on the matrix and reinforcement type, provides value in applications as diverse as consumer products, construction, and aerospace.

A distinction must be made between reinforced plastics and advanced composites. The term *reinforced plastics* generally refers to plastic materials fabricated with a relatively low percentage of discontinuous, randomly oriented fibers, with rather moderate properties, and used in commodity applications. *Advanced composites*, on the other hand, refers to a class of materials where a high percentage of continuous, highly oriented fibers are combined with a suitable polymeric matrix to produce articles of high specific strength and specific stiffness. At present, composites are widely used in the aerospace and sporting

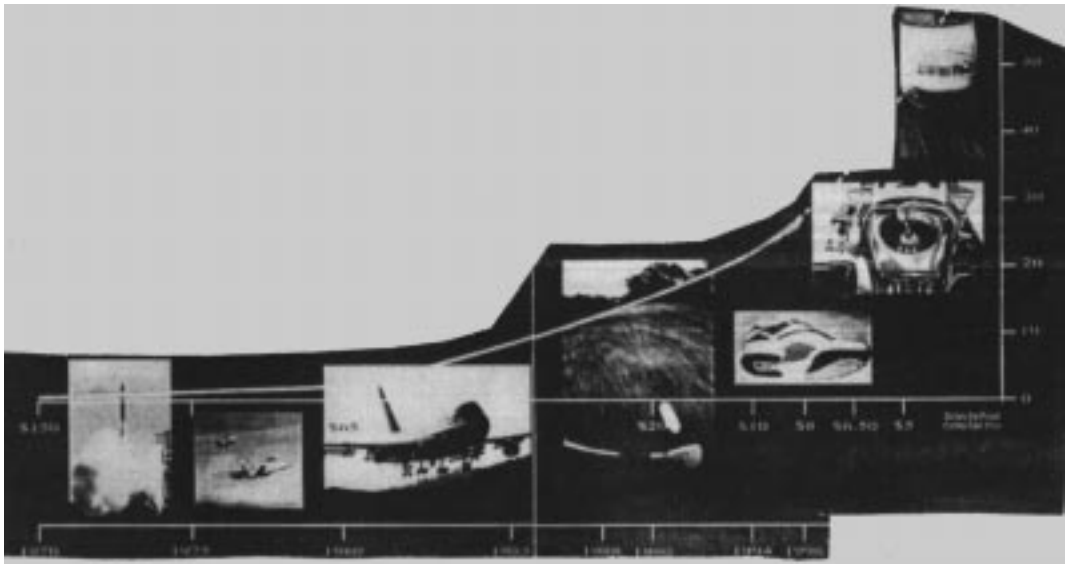

FIGURE 12.6.2 The evolution of carbon fiber composite applications since 1970 with fiber price and industry volume illustrated. (Source: Zoltek Co. Inc.)

goods industries for their superior performance. Figure 12.6.2 illustrates the evolution of applications for carbon fibers.

Polymers are also often "filled" with particulate reinforcements to increase certain properties, such as deflection temperature under load (DTUL). Although these materials are formally composites, they are usually regarded as filled polymers and not composites and thus will not be discussed explicitly in this section. Refer to the polymer section of this chapter.

Architecture

Each of the constituent materials in advanced composites must act synergistically to provide aggregate properties that are superior to the materials individually. The functional effectiveness of composites is principally due to the anisotropy of the materials and the laminate concept, where materials are bonded together in multiple layers. This allows the properties to be tailored to the applied load so that the structure can be theoretically more efficient than if isotropic materials were used. The reinforcements come in a variety of forms. Unidirectional tapes with all fibers along a common axis, woven fabrics constructed with fibers along both axes in the x–y plane, and 3-D architectures with reinforcements in more than two axial directions are just a few of the building blocks of composite structures.

The concept of laminate is illustrated in Figure 12.6.3. On the left is the unidirectional composite where all reinforcements are aligned in one direction. This construction provides excellent properties in the fiber direction but is limited to the properties of the resin in the transverse directions. The cross-plied construction on the right creates a structure that has common properties in the x- and y-direction but is limited to the characteristics of the resin in the z-direction. A large number of variations exist, allowing the designer to tailor the properties of the structure by varying the type of fibers and fiber orientations. Shown in Figure 12.6.4 are typical values of specific tensile strength (strength-to-density ratio) and specific tensile modulus (modulus-to-density ratio) for 65% volume fraction, cross-plied quasi-isotropic composites. Also included in the plot for comparison are properties of mild steel, titanium (Ti-6A1-4V), and aluminum (2024-T6). The actual properties of a composite will vary significantly due to flaws created during processing.

In selecting polymer composite materials for design, one should consider both the potential advantages and concerns typical to composites as illustrated in Table 12.6.1. Clearly, the advantages of materials should be put into use to achieve higher levels of performance in many kinds of products. On the other

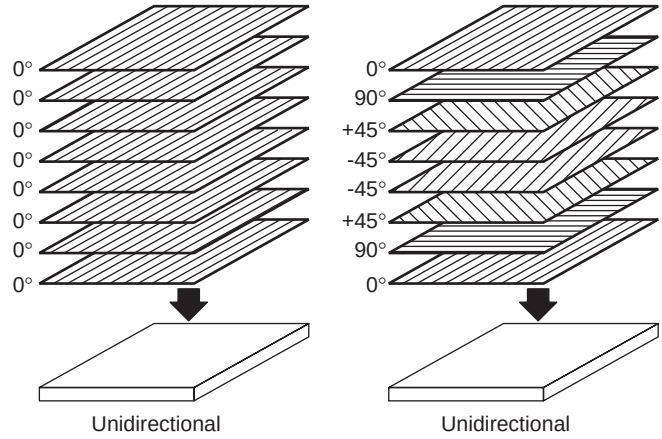

FIGURE 12.6.3 The basic concept of composite laminate.

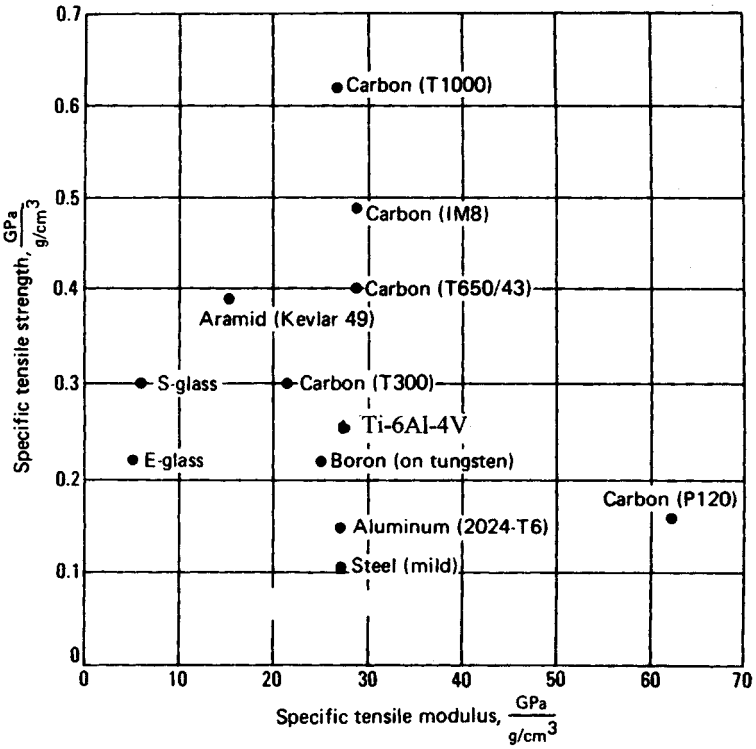

FIGURE 12.6.4 A comparative plot of specific tensile strength (strength-to-density) and specific tensile modulus (modulus-to-density) of composite material.

hand, potential issues in higher raw material cost and lower production volume and yield should also be weighed.

Fiber

Introduction. The most common reinforcement in polymer composites are fibers. Fibrous reinforcements come from compounds of light elements, (e.g., B, C, Si, O). These compounds typically contain

TABLE 12.6.1 Advantages and Limitations of Polymer Matrix Composites

Potential Advantages	Potential Limitations
High strength-to-density ratio	Low–volume production methods
High stiffness-to-density ratio	High raw material cost
Excellent corrosion resistance	Poor impact resistance
Good fatigue resistance	Poor high-temperature performance
Low thermal expansion	Delamination/out-of-plane loading

stable covalent bonds which impart greater strength and stiffness compared with metallic or ionic bonds. The compounds are processed to the final unable form of a fiber or filament with a highly aligned and directional microstructure so that the strength and stiffness properties are optimized along the fiber axis. Glass, graphite/carbon, aramid, and boron are among most notable fibers currently used in polymer composites.

Glass Fiber. Glass fiber reinforcements represent the largest volume used in the composites industry. These fibers are characterized by their low cost, clear to white color, good mechanical and electrical properties, high moisture and chemical resistance, and excellent dimensional stability with operational service to 550°C. Manufacturing of the fibers begins with molten glass which is drawn through a furnace into a fibrous form of final diameter of about 10 μm and then quenched to secure the final amorphous microstructure prior to applying final coatings or sizing. Common types of commercially available glass fiber are E-glass and S-glass, both of which are low alkali boro-alumino-silicate glasses. E-glass fiber, the workhorse of glass fiber applications, is the lower-cost fiber and is used in both structural and electrical applications. S-glass provides higher tensile properties and increased temperature resistance needed for aerospace and aircraft applications with a price premium. Representative properties for the glass fibers are shown in Table 12.6.2.

TABLE 12.6.2 Fibers Used in Polymer Composites — Mechanical Properties

Carbon Fiber. Graphite/carbon fibers are the reinforcement of industrial choice for advanced composite applications where stiffness and performance are critical. Typical attributes of these fibers are excellent tensile strength and elastic modulus, ease of handling, black color, and a wide range of properties and cost. Graphite fibers are initially formed as from polymer precursor compounds such as polyacrylonitrile (PAN) or rayon and pitch, an amorphous, aromatic by-product of petroleum distillation. PAN-based graphite fiber, the predominant commercial fiber, starts with the liquid PAN polymer, which is spun into a fiber and stretched to align the microstructure. It is then stabilized and the microstructure is aligned at 400 to 500°F in an oxidizing atmosphere under tension. Next, carbonization occurs in an inert atmosphere at 1800 to 2300°F to remove most noncarbon elements. Finally, the graphitization step is performed on the carbon fiber by applying tension to the fiber in an inert atmosphere at 3600 to 6500°F. The result is a highly aligned, highly graphitic fiber with preferred graphite orientation along the fiber axis. The temperature and tension fabrication parameters of the graphitization step, along with the purity of the initial PAN polymer, are the variables which are modified to differentiate “low-end” (low strength,

modulus, cost) from the "high-end" fiber (high strength, modulus, cost) and all of the grades in between. Typical properties of several commercial grades of carbon/graphite fiber are listed in Table 12.6.2.

Aramid Fibers. The aramid fiber derives its properties from long, rodlike aromatic polyamides. These fibers are characterized by low density, white yellow color, extremely high tensile properties, poor compressive strength, and high toughness, and they are difficult to cut mechanically. The manufacturing process for these fibers involves complex polymerization steps as the liquid polymer in acid is extruded or spun into a fiber form, water washed, dried, and finally heat treated under tension. The result is a highly aligned radial system of axially pleated lamellae in the microstructure. Aramid fibers have proved extremely useful in tension-critical application where the intrinsic compressive weaknesses of the fiber cannot be exploited. Commercially known as Kevlar, the most notable applications for aramid fibers are bulletproof vests (without matrix), and various high-pressure composite vessels. Typical properties for Kevlar 49 are listed in Table 12.6.2.

Boron Fibers. Boron reinforcements are referred to as filaments rather than fibers since they are made by the chemical vapor deposition of boron onto a fine tungsten wire. This fabrication process produces a large-diameter, stiff, and expensive reinforcement that is somewhat difficult to handle and produce into subsequent product forms such as fabrics and contoured structures. Although boron filaments possess the combination of high strength and high specific modulus that glass could not achieve, its use has been reduced to a minuscule level. Carbon/graphite fiber varieties have supplanted boron where high specific modulus is a requirement. A small volume of boron filaments still remain in a handful of military aircraft as well as in some recreational products such as golf club shafts. Typical properties of boron filaments are shown in Table 12.6.2.

Polymer Matrix Materials

Introduction. While fibers provide much of the strength and stiffness in advanced composites, equally important is the matrix resin. The matrix holds the fiber network together, to protect the structure from environmental attack and to support the fibers so that loads can be transferred throughout the structure through a shear mechanism. Polymeric matrices can either be thermoset or thermoplastic resins.

Thermosets cannot be reformed or thermally reworked after polymerization (curing). They are subdivided into categories based on their chemical reactions. The first are addition-type polymers, generally considered easier to process, where two (or more) reactants combine to form the final cured product. The second is the condensation type, in which the reactants combine to form products in addition to water and other volatile constituents. These systems are more difficult to process due to the required management of the volatile to minimize process defects such as porosity.

Thermoplastic materials, on the other hand, are polymers which can be softened and melted with the application of heat. Although they can be recycled, thermoplastic matrices have found more-limited applications in the advanced composite applications since they are particularly susceptible to attack by fluids and to creep at high stresses, and are relatively difficult to handle in laminate or structural form prior to final consolidation. The remainder of this discussion will focus on thermoset matrices which account for more than 90% of present-day advanced composite applications. Three principal organic matrix materials will be discussed: polyesters, epoxies, and polyimides.

Polyester Matrix. Low-cost polyester resins constitute the highest volume usage for the general composite industry. There are many resins, formulations, curatives, and other additive constituents that provide a wide array of properties and performance characteristics, such as mechanical strength, toughness, and heat resistance. The vast majority of applications utilize glass since its interfacial adhesion to these resins has been optimized by the development of silane surface treatments. These resins when combined with glass have found wide application in the chemical processing construction, and marine industries where cured properties and low cost are tailor-made for design requirements. Applications with carbon/graphite and aramid fibers are far less frequent since adhesion to these fibers is generally

poor and cure shrinkage on these resins is quite high. Additionally, structures requiring the high performance of carbon/graphite can often justify the use of more-expensive epoxy resins.

Epoxy Matrix. Epoxy resins are the prevalent polymer used with advanced composites. Their extensive use is primarily due to their superior mechanical properties, excellent adhesion, good processibility utilizing addition-type reactions, low cure shrinkage and low cost. When choosing epoxy resins two elements are crucial: the base resin and the curing agent or hardener. Since there are many base resins and curing agents, the following general relationships are given to provide a practical framework when utilizing epoxy compounds:

- *Chemistry*: Aromatic compounds are more thermally stable, stronger, and more resistant to fluids than are aliphatics.
- *Cross-link density*: Higher-temperature cures and longer cure times will increase cross-link density and therefore strength/modulus, service temperature, and chemical resistance.
- *Curing agents*: Amine-cured systems have better chemical resistance and superior thermal stability, but are more brittle than anhydride-cured systems.

Epoxies are categorized by the cure temperature. The "250 F epoxies" are those that cure at 250°F and are suitable for service up to 250°F. The "350 F epoxies" are those with higher processing and service temperatures. One of the design concerns with epoxies is moisture absorption. The effects of moisture often require design stresses to be reduced in applications where moisture is a concern. Modern epoxy formulations include lower cost, higher toughness, and other properties which continue to make epoxies attractive to the end user.

Polyimide resins span the temperature spectrum from 350 to 600°F. There are three general types of polyimides:

1. *Addition-reaction* polyimides such as bismaleimides (BMI)
2. *Condensation-reaction* polyimides such as commercial Monsanto Skybond resin
3. *Combination* condensation/addition-reaction polyimides such as PMR-15

BMIs are similar to epoxies in that they undergo addition reactions, are easy to process, and share many of the handling characteristics that make epoxies desirable. These materials are the composite resins of choice for temperatures in the range of 350 to 450°F to bridge the temperature gap between epoxies and other polyimides. They are more expensive and tend to be more brittle than epoxies. Condensation polyimides are used for composite applications from 450 to 520°F. These materials are difficult to process and tend to be quire brittle so their application is limited to adhesive bonding with some structural composite hardware. Combination-reaction polyimides have the highest thermal and oxidative stability and are used at service temperatures to 600°F. These resins are considerably more complicated because of their reaction mechanisms and the handling difficulties of the chemicals. Their application is principally restricted to aerospace composite structures where the performance needs to justify the difficult processing and high cost.

Processing

Continuous-fiber composites are manufactured in two steps, preform fabrication and consolidation/curing. The material comes in either the dry-fiber (without resin) form or with resin included called *prepreg*. Dry fibers are used in filament winding, pultrusion, weaving, braiding. In the case of filament winding and pultrusion, resin is introduced at the same time fibers are during the time of winding and pultrusion. Resin can also be introduced to the fiber later by resin-transfer molding (RTM). Prepreg, at a higher material cost, eliminates the step of resin addition and provides the adhesion to hold the material together. Layup of prepreg, a time-consuming process, is a common method used in the aerospace industry where complex contoured surfaces are present.

Consolidation and curing consist of compacting the material to remove entrapped air, volatile, and excess resins while developing the structural properties by increasing the polymer chain length and

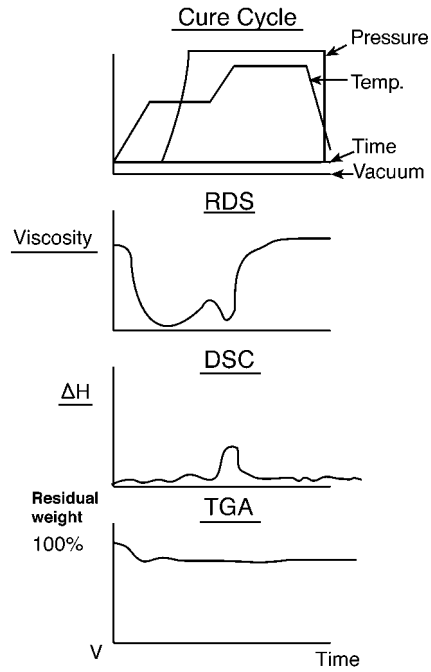

FIGURE 12.6.5 A typical curing cycle of epoxy composite with corresponding Rheometric Dynamic Spectroscopy (RDS), Differential Scanning Calorimetry (DSC), and Thermogravimetric Analysis (TGA) curves.

cross-linking. Thermosetting polymer matrices must be cured *in situ* with the fibers to form composites. The goals of a successful cure are good consolidation with low porosity and high conversion of initial monomeric constituents to polymer (degree of cure).

The cure cycle of an epoxy resin composite is shown in Figure 12.6.5. At the start of the cure cycle, the material is normally under vacuum to remove residual volatile. The temperature is then ramped to the point where the polymer is melted. The ramp rates on heating must be slow enough as not to cause unnecessary thermal gradients and to avoid dangerous exotherm (runaway reactions) but not so slow as to cause excessive process time or premature cross-linking. Normal ramp rates are generally in the 1 to 5°F/min range. An isothermal hold of about 30 to 60 min is performed at the point where the resin reaches its minimum in viscosity, during which pressure is applied and the polymer allowed to flow, thus consolidating the laminate. Following consolidation, the temperature is increased to the point where cross-linking occurs (350°F for this example). An additional hold of about 30 to 90 min is performed at this temperature to allow for the material to complete cross-linking. This event is shown as the end of the exothermic peak in the DSC curve as well as the asymptotic high-viscosity region.

Epoxies cure via addition reactions where no volatile is generated during the cross-linking process. However, many other matrix materials (e.g., phenolics and many polyimides) cure via condensation reactions.

Mechanical Properties

Mechanical properties of polymer composites depend substantially on the processing and fabrication methods used, as well as on the fiber orientation. Thus, standard materials do not exist and it is difficult to generalize regarding properties. The three most significant factors in determining properties are the type of fiber, the volume fraction fiber, and the orientation of the fiber. High-strength high-modulus graphitic carbon fibers will, of course, produce stronger, stiffer composites than those produced from fiberglass. Similarly, 60 vol % fiber composites will be stronger and stiffer than 30 vol %, and uniaxially aligned fiber composites will have maximum properties along the alignment axis, but will be highly

anisotropic and will have poor properties in off-axis orientations. Cross-ply and laminated structures are standard approaches to reducing anisotropy.

Composite stiffness, E_c, can be approximated for polymer composites by application of the rule of mixtures:

$$E_c = E_f V_f + E_m\left(1 - V_f\right)$$

where E is the modulus of elasticity and V is the volume fraction fibers. Subscripts c, f, and m refer to composite, fiber, and matrix, respectively. Similar expressions approximate other properties. Properties of commonly used commodity composite materials are given in Tables 12.6.3 to 12.6.5. Advanced engineering polymer composites have specialized properties which depend on the parameters discussed previously. Expected properties of such advanced polymer composites can only be approximated once the component and material variables are determined during the design stage. The recommended approach is to work with a composite fabricator during the design phase to establish the expected mechanical properties.

Notes: Most nylon resins listed in this table are used for injection molding, and test values are determined from standard injection-molded specimens. In these cases a single typical value is listed. Exceptions are MoS_2-filled nylon and direct-polymerized (castable) nylon, which are sold principally in semifinished stock shapes. Ranges of values listed are based on tests on various forms and sizes produced under varying processing conditions.

Because single values apply only to standard molded specimens, and properties vary in finished parts of different sizes and forms produced by various processes, these values should be used for comparison and preliminary design considerations only. For final design purposes the manufacturer should be consulted for test experience with the form being considered. Listed values should not be used for specification purposes.

Metal Matrix Composites

Introduction

The term *metal matrix composites* is usually reserved for fiber-reinforced materials, although technically it applies to particulate-reinforced systems also. The general term for particulate-, whisker-, and chopped-fiber-reinforced systems is *cermet*. A majority of commonly used systems are based upon particulate reinforcements.

Cermets and Cemented Carbides — Particulate-Reinforced MMCs

The term *cemented carbide* is applied to particulate composites based upon tungsten carbide in a cobalt matrix. This distinction is largely historical, not technical. The tungsten carbide–cobalt-based materials were first developed in Germany, while development of other cermets (including noncarbide-, oxide-, and nitride-based systems) occurred in the United States during and immediately after World War II. Thus, a distinguishing nomenclature was developed both because "carbide" was no longer completely appropriate with oxide systems available and for geopolitical reasons. This nomenclature confusion between the most common cermets, the cemented carbides, and other materials still survives. The structure consists of a continuous metal alloy functioning as cement which holds together particles of carbide, oxide, or nitride ceramic. These materials provide strength, high hardness, wear (abrasion) resistance, low sliding friction, and precise tolerance even at quite high temperatures. Cermets and cemented carbides derive their usefulness when the compressive strength, hardness, and thermal resistance of the ceramic reinforcement is coupled with the ductility, toughness, adhesion, and lubricity provided by the metal. Common applications include metal and rock cutting and grinding tools, high-temperature containers, and pouring spouts, rocket nozzles, turbine parts, flame nozzles, friction and glide parts, seals, magnetron tube cathodes, flame nozzles, and ballpoint pen tips.

A cermet is usually fabricated by mixing the ceramic and metal powders together with a binder incorporated. This often requires high-energy mixing because of density differences with tooling made of the same cermet to avoid contamination. Subsequently, the part is formed, commonly by unidirectional or isostatic pressing, to final shape (accounting for shrinkage) with a wear-resistant die and with the formed object then liquid phase sintered in a controlled-atmosphere furnace. The chemistry is often quite complex in order to control the structure and the interfacial bond between metal and ceramic. Molybdenum promotes wetting of titanium carbide by molten nickel. Tantalum and titanium carbides are usually added to tungsten carbide–cobalt cemented carbides. Some cermets are prepared by slip casting, liquid metal infiltration, hot pressing, or solid-state sintering of parts. In some cases the material is "deficient" in metal to provide porosity for the passage of ink (pen tips) or incorporation of lubricant.

As indicated in the introduction to this section, a good bond between ceramic grain and metal "cement" is required for proper load transfer and to provide a homogeneous structure for good load bearing and uniform deformation. This normally requires a good wetting between liquid metal and ceramic grains. This is affected by minor alloying additions to the metal and the firing atmosphere.

The distribution, stability, and composition of phases have profound effects on properties. The production of WC–6 $^{w}/_{o}$ Co is a good example of the need for strict compositional control. The tertiary-phase diagram shows that the composition range from 6.00 to 6.12 $^{w}/_{o}$ must be adhered to in order to prevent formation of phases other than WC and Co — a composition range of less than 0.12 $^{w}/_{o}$! Embrittlement by graphite occurs at higher carbon content and by eta phase (η–WC_{1-x}) at lower carbon levels. Precise formulation and furnace atmosphere control is required, usually assisted by using a graphite-lined furnace. About 0.1% outside the acceptable composition range there is a drop of about 25% from the optimum strength.

It is important to engineer the microstructure of cermets in order to optimize properties. A uniform dispersion of round oxide, carbide, or nitride grains in the matrix of metal binder is desired. Inhomogeneity and sharp grain corners can act as failure origins. Round grains result from powder preparation and/or partial dissolution of sharp contours in the molten metal. As the amount of binder increases (Figure 12.6.6), the indentation hardness of the composite decreases, because metal, compared with

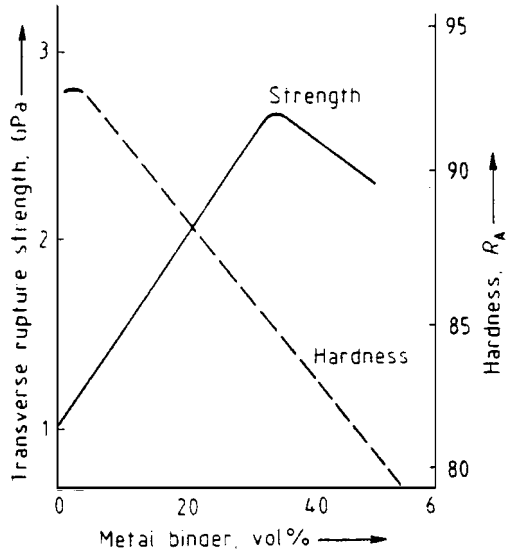

FIGURE 12.6.6 Effect of increased binder on strength and hardness of a TiC-Ni-Mo cermet with a 1 μm average carbide particle size.

ceramic, has a lower elastic modulus and will deform more easily. Fracture strength increases with binder because the metal phase confers fracture toughness. Generally, as ceramic grain size decreases, hardness and resistance to deformation increase for a fixed relative amount of ceramic. However, if the surface area increases sufficiently because of small grain size, there may not be sufficient metal to wet all the grain.

With these diverse factors a simplified way of looking at microstructural features and adjusting them for optimum performance is the mean free path, the average distance between neighboring ceramic grains (the average thickness of the binder phase). The mean free path depends on the size and shape of the grains and the amount of metal matrix available. Hardness, elevated-temperature hardness, strength, and toughness depend on the mean free path because it is the zone for absorption of crack energy and the medium for load transfer from grain-to-grain. Figure 12.6.7 shows that hardness varies with mean free path for a variety of cobalt contents and tungsten carbide grain sizes in cemented carbide. The curve does not continue below 0.1 μm because the metal binder becomes discontinuous.

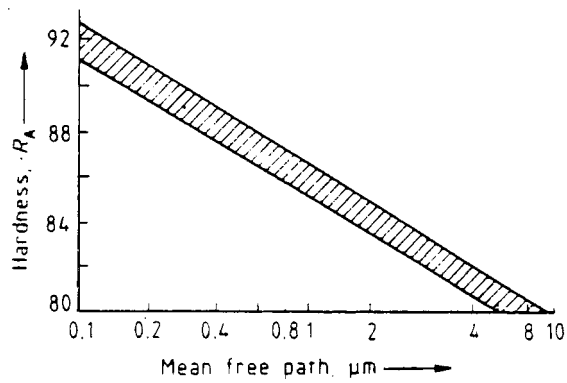

FIGURE 12.6.7 Effect of mean free path on hardness for a cemented carbide.

Uranium	Al_2O_3	4–7	900–1100	2–3

[a] The tensile strength of the final product is two to four times the strength of the aluminum.

Table 12.6.6 presents data for selected metal matrix systems with particulate reinforcement, including strength values at elevated temperatures. A section of Table 12.6.7 provides stiffness values for cobalt and nickel strengthened with sintered carbides.

Fiber-Reinforced MMCs

Fiber-reinforced MMCs may still be classed as an emerging materials area. A number of applications have been practiced driven by the need for a lightweight, high-stiffness material and/or for elevated-temperature resistance in structures. These applications are typically for aerospace and similar advanced applications which can use a premium material. The limited scope of current practical application and the limitations placed on technology disclosure by the Export Control Act and International Traffic-in-Arms Regulations make this section brief.

High-strength/high-elastic-modulus fibers such as boron, silicon carbide, graphite, aluminum oxide, and tungsten metal are typically incorporated in light metal matrices such as aluminum, magnesium, and titanium. The specific modulus (elastic modulus divided by density) has been shown to be two to four times that of high-strength structural metals. The specific strength may be substantially higher than the metal. These properties are maintained to many hundreds of degrees above ambient, while those of many advanced structural metals deteriorate both in immediate heating and long-term creep. Some systems have been shown to have considerable fatigue resistance, showing several times the stress for equivalent cycle lifetimes. These properties are important for structural shapes in which light weight and elevated-temperature resistance can afford a premium. Some applications have been struts and tubes

for space structures, bicycle frames, turbine parts, propellers, and engine components. The fiber may be incorporated unidirectionally, as a woven 2D laminate or a 3D structure. Fabrication methods include diffusion bonding, pultrusion (hot isostatic drawing), hot rolling, molten metal infiltration, and casting.

Table 12.6.7 gives metal matrix strengthening values for fiber reinforcements added in volume percentages from 8 to 60%.

Ceramic Matrix Composites

Richard L. Lehman and Daniel J. Strange

CMCs are ceramic matrix materials, either oxide, carbide, nitride, boride, or similar material, reinforced with particulates, whiskers, or continuous fibers. The reinforcing phase may be of any material, but most interest is directed toward ceramic reinforcement media. The following sections address fiber- and whisker-reinforced ceramic composites, the materials which offer the greatest potential for ameliorating the brittleness of ceramics and for developing exceptional mechanical and structural properties.

Ceramic Matrix Fiber Composites

Introduction. Ceramic matrix fiber composites (CMFCs) are the focus of substantial research but of limited commercial application as of this writing. The research enthusiasm is stimulated by the potential of high strength and toughness, mechanical and chemical durability, hardness, and oxidation resistance, all at elevated temperatures in the range 1000 to 1400°C. The limited commercialization, which is principally in military and aerospace applications, stems from the substantial cost of the fabricated materials, often in the range of thousands of dollars per kilogram. Fiber and matrix materials and properties used in CMFCs are presented in Table 12.6.8.

TABLE 12.6.8 Ceramic Matrix Composites: Fiber and Matrix Properties

Material	*E*	*a*	*R*	UTS	*e**	*g*(*Kc*)	*T*	*r*

Mechanical Behavior. The primary goal of reinforcing a ceramic material with ceramic fibers is to increase the fracture toughness of otherwise brittle ceramic materials. In a monolithic ceramic, a flaw will propagate through the material under tension due to stress concentration at the crack tip. CMCs are designed with $E_f/E_m > 1$ so that the reinforcing fiber absorbs stresses which tend to open and propagate cracks. Thus, the stress at the crack tip is reduced. Fiber debonding at the crack front, sliding, crack deflection, and other mechanisms also contribute to toughness. Often this is referred to as "rising R-curve" behavior, indicating that the strength of the ceramic at a crack tip increases with increasing crack length, stopping or slowing further crack growth. The most significant feature of CMFCs is the extensive fiber pullout, which occurs during failure. The fiber pullout results from low interfacial shear strengths, τ, which is designed into the composite by modifying interfacial properties and by using fibers with a *low* Weibull modulus. Loading is characterized by an initial elastic region followed by progressive failure of the matrix. The behavior is illustrated in Figure 12.6.8. During this matrix failure region, monotonically increasing loads are supported by the fibers. Ultimately, the fibers begin to fail according to bundle theory and the remaining load support is provided by the frictional resistance to fiber pullout, a highly significant effect which absorbs large amount of energy and contributes a high strain-to-failure performance previously unknown in ceramics. This "graceful" failure allows for a less catastrophic failure than normally encountered in ceramics and is of great significance in the design of such materials as turbine blades where the consequences of catastrophic failure are severe.

Continuous and Chopped Fiber Composites. The use of a continuous fiber reinforcement can have several advantages over the use of chopped fibers. There is a larger strain to pullout due to the increased fiber length, and the continuous fibers do not have stress-concentrating "flaws" as do the exposed ends of chopped fibers. Also, the prearrangement of the fibers allows very careful control of the properties in each direction, and the properties parallel to the fiber orientation will more closely mirror those of the fibers themselves than of the matrix. However, this type of composite is much more difficult to fabricate because of the problems of fiber weaving and forming, resistance to matrix infiltration, and

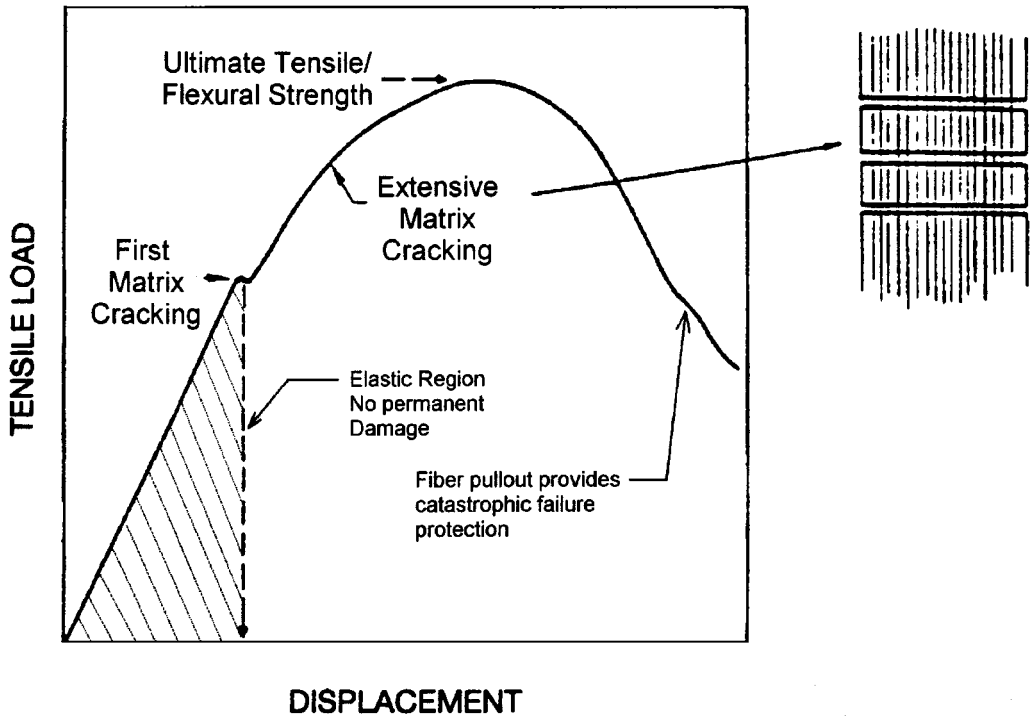

FIGURE 12.6.8 Load deflection behavior of CMFCs illustrating regions of fracture behavior.

resistance to densification, which necessitates expensive densification techniques, such as hot pressing, chemical vapor infiltration, polymer pyrolysis, directed metal oxidation, or sol–gel infiltration.

Glass Matrix CMFCs. A broad class of CMFCs has been developed and commercialized based on glassy matrix materials. The incentive for using a glassy matrix is the ease with which the matrix can be densified at low temperatures by vitreous sintering as opposed to the high-temperature solid-state sintering required for crystalline matrices. The low-temperature processing, in addition to being lower cost, preserves the high-strength properties of the fibers, which can easily be degraded at high temperatures. Unfortunately, the useful temperature of a glass-based CMC is limited to the T_g of the matrix, or slightly above, which prohibits traditional glass matrix CMCs from being used in extreme temperature applications (above approximately 1000°C). Newer glass and glass–ceramic compositions in the CaO-Al_2O_3-SiO_2 system are pushing this limit to the region of 1300°C. Two commercial glass matrix composites are Compglas™ and Blackglas™, both glass and glass/ceramic matrix materials reinforced with SiC fibers.

Polycrystalline matrix CMCs achieve higher temperature stability than the glass matrix composites, allow a wider choice of matrix materials, and generally have fewer problems with matrix reactivity. Typical crystalline matrix materials are the SiC, Si_3N_4, Al_2O_3, ZrO_2, and mixed silicates. Unfortunately, it is extremely difficult to sinter a CMC with a polycrystalline matrix to full density because of the interference of the fibers. This is particularly true with the nonoxide matrix materials. Pressureless sintering is ineffective for these materials, which necessitates the use of hot pressing or other exotic forming processes which raise material costs considerably.

Ceramic Matrix Whisker Composites (CMWCs)

Whisker reinforcement of ceramic matrices, while not as exotic, can dramatically increase toughness while preserving relatively inexpensive forming techniques. Figure 12.6.9 illustrates the "rising R-curve" behavior of alumina with the addition of SiC whiskers, while Figure 12.6.10 shows the increase in

fracture strength. The composites can generally be fully densified with hot pressing or hot isostatic pressing (HIP). Unfortunately, the toughness values achieved to date with whisker reinforcement are not as high as those for continuous-fiber reinforcement, although the lower cost of whisker composites has stimulated industrial applications. Cutting tool inserts, which must withstand high stresses at elevated temperatures (1200°C), are fabricated commercially from SiC-whisker-reinforced Al_2O_3 (SiC/Al_2O_3). These composite inserts have been a commercial product for a decade and are an excellent example of cost-effective CMCs, i.e., high-value-added material applied to a small part exposed to extreme conditions. Health concerns regarding highly durable ceramic whiskers produced from SiC or Si_3N_4 have severely limited development and commercialization of these composites in the United States and Europe.

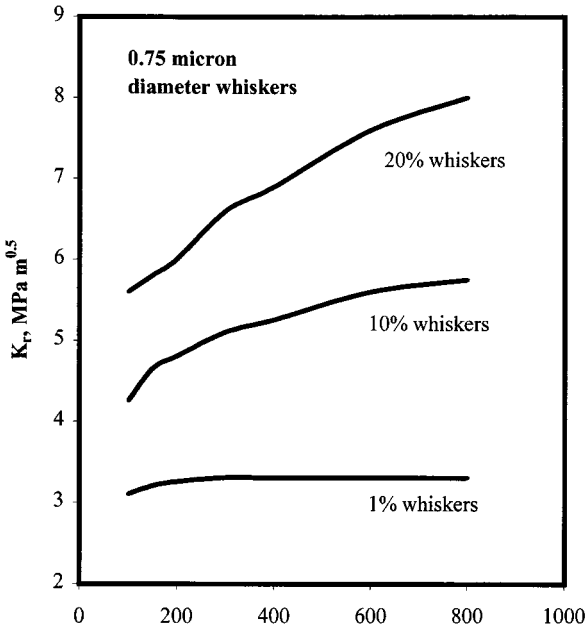

FIGURE 12.6.9 Fracture toughness and R-curve behavior of ceramic matrix whisker composites.

Carbon–Carbon Composites

Introduction

Carbon–carbon composites were originally developed for rocket nose cones in the 1960s because of their high specific strength, fracture toughness, thermal shock, and erosion resistance. Today, carbon–carbon composites are used in a broader range of applications, including brake components, fasteners, heaters, crucibles, and other assorted high-strength/high-temperature products.

High-Temperature Oxidation

Perhaps the greatest obstacle to the use of carbon–carbon composites as an engineering material, aside from high cost, is low oxidation resistance above 500°C. Although carbon–carbon maintains its mechanical properties to very high temperatures (>2000°C), it must be protected from oxidizing atmospheres at these temperatures or it will quickly degrade. Generally this is accomplished with SiC coatings with varying degrees of success. For most high-temperature oxidizing applications, carbon–carbon composite components are simply replaced when erosion reaches specified limits.

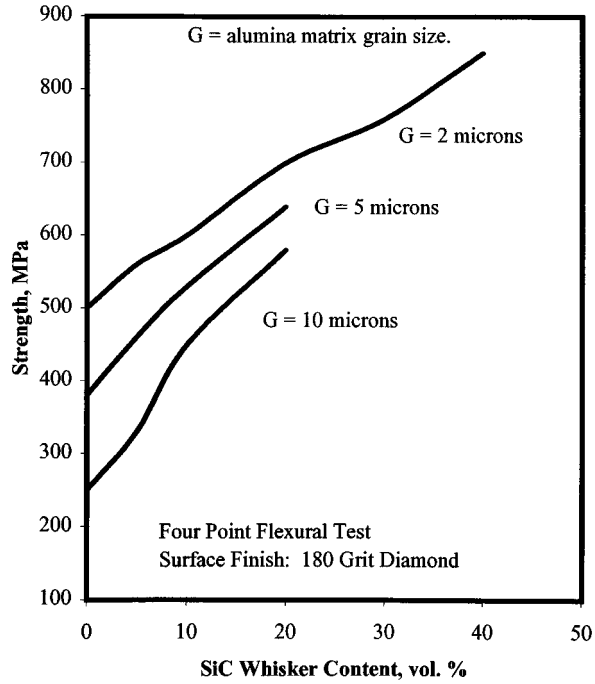

FIGURE 12.6.10 Strength behavior of SiC whisker-reinforced alumina matrix ceramic composite.

Fabrication

Most carbon–carbon composites are fabricated by polymer pyrolysis, the process of soaking carbon fiber yarns in a solution of a suitable polymer, then winding or laminating the fibers into the desired shape. Coal tar–based pitches, phenolics, and polyimides are also used as precursors.

The resulting green composite is then pressed, cured, and heated to 800 to 1200°C in an inert atmosphere, carbonizing the precursor. Some structures are heated to 2500°C to graphitize the matrix. The matrix after carbonization will contain a high porosity, typically 30%. This porosity is reduced by infiltrating the matrix with the precursor again and repeating the carbonization cycle. The densification cycle is repeated until the desired density is reached.

Carbon–carbon composites can be formed in random, unidirectional, 2D, 2.5D, and 3D weaves. Unidirectional weaves provide the highest strength along the fiber axis, but much lower strength in other directions. Unidirectional weaves are generally only used in laboratory investigations, as they have little technical value. 2D weaves (fabrics) are by far the most common due to the relative ease of manufacture and good mechanical properties in the plane of the fabric. 2.5D and 3D weaves allow the weaving of very complex structures with good properties in any desired direction, yet the weaving costs can be prohibitive and unnecessary for most industrial applications.

Mechanical Properties

Properties of some carbon–carbon composite materials are given in Table 12.6.9. The properties can vary considerably, however, depending upon factors such as the weave, tow diameter, precursor, pressing pressure, heat-treatment temperature, and number of densification cycles.

Under cyclical loading, carbon–carbon withstands 70 to 80% of its ultimate tensile strength. Carbon–carbon composites also have large strains to failure, exhibiting pseudoplastic behavior. This is unusual for a high-temperature ceramic material and is one of its prime attractions. The responsibility for this behavior lies with the low fiber–matrix interfacial bond strength and matrix microcracking. Unlike most high-temperature materials, the mechanical properties of carbon–carbon do not degrade at

TABLE 12.6.9 Properties of Selected Carbon–Carbon Composites

Property	Units	Structural Grade[a]			Fastener Grade[b]		
		Warp Direction	Fill Direction	Across Ply	Warp Direction	Fill Direction	Across Ply

high temperatures. In fact, in inert atmospheres the strength of carbon–carbon composites increases by 40 to 50% up to a temperature of 1600°C.

Thermal conduction, electrical conduction, and thermal expansion are all much greater along the direction of the weave than perpendicular to it. Interestingly, thermal expansion is negative in 2D weaves perpendicular to the fibers. It is therefore possible to use the fiber architecture to achieve near zero thermal expansion in some directions.

12.7 Ceramics and Glass

Richard L. Lehman, Daniel J. Strange, and William F. Fischer, III

Traditional Ceramics

Traditional ceramics encompass many materials, not simply pottery, dinnerware, tile, and sanitaryware, but also technical whitewares, structural clay products, refractories, glazes, and enamels. The product and processing technology of these materials has advanced substantially in recent years which has improved products, reduced costs, and expanded application. Refer to Table 12.7.1 for properties of selected ceramics in this group.

TABLE 12.7.1 (Part I) Physical Properties of Selected Ceramics

Material	Porcelain	Cordierite Refractory	Alumina, Alumina Silicate Refractories	Magnesium Silicate
Specific gravity	2.2–2.4	1.6–2.1	2.2–2.4	2.3–2.8

Dielectric constant	6.0–7.0	4.5–5.5	4.5–6.5	5.0–6.0

Whitewares

Whitewares are principally comprised of traditional ceramic bodies that are white, cream, ivory, or light gray in appearance. Most whiteware materials are formulated from clay, flint, and feldspar (triaxial compositions) although other additives may be incorporated. The engineering properties of whitewares are strongly affected by porosity, a characteristic that reduces frost resistance and cleanability but is essential for certain aesthetic effects.

Vitreous. Vitreous whiteware bodies are translucent and have no open porosity, while earthenware and wall tile, for example, have substantial porosity, and semivitreous bodies bridge the gap in both porosity and translucency. The firing temperature is largely responsible for the differences in properties of the bodies by affecting the degree of vitrification. The general categories of products within the whiteware group are given in Table 12.7.2.

Earthenware. Earthenware materials are defined as a nonvitreous clay-based ceramic ware of medium porosity (4 to 20%). They can be glazed or unglazed in their finished form. There are four primary subclasses of earthenware, natural clay, fine, semivitreous, and talc earthenware. Natural clay earthenware is derived from a single, unbeneficiated clay, whereas fine earthenware possesses beneficiated clays, as well as nonplastic materials, to comprise a triaxial body. Semivitreous earthenware is also a triaxial body, but it is fired to a higher temperature to form a more glassy phase, thereby creating a body with

TABLE 12.7.2 Whiteware Materials

Class and Subclass	Percent Water Absorption	Example Product Type
Earthenware		
Natural clay	>15	Artware and tableware
Fine earthenware	10–15	Tableware, kitchenware, and artware
Semivitreous Earthenware	4–9	Tableware and artware
Talc earthenware	10–20	Ovenware and artware
Stoneware		
Natural stoneware	<5	Kitchware, artware, and drainage pipes
Fine stoneware	<5	Cookware, tableware and artware
Jasper stoneware	<1	Artware
Basalt stoneware	<1	Artware
Technical vitreous stoneware	<0.2	Chemicalware
China		
Vitreous china	0.1–0.3	Sanitaryware
Hotel china	0.1–0.3	Tableware
Cookware	1–5	Ovenware and stoveware
Technical china	<0.5	Chemicalware and ball mill jars and media
Fine china	<0.5	Tableware and artware
Porcelains		
Technical porcelains	<0.2	Chemicalware
Triaxial electrical porcelains	<0.2	Low-frequency insulators
High-strength electrical porcelains	<0.2	Low-frequency insulators
Dental porcelains	<0.1	Dental fixtures

the lowest porosity of the earthenware group, usually between 4 and 9%. The final earthenware body is talc earthenware, produced principally from raw talc, with porosity ranging up to 20%. Earthenware bodies range in color from white for the talc and triaxial bodies, to tan and brown for many artware bodies, to a rusty red for terra-cotta.

Stoneware. Stoneware bodies can be either vitreous or semivitreous. They are primarily composed of nonrefractory fireclays or a combination of triaxial materials that matches the forming, firing, and finished properties of a natural stoneware body, bodies made from a single, naturally occurring, largely unbeneficiated clay-bearing material. Fine stonewares incorporate beneficiated clays, as well as nonplastics. Jasper stonewares are composed primarily from barium-containing compounds, while basalt stonewares contain large amounts of iron oxide.

Vitreous stoneware bodies are made from blends of a variety of beneficiated materials that are fired to higher temperatures to achieve low porosity levels (0 to 5%) necessary for many applications. Stoneware bodies are usually quite durable and resistant to chipping. However, translucency is less than that of china and the colors are not as white because of the presence of iron and other impurities.

China and Porcelain. China and porcelain are nearly synonymous terms which refer to fully vitreous (no porosity) clay, flint, feldspar compositions which are typically glazed, fired to high temperatures, and exhibit strength, hardness, and chemical durability. The term *china* is used to describe exceptionally fine materials prepared from low-impurity raw materials and used in artware and dinnerware. In modern times there has been a trend toward highly vitreous and highly translucent china compositions. Porcelain is used to describe mostly technical ceramics of the triaxial composition which are used as electrical insulators, sanitaryware, and chemical ware.

Subclassifications of china exist, such as vitreous china, hotel china, cookware, technical ceramics, fine chinas, and porcelains. Body formulations are usually based on the triaxial body, clays, flint/silica and fluxing agents, most usually feldspathic materials. However, there are a large number of bodies that are composed of a large fraction of other materials. Inclusive of these are alumina, bone ash, cordierite,

other fluxes, and/or lithium compounds. Vitreous china is a category of traditional ceramics referring to the various sanitaryware plumbing fixtures and accompaniments. Hotel chinas, as the name implies, are generally used in commercial food establishments. Both bodies are glazed in a single firing operation in which both the body and glaze mature at the same time.

Technical whitewares account for a wide variety of vitreous ceramics used in the chemical, dental, refractory, mechanical, electrical, and structural areas. The compositions of most of these materials are similar to that used in the hotel chinas, with the possible substitution of alumina and zircon for some or all of the silica. These materials can be either glazed or unglazed with water absorption less than 0.5%.

Fine china bodies, including bone china, are highly vitrified and translucent materials that are usually fired in two or more separate operations. The first, higher-temperature firing matures the body and a second, lower-temperature firing matures the newly applied glaze. The separate firing conditions allow for the use of high-gloss glazes. Subsequent firings are used to apply decals and metallic decorations.

Porcelain ceramics are mostly used in technical applications. The typical body is triaxial (Table 12.7.2), although some or all of the silica can be replaced with alumina to increase the mechanical properties. Aside from triaxial porcelains, compositions in the $MgO \cdot Al_2O_3 \cdot SiO_2$ composition range are popular for electronic applications due to the absence of mobile alkali ions.

Refractories

Introduction. Refractory ceramic materials are by nature inert, high-melting-point compounds that are resistant to corrosion throughout the temperature range of use. Refractories must also withstand thermal cycling, thermal shock, mechanical fatigue, and a range of chemical attack from the elevated-temperature environments typical of most applications. Refractory materials are used in the processing of metals (75% of all refractories), glass, cement, and in the processing of nearly all ceramics.

Temperature Tolerance. A quality refractory must be stable at the intended use temperature. Refractoriness is a measure of the highest use temperature the material can withstand and is limited by the softening or melting point of the constituent oxides. Most refractories are a mixture of phases, and, as such, do not display a distinct melting point, but have a range of temperatures where the material starts to soften or melt. Most frequently, a refractory is categorized by an upper use temperature, but sometimes the refractoriness is quantified by the PCE or pyrometric cone equivalent. The PCE is a measure of the heat content that the refractory can withstand before beginning to soften, which is determined by the slumping of pyrometric cones during thermal cycle testing. This value may correspond to different temperatures under different environments or atmospheres and is thus a good indicator of maximum-use conditions. Refractory suppliers can provide PCEs for specific products. Another measure of a refractory quality is the failure under load temperature. The temperature where a refractory sags or deforms is part of all refractory specifications and is related to the amount and composition of the glassy phase within the material.

Dimensional Stability and Spalling. Dimensional stability and resistance to spalling are important performance criteria for most refractories. Spalling is the cracking or flaking of the refractory which usually results from thermal cycling, thermal gradients within the refractory, or compression effects due to differing thermal expansion of the different system materials. Spalling reduces the effectiveness and lifetime of the refractory. The dimensional stability of the refractory is also important. Since the refractory is subjected to both heating and cooling cycles, as well as thermal gradients in use, the expansion of the material is very important when choosing a refractory. Large changes in the size of a refractory set up stresses that can reduce the effectiveness of the refractory and may result in its failure.

Porosity. Refractory porosity is closely controlled in manufacturing since it leads to a reduction in the mechanical strength of the material and allows for the penetration and chemical attack of liquids or gases to the internal surface of the refractory. However, on the positive side, the presence of internal pores reduces the thermal conductivity of the material and increases fracture toughness, K_{IC}.

Fireclay Refractories. Fireclay refractories are composed of hydrated aluminosilicates with silica content of up to 75% or more with alumina and other minor contents of less than 40%, although alumina-fortified fireclay refractories are made with considerably higher alumina contents. Properties vary greatly over this wide range of compositions — generally, the higher the alumina content, the higher the performance. Fireclay refractories based on kaolin have a high refractoriness and high load resistance. Resistance to chemical attack and thermal conductivity decrease with increasing porosity, whereas spalling resistance increases. Increased alumina content raises the resistance of the material to attack in molten environments. Fireclay refractories are the most widely used refractory and find application in many industries.

Alumina Refractories. High-alumina refractories contain 80 to 99% or more aluminum oxide. As with fireclay materials, the higher the alumina content, the higher the refractoriness and the higher the load-bearing capacity. The chemical resistance of alumina refractories is greater than that of the fireclay refractories. Alumina brick is used to replace fireclay brick in more severe applications in the steel industry. Alumina bricks with phosphate bonding are used in the production of aluminum because of their refractoriness and the resistance of the phosphate bonding to chemical attack by the molten aluminum. Mullite ($3Al_2O_3 \cdot 2SiO_2$) refractories are similar to alumuna refractories in performance, but are cheaper and more resistant to thermal shock at the expense of some temperature capability.

Silica. Silica brick refractories, used in the glassmaking industry, range in composition from almost pure silica to mixtures containing lime, iron oxide, and alumina, depending on the degree of beneficiation of the raw materials. These refractories show a high degree of volume stability below 650°C (1200°F) and a lower degree of spalling than the fireclay bricks, largely because of the low thermal expansion of the silica.

Basic Refractories. Basic refractories are constituted from magnesite (MgO), calcia (CaO), and chrome (Cr_2O_3) and are used widely in metallurgical industries where basic slags predominate. They are not suitable in acid, or high-silica, environments. Refractories in this group, such as pure magnesite, dolomite (CaO-MgO), and chrome magnesite materials, have high refractoriness, volume stability, and are very resistant to chemical attack. Magnesite refractories have between 80 and 95% MgO content, a level at which the refractoriness and resistance to chemical attack is extremely high. Chromite refractories also have excellent chemical resistance in basic environments, with moderate resistance in acidic environments. The chrome content in these refractories ranges between 30 and 45%. Chrome–magnesite refractories are composed of over 60% MgO. Compositions and properties of selected basic and high-duty refractories are given in Table 12.7.3.

Glazes and Enamels

A glaze is a continuous glassy layer that is bonded to the surface of a ceramic. The glaze is typically hard, impervious to moisture, and easily cleaned. An enamel is similar in properties to a glaze, but the substrate is metallic. The surface finish of either can be altered from glossy to matte by varying the composition or the firing conditions. A glaze is usually composed of an aqueous suspension of ceramic particles that is applied to the surface of a material, dried, and fired. During firing, the materials within the glaze react and melt, forming a thin glassy layer on the surface of the ceramic material. Some materials are prefired and then the glaze is applied, or, as is becoming more common, the glaze can be fired along with the body. The maturing temperature of most glazes is on the order of 500 to 1500°C, or 930 to 2730°F. Glazes can be either clear, transparent, or opaque. Some glazes are formulated to form crystals within the glaze for a variety of optical effects, such as opalescence.

There are three main types of glazes used. The first of these are the raw glazes. Raw glazes can be further broken down into leaded, leadless, zinc-containing, slip, and porcelain glazes. Lead promotes the processing of the glaze via low viscosity and surface tension and imparts a high refractive index to the finished glaze. However, due to the health hazards associated with free lead, there has been a movement toward lead-free glazes in certain applications. Lead-free glazes require an increase in the

TABLE 12.7.3 Compositions and Properties of Selected Basic and High-Duty Refractories

Refractory	Composition	Maximum Use Temperature in O_2 (°C)	Maximum Use Temperature in O_2 (°F)	Thermal Conductivity 100°C/212°F	Thermal Conductivity 500°C/930°F	Thermal Conductivity 100°C/1830°F
Basic Refractories						
Silica	93–96% SiO_2	1700	3090	0.8–1.0	1.2–1.4	1.5–1.7
Fireclay	55–80% SiO_2 and 15–45% Al_2O_3	1300–1450	1370–2640	0.8–0.9	0.9–1.1	2.4–2.6
Magnesite	80–95% MgO Fe_2O_3 Al_2O_3	1800	3270	3.8–9.7	2.7–4.7	2.2–2.6
Chromite	30–45% Cr_2O_3, 14–19% MgO, 10–17% Fe_2O_3, 15–33% Al_2O_3	1700	3090	1.3	1.5	1.7
Chromite–magnesite	60+% Fe_2O_3 Al_2O_3	1800	3270	1.9–3.5	1.2–2.3	1.6
High-Duty Refractory						
Alumina	100% Al_2O_3	1950	3540	26	9.4	5.3
Magnesia	100% MgO	2400	4350	31	12	6
Silica	100% SiO_2	1200	2190	0.8	1.4	1.8
Mullite	72% Al_2O_3, 28% SiO_2	1850	3360	5.3	3.8	3.4

firing temperature of approximately 150°C, from 1030 to around 1190°C. Porcelain glazes mature at temperatures in the same regime as the underlying body from which they get their name. Zinc-containing glazes are similar to porcelain glazes except that they mature at lower temperatures. Slip glazes are used in artware glazing and high-tension electrical insulators. Fritted glazes are in the form of prereacted glass which has been ground to form a powder. Special glazes offer special optical properties in the finished surface. Salt glazes are formed by injecting salts into the firing kiln, with the resulting glaze having a complex pattern of crystalline and glassy phases. Crystalline glazes are often zinc based and produce crystals within the glaze, again for artistic value. Luster glazes form a metallic coating on the glaze.

Structural Clay Products

Ceramic materials are used in a wide variety of applications in the construction industry, ranging from concrete and cement for buildings and highways, to structural clay materials for use in piping and roofing. For a discussion of concrete materials refer to Section 12.5.

Structural clay products have been used for millennia. Original uses included tile and clay brick for building construction, as well as pipes in water supply and sewer applications. These materials are still used today because of their high compressive strength and imperviousness to water. Structural ceramics are coarse-grained materials with the one exception of ceramic tile. Typical raw material compositions for these bodies are 35 to 55% clay, 25 to 45% filler, usually silica, and 25 to 55% fluxing material. Colors range from white for the kaolinitic clay products, to a buff for the fireclay materials, to red for the illitic materials. Properties vary widely between the different materials. Most concern is placed on the water absorption, which relates to freeze/thaw durability and compressive strength.

Advanced Ceramics

Classes of Advanced Ceramics

Advanced ceramic materials are materials which have been engineered to possess exceptional levels of mechanical, optical, thermal, or other property. Most often the materials possess high strength, high stiffness, or are chemically inert. Typical materials contain oxides, nitrides, or carbides which may be monolithic structures or reinforced with various particulate and/or fibrous materials. Refer to Section

12.6 for a detailed discussion of composites. The reinforcement phase usually, but not necessarily, differs from the matrix material. Phases used in designing engineered ceramics are listed in Table 12.7.4 with specific property characteristics as indicated. Advanced ceramic materials are currently much more varied and less standardized than metals, and materials from different manufacturers, or even from different production lots, will have varied properties.

TABLE 12.7.4 Selected Properties of Crystalline Phases Used in Engineered Ceramics

Crystalline Phases	Formula	Melting Temperature (C)	Thermal Expansion α (ppm/°C)	Dielectric Constant κ
Magnesia	MgO	2852	14	5.5
Magnesia spinel	$MgO \cdot Al_2O_3$	2135	8	8.0
Alumina	Al_2O_3	2072	9	10.0
Mullite	$3Al_2O_3 \cdot 2SiO_2$	1920	5.5	4.5

Zinc ferrite	$ZnO \cdot Fe_2O_3$	—	—	—

Structural Ceramics

Required Properties. Structural applications involve the use of ceramic materials in load-bearing situations. Material properties required for these conditions include strength over a wide temperature range, often as high as 1400°C, stiffness, creep resistance, resistance to corrosion and oxidation, and, ideally, damage tolerance or toughness. The major difficulty in the use of ceramics for structural applications is their low fracture toughness compared with metals. Conversely, ceramics excel at high-temperature behavior, have low density/weight ratios, high stiffness, and chemical inertness. At the present level of technology, there is a trade-off between high strength and high toughness. To get a high-strength material usually requires a fine-grain-sized ceramic, while a tough ceramic material often has elongated grains or reinforcement phases that are usually quite large.

Applications. Existing and potential applications include automotive, biomedical, power generation, heat exchangers, wear materials, aerospace and military applications, cutting tools, and various other technologies. Table 12.7.5 provides the mechanical properties of selected advanced ceramics. The property values listed are guidelines; exact properties are difficult to specify since the exact properties depend largely on processing. Material selection is governed by the environmental conditions of each application.

Electronic and Magnetic Ceramics

Electronic and magnetic ceramic materials have a variety of useful functions. Alumina, alumina titanate, and aluminum nitride are used as substrate materials, zirconia is used in oxygen sensors, lead zirconate

TABLE 12.7.5 Mechanical Properties of Selected Advanced Ceramic Materials

Material	Composition	Density (g/cc)	Elastic Modulus (GPa)	Fracture Strength (MPa)	Fracture Toughness K_{IC} (MPa · $m^{0.5}$)	Hardness (Vickers)

[b] With Co additions.

titanate (PZT) and lead magnesium niobate are common actuator and transducer materials, and barium titanate and related materials are used in capacitors. Ceramic materials are used not only in military and aerospace applications, but also in consumer electronics, computers, automotive and transportation systems, and power generation systems. Electronic/magnetic ceramics are useful as a result of a variety of properties. Refer to Table 12.7.1 for dielectric property data of selected compositions.

Optical Ceramics

Zirconia and transparent alumina, or sapphire, are often used as high-temperature windows, due to their high melting points, chemical inertness, and high transparency. They are also used as watch crystals, due to their high scratch resistance. Mirrors made from silicon carbide are being evaluated because of the higher strength-to-weight ratio compared with glass materials and the relatively low coefficient of thermal expansion of SiC. Laser crystals are a group of materials which are often based on doped crystals — yttrium aluminum garnet (YAG) is representative, Infrared (IR) transparent windows and shields are used principally in military and aerospace applications to protect IR sensors from damage. Missile nose cones, or randomes, must possess high mechanical strength and be resistant to mechanical erosion and thermal shock. Typical materials include aluminum oxynitride, spinel, zinc sulfide, calcium fluoride, yttria, and sapphire. Refer to Table 12.7.6 for IR absorption ranges of important ceramic materials.

Effect of Finishing and Machining on Properties

Final finishing of many advanced ceramics is required to obtain the optimum mechanical properties or to meet design tolerances. Since sharp corners act as stress concentrators and are not associated with good design, they are usually machined to a several-millimeter radius if they occur in the as-manufactured product. Other operations include surface grinding, polishing, or lapping operations. Ceramics are very hard materials, which makes final matching machining extremely time-consuming and expensive. Every effort should be made to fabricate components to close to net shape tolerances, or to machine the piece as much as possible prior to final firing.

Traditional Glasses

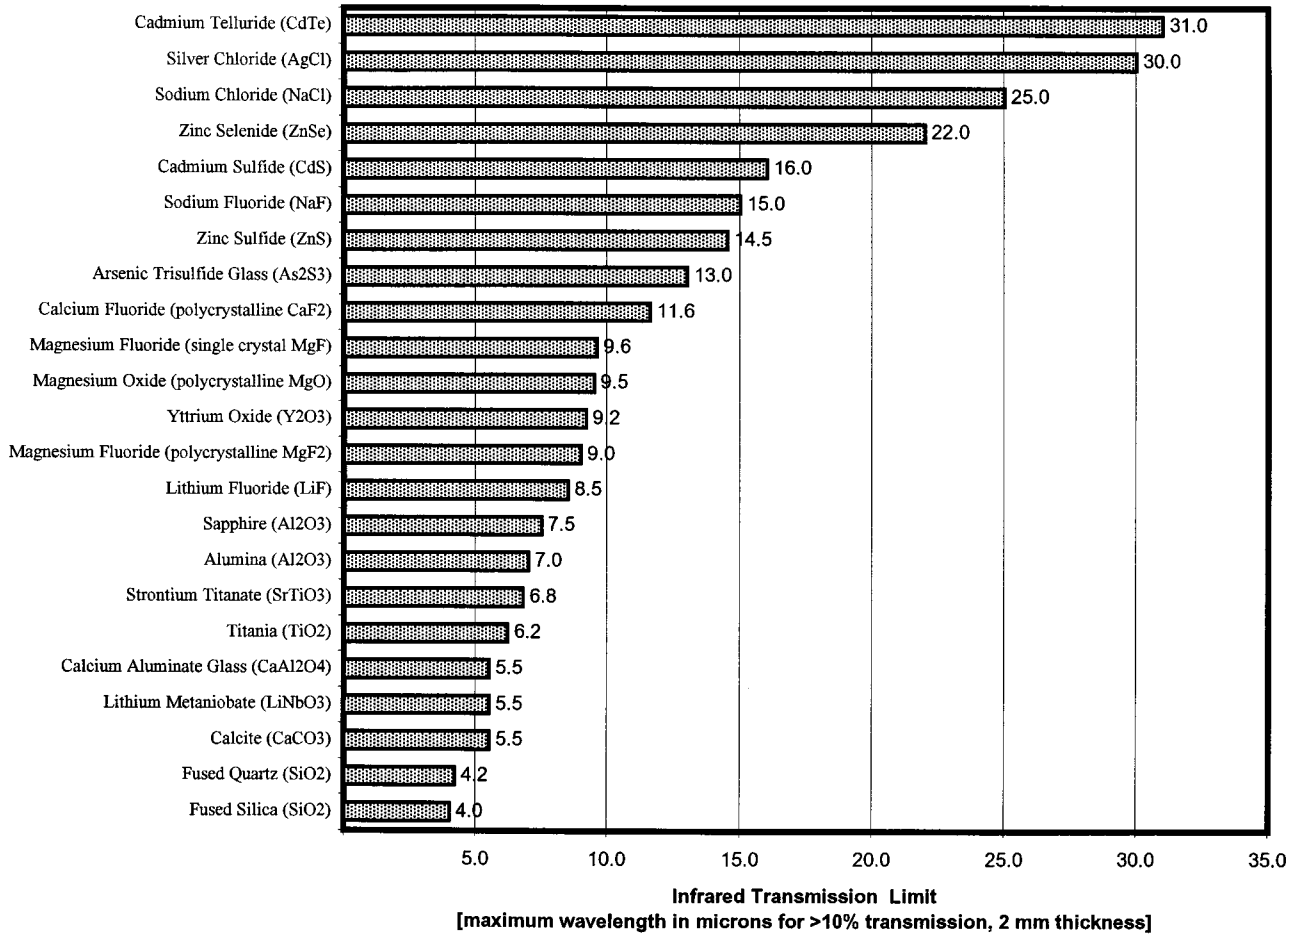
Definition and Introduction

Traditionally, glass is defined as an inorganic product of fusion which has cooled to a rigid state without crystallizing. This broad definition says nothing about the chemistry of the glass but rather refers to the traditional concept of cooling liquid melts below the melting point to form substances which are rigid elastic mechanical solids but which have not crystallized. The historical model for this process is the melting of soda–lime silicate glass by fusing the raw materials at high temperature and cooling quickly to form the well-known window and container glass still in wide use today. Although this definition is still generally valid, processes exist today in which glass is made without fusion. Chemical and physical vapor deposition, and sol–gel processes are examples. Many organic and metallic materials form glasses and are in commercial use today, thus rendering the “inorganic” part of the historical definition inappropriate.

A more applicable definition of glass is an X-ray diffraction amorphous material which exhibits a glass transition. A glass transition is the temperature point at which the amorphous solid exhibits a continuous change in thermodynamic quantities such as heat capacity and expansion coefficient. Because the structure of the glass is frozen before it reaches equilibrium, a glass is metastable with respect to its corresponding crystalline phase. Unlike the crystalline phase, the glass can have a range of physical properties depending upon the rate of cooling (thermal history) and these properties are universally isotropic.

Although glass can be made from an enormous range of polymers, oxides, metals, and inorganic and organic salts, the principle glasses of interest to a mechanical engineer will be glasses with oxide network formers such as SiO_2, B_2O_3, P_2O_5. These oxides, among others, are known as glass formers. They are capable of forming the three-dimensional network essential to the existence of the glassy state. Other

TABLE 12.7.6 IR Transmission Limits for Selected Materials



oxides, such as alkalis, alkaline earths, and various transition elements simply serve to modify the basic network to produce varying properties.

The most common glass in use today is the very old soda–lime–silicate glass composition based on the weight composition: 74% SiO_2, 16% Na_2O, and 10% CaO. In this composition the silica is the network former, the sodium breaks up the silicate network to permit melting and fabrication at reasonable temperatures, and the calcia provides ionic bonding within the network to provide chemical durability. This composition is used today, with minor variations, for early all container, window, and tableware glass articles.

Composition/Properties

Traditional glasses are silicate glasses, i.e., glass which contain SiO_2 as the principal network-forming oxide. Table 12.7.7 give compositions for a representative range of commercial glasses, and Table 12.7.8 lists properties for flat glass. All glasses in Table 12.7.7 contain at least 50% SiO_2 and many are quite close to the traditional 74/16/10 composition mentioned above. The types and amount of modifier oxides are determined by the properties required in use. A more specific list of technical glass compositions from Corning, Inc., and identified by Corning glass codes, is given in Table 12.7.9. Principal glass types are discussed in the following sections.

Pure Silica Glass. Pure silica glass (fused silica) has excellent thermal, mechanical, chemical, and optical properties. Thermal expansion is $5.5 \times 10^{-7}°C^{-1}$, use temperature is above 1000°C, and it has excellent visible and ultraviolet (UV) transmission. However, the melting point is greater than 2000°C, which makes manufacture extremely difficult and expensive. Therefore, fused silica is used primarily for such demanding applications as optical fibers, semiconductor process equipment, UV lamps, optics, and space shuttle windows. If 7 wt% titanium dioxide (TiO_2) is added, the thermal expansion coefficient is reduced to zero in normal temperature ranges. This glass (ULE, or ultra low expansion) is used in applications which require exceptional dimensional stability. Telescope mirrors are an example.

High-Silica Glass. The high melting temperatures needed to produce pure SiO_2 glass can be avoided by first melting a special sodium borosilicate glass which can be formed into the desired shape. This glass (Vycor®) phase separates and after acid leaching results in a high (>96%) silica glass with nearly the same properties as pure vitreous silica.

Soda Silica. In order to lower the melting point, a flux is added. The most common flux is sodium oxide (Na_2O), which makes a low-melting glass that is soluble in water and is called water glass. Dissolved glass is used to seal or bond materials such as low-speed grinding wheels.

Soda–Lime–Silica. This is the most common glass and accounts for more than 90% of all the glasses made today. In this glass, lime (CaO) has been added to improve the durability of simple soda–silica glass. Small amounts of other oxides such as alumina (Al_2O_3), magnesium oxide (MgO), and potassium oxide (K_2O) are also added to further enhance the desired properties. The lime is usually obtained from limestone, and the sodium monoxide is obtained from any number of sodium compounds, notably sodium bicarbonate or common baking soda.

Aluminosilicate Glass. Aluminosilicate glass is produced by adding up to 20% Al_2O_3 to soda–lime glass. Aluminosilicate glasses are resistant to thermal shock and high temperatures, and they are not as difficult to produce as silica glass. They find wide use in electronics and in high-temperature laboratory equipment.

Borosilicate Glass. In borosilicate glass much of the soda and lime of ordinary glass is replaced by boric oxide. The result is a glass that has a low thermal expansion and is thus resistant to heat and to sudden changes in temperature. The first borosilicate glass was developed by the Corning Glass Works under the trade name Pyrex. Borosilicate glasses are used in laboratory glassware, as well as in home ovenware. Because of their low thermal expansion they are suitable for applications requiring dimensional stability.

Property	Value
Specific gravity	2.5
Specific heat	0.21
Hardness (Moh's)	5–6
Softening point, °C	729
Refractive index, sodium D-line	1.52
Modulus of elasticity, GPa	70
Tensile strength, MPa	45
Poisson's ratio	0.23
Coefficient of linear expansion, ppm/°C	8.8
Dielectric constant, 1 Mhz	7.1

Lead Silicates. Lead silicate glass has a higher index of refraction and also a higher dispersion than soda–lime–silicate glass and thus finds use in optical applications. The high gloss resulting from high Fresnel reflection makes lead glasses of 24 to 35% PbO popular for consumer products in the form of artware and lead crystal glass. Lead glasses of different compositions are used widely in electronic applications since low-melting sealing glasses can be formed with little or no alkali, a constituent which promotes high electrical loss.

Strength of Glass

Theoretical Strength. Glass below the glass transition temperature (T_g) is a brittle solid, with failure originating at flaws (scratches, defects, minute compositional differences) which act as stress concentrators. Without flaws of any kind the strength of glass approaches theoretical levels of about 17 GPa (2.5×10^6 psi). Unfortunately, unless glass is processed under the utmost pristine conditions and then immediately coated to prevent surface abrasion by dust or other environmental agents, the glass will contain flaws which decrease the strength by several orders of magnitude from theoretical levels. Synthetic silica glass optical fibers, prepared under meticulous conditions and tested at 77 K, are among the few glass materials which exhibit nearly theoretical strength.

Nominal and Design Strength. The exact failure stress for a specific piece of glass will depend upon the configuration and size of the defect at the crack origin. Since these defects vary in size over a wide range, the standard deviation in the strength of glass will also be large. The glass design engineer must allow large safety factors, often 20 to 50%, to account for the statistical variation. For most types of glass a nominal strength of 70 MPa and a design stress of 7 MPa are typical. Table 12.7.10 summarizes strength and variability in the strength of glasses.

Strengthening and Tempering. Glass can be substantially strengthened, or tempered, either by rapid cooling or by ion-exchange of the surface to develop compressive stresses. Fast, uniform cooling of glass plates heated to the softening point will introduce surface compressive stresses on the glass (with corresponding tensile stress in the center) which become permanently frozen into place upon cooling to room temperature. These compressive stresses, typically 70 to 200 MPa, will resist externally applied tensile stresses and help to prevent crack propagation. Tempering will increase the strength of glass by as much as three to six times. Tempered glass will shatter violently when it fails as a result of the sudden release of stored elastic energy, although the broken pieces will not be sharp. Generally, only simple shapes can safely be thermally tempered.

Ion-exchange tempering also improves the strength of the glass by introducing surface compression. In the ion-exchange process large ions are "stuffed" into the interstices in the glass structure previously occupied by smaller ions. This is done by immersing the glass in a molten bath of the alkali salt (typically KNO_3 for a sodium-containing glass) at an elevated temperature. The larger ions will introduce a compressive strain as they force their way into the glass network. The strains obtainable are much higher

than those from thermal tempering, generating stresses as high as 700 MPa, although the surface compressive layer is quite shallow and subject to penetration. Ion-exchanged glasses can be more than 10 to 20 times as strong as normal glass and are used, for example, in aircraft windshields to resist bird impacts.

Behavior at Elevated Temperatures

Glasses do not have a clearly defined melting temperature. Instead, there is a temperature range where the viscosity of the glass changes smoothly from solid (greater than 10^{14} Pa · sec) to liquid (less than 10 Pa · sec). It is useful to define some points on the viscosity–temperature curve to create a clearer

TABLE 12.7.10 Ideal and Practical Strengths of Glass, Glass Fibers, and Glass–Ceramics

Type of Glass	Tensile Strength, psi	Strength/Weight Ratio, psi/lb per cu. in.

Compiled from several sources.

picture of the viscosity behavior of a glass. The strain point is defined as the temperature at which a glass will release 95% of its stresses within a period of 6 hr. This occurs at a viscosity of approximately $10^{13.5}$ Pa · sec. The annealing point occurs at 10^{12} Pa · sec a viscosity at which 95% of stresses will be released in 15 min. At $10^{6.6}$ Pa · sec, the softening point, the glass will deform under its own weight. The working point is defined as 10^3 Pa · sec, and is a typical minimum viscosity for machine working during forming. Refer to Table C.12 in the Appendix, Properties of Silicate Glasses. Many properties of glasses are presented in this comprehensive table, including maximum application temperatures (upper working temperature) and viscosity data for most common glasses. Generally, the extreme upper working temperature corresponds to the strain point of the glass. Normal service conditions are typically 50 to 60% of the strain point on the Kelvin temperature scale. Under normal service conditions glass is a brittle, mechanical solid, it possesses no mechanical characteristics of a liquid, and it will not flow. Specific heat and thermal conductivity data are presented in Table 12.7.11. Below the glass transition, glass is not a supercooled liquid, it is a glass. Old windows are not thicker at the bottom because of viscous flow.

Chemical Durability

Although glass is often considered an extraordinarily inert material, even the most durable glasses undergo some environmental degradation and many glasses are rapidly attacked by strong acid or basic solutions. Corrosive aqueous environments can cause the ions in the glass to be extracted by a leaching process. Chemical durability behavior is difficult to generalize and trial-and-error testing is usually required for each application. The most severe attack is experienced at extreme high and low pH values; neutral pH solutions rarely attack glass at significant rates. Glasses high in SiO_2, Al_2O_3, and CaO are generally most durable. Glasses high in alkali, such as Na_2O or K_2O, are less durable. B_2O_3 and PbO are intermediate.

A notable form of chemical degradation which occurs under simple, apparently benign, conditions is weathering. Standard soda–lime–silicate window glass can be permanently damaged in a short time (~30 days) if held under high humidity with a means to retain adsorbed moisture on the surface. Such a means

TABLE 12.7.11 Thermal Properties of Several Glass Types

Material	Specific Heat			Thermal Conductivity, cal/cm sec°C × 10^4[a]			
	25°C	500°C	1000°C	–100°C	0°C	100°C	400°C

can be a dirt film or perhaps a sheet of newspaper. The moisture ion-exchanges with sodium ions in the glass, which form a high-pH surface film which accelerates the attack on the glass. Pitting and adherent surface deposits can quickly form, making the glass unusable.

For container applications requiring extremely high purity, it is common to use a durable glass such as a borosilicate or to increase the chemical resistance of the glass using surface treatments of SO_2, SnO_2, or TiO_2.

Optical Properties

Traditional glasses are principally used because they are transparent in the visible region of the spectrum; windows, containers, and precision optics are examples. Although pure silica is highly transmissive overt the entire visible spectrum, impurities impart coloration which detract from the performance of some glasses but which can also be used to produce beautiful and useful colored glasses. Table 12.7.12 lists impurity ions and their resulting colors. Iron is the most common impurity, imparting a blue-green-yellow tint depending on the oxidation state. It is possible to neutralize but not bleach impurity colors by "decolorization," the addition of complementary coloring oxides to produce an overall neutral gray absorption. Traditional glasses do not transmit well in the UV or IR range, with the exception of certain specialty glasses. Pure silica is the best example, enabling high transmission levels (>10%, 2 mm thickness) from 160 nm to 4 μm.

The refractive index of common silicate glasses are in the range of 1.5 to 1.7 and specific values are given in Table C.12 in the Appendix, *Properties of Silicate Glasses*.

Specialty Glasses

Non-Silica-Oxide Glasses

Glasses made from B_2O_3 and P_2O_3 glass formers rather than SiO_2 possess some special thermal, optical, and chemical properties which make them of interest in certain narrow engineering fields. Borate glasses, often in combination with PbO, are useful solder and sealing glasses for electronic applications; phosphate glasses have special optical properties and are also used as water-soluble chemicals in industry. Tellurite glasses have high refractive indexes and, hence, are used in some demanding refractive optic applications. Glasses based on Bi_2O_3, Sb_2O_3, TeO_2, or V_2O_5 have very low melting points, suggesting their use as low-temperature electrical seals. Boro-aluminates have very high electrical resistivities. Alkaline earth aluminates have excellent IR transmitting properties and make excellent high-temperature

TABLE 12.7.12 Coloring Additives to Glass

Color	Additive
Red	Colloidal Au or Cu, Cd-Se (S, Te)
Pink	$MnO_2 \cdot CeO_2$, Se^{2-}
Orange	CdS (Se)
Amber	FeS_x, $Fe_2O_3 \cdot TiO_2$
Yellow	UO_2, $CeO_2 \cdot TiO_2$, CdS
Green	Cr_2O_3, Fe_2O_3, CuO, U_2O_3
Blue	CoO, FeO, CuO
Violet	NiO, Mn_2O_3
Gray	$Co_3O_4 \cdot NiO$
Black	$Mn_2O_3 \cdot Cr_2O_3$, PbS, FeS, $CoSe_x$
UV absorption	CeO_2, TiO_2, Fe_2O_3, V_2O_5, CrO_3
IR absorption	FeO, CuO
Decolorization, i.e., mask Fe_2O_3 color	MnO, Se^{2-}, NiO, Co_3O_4
Opacification, i.e., white opals	CaF_2, NaF, ZnS, $Ca_2(PO_4)_3$
Solarization	Cerium, arsenic

lamp seals. Despite their unique properties, non-silica-oxide glasses are costly and make up only a very small percentage of the glass produced annually.

Chalcogenide Glasses

A class of excellent IR-transmitting glasses, the chalcogenides, are obtained by combining group VI elements with group V and IV elements. Glasses in this group also exhibit photoconductivity and semiconductivity. Applications for these glasses consist of IR-transmitting optical waveguides (to 20 μm), high-performance IR optical applications, and specialty applications which utilize their photoconductivity properties. Most notable of these applications is the photosensitive coating applied to photocopy drums. Purity issues have limited applications in optical fibers as of this writing.

Heavy Metal Fluoride Glasses

Heavy metal fluoride glasses (HMFG) are an important new (1975) composition group because of their extremely low theoretical optical attenuation (10^{-3} dB/km at 3.5 μm), which makes them candidates for repeaterless transoceanic communication links. Unfortunately, this magnitude of transmission has not been obtained in practice because of problems with high oxygen impurities and crystallization. Furthermore, HMFGs are readily attacked by water, and current development efforts are aimed at improving chemical durability. At present, HMFGs are limited to short transmission distance IR optical applications.

Amorphous Metals

Certain metal compositions can be fabricated as glasses by subjecting streams of the molten metal to extremely rapid quenching rates (10^5 to 10^8°C/sec). The resulting glasses possess intriguing properties. Strengths approach theoretical limits, and electrical resistivities are greater than their crystalline counterparts yet decrease with temperature. Most importantly, they have extremely low B–H hysteresis curves. For this reason they are used commercially as power transformer core laminations.

Amorphous Semiconductors

Many elements and compounds which exhibit semiconducting properties in the crystalline state are also semiconductors in the amorphous state. Si, Ge, P, As, $CdGe_xAs_2$ (x = 0 to 1.2), $Si_{1-x}H_x$ (x = 0.1 to 0.2) are important examples. These materials are use in fabrication of inexpensive vapor deposition fabrication of photovoltaic cells.

Glass Ceramics

A useful group of materials is made by batching, melting, and forming a product as a glass followed by heat treatment to nucleate and grow crystalline phases from the glass to produce a ceramic with up to 99% crystalline phase content. The microstructure contains crystals of about 1 μm size, a glassy matrix, and no porosity. The processing route is a principal advantage since high-speed glass-forming methods can be used, no porosity exists, the formed shape can be inspected as a transparent glass, and rejects at the forming stage can be recycled.

Glass ceramics are typically stronger than most ceramics as a result of zero porosity, and they are tougher than glass because of the deflection of crack fronts around the crystals. High-temperature properties are generally not good due to the glassy phase and the nature of the process, thus limiting most glass ceramics to low- and intermediate-temperature applications (<1000°C). A wide range of products has been made from glass ceramics, from home cookware to industrial bearings and aerospace radomes.

13.1 Introduction

Jay Lee and Robert Shafrik

Manufacturing is the means by which the technical and industrial capability of a nation is harnessed to transform innovative designs into well-made products that meet customer needs. This activity occurs through the action of an integrated network that links many different participants with the goals of developing, making, and selling useful things.

Manufacturing is the conversion of raw materials into desired end products. The word derives from two Latin roots meaning *hand* and *make*. Manufacturing, in the broad sense, begins during the design phase when judgments are made concerning part geometry, tolerances, material choices, and so on. Manufacturing operations start with manufacturing planning activities and with the acquisition of required resources, such as process equipment and raw materials. The manufacturing function extends throughout a number of activities of design and production to the distribution of the end product and, as necessary, life cycle support. Modern manufacturing operations can be viewed as having six principal components: materials being processed, process equipment (machines), manufacturing methods, equipment calibration and maintenance, skilled workers and technicians, and enabling resources.

There are three distinct categories of manufacturing:

- *Discrete item manufacturing*, which encompasses the many different processes that bestow physical shape and structure to materials as they are fashioned into products. These processes can be grouped into families, known as unit manufacturing processes, which are used throughout manufacturing.
- *Continuous materials processing*, which is characterized by a continuous production of materials for use in other manufacturing processes or products. Typical processes include base metals production, chemical processing, and web handing. Continuous materials processing will not be further discussed in this chapter.
- *Micro- and nano-fabrication*, which refers to the creation of small physical structures with a characteristic scale size of microns (millionths of a meter) or less. This category of manufacturing is essential to the semiconductor and mechatronics industry. It is emerging as very important for the next-generation manufacturing processes.

Manufacturing is a significant component of the U.S. economy. In 1995, 19% of the U.S. gross domestic product resulted from production of durable and nondurable goods; approximately 65% of total U.S. exports were manufactured goods; the manufacturing sector accounted for 95% of industrial research and development spending; and manufacturing industries employed a work force of over 19 million people in 360,000 companies. In the modern economy, success as a global manufacturer requires the development and application of manufacturing processes capable of economically producing high-quality products in an environmentally acceptable manner.

Modern Manufacturing

Manufacturing technologies address the capabilities to design and to create products, and to manage that overall process. Product quality and reliability, responsiveness to customer demands, increased labor productivity, and efficient use of capital were the primary areas that leading manufacturing companies throughout the world emphasized during the past decade to respond to the challenge of global competitiveness. As a consequence of these trends, leading manufacturing organizations are flexible in management and labor practices, develop and produce virtually defect-free products quickly (supported with global customer service) in response to opportunities, and employ a smaller work force possessing multidisciplinary skills. These companies have an optimal balance of automated and manual operations.

To meet these challenges, the manufacturing practices must be continually evaluated and strategically employed. In addition, manufacturing firms must cope with design processes (e.g., using customers' requirements and expectations to develop engineering specifications, and then designing components),

production processes (e.g., moving materials, converting materials properties or shapes, assembling products or components, verifying processes results), and business practices (e.g., turning a customer order into a list of required parts, cost accounting, and documentation of procedures). Information technology will play an indispensable role in supporting and enabling the complex practices of manufacturing by providing the mechanisms to facilitate and manage the complexity of manufacturing processes and achieving the integration of manufacturing activities within and among manufacturing enterprises. A skilled, educated work force is also a critical component of a state-of-the-art manufacturing capability. Training and education are essential, not just for new graduates, but for the existing work force.

Manufacturing is evolving from an art or a trade into a science. The authors believe that we must understand manufacturing as a technical discipline. Such knowledge is needed to most effectively apply capabilities, quickly incorporate new developments, and identify the best available solutions to solve problems. The structure of the science of manufacturing is very similar across product lines since the same fundamental functions are performed and the same basic managerial controls are exercised.

13.2 Unit Manufacturing and Assembly Processes

Robert E. Schafrik

There are a bewildering number of manufacturing processes able to impart physical shape and structure to a workpiece. However, if these processes are broken down into their basic elements and then examined for commonality, only a few fundamental processes remain. These are the building blocks, or unit processes, from which even the most complicated manufacturing system is constructed. This section describes these unit processes in sufficient detail that a technically trained person, such as a design engineer serving as a member of an integrated product and process design team comprised of members from other specialties, could become generally knowledgeable regarding the essential aspects of manufacturing processes. Also, the information presented in this section will aid such an individual in pursuing further information from more specialized manufacturing handbooks, publications, and equipment/tool catalogs.

Considering the effect that a manufacturing process has on workpiece configuration and structure, the following five general types of unit manufacturing process can be identified (Altan et al., 1983; NRC, 1995):

Material removal processes — Geometry is generated by changing the mass of the incoming material in a controlled and well-defined manner, e.g., milling, turning, electrodischarge machining, and polishing.

Deformation processes — The shape of a solid workpiece is altered by plastic deformation without changing its mass or composition, e.g., rolling, forging, and stamping.

Primary shaping processes — A well-defined geometry is established by bulk forming material that initially had no shape, e.g., casting, injection molding, die casting, and consolidation of powders.

Structure-change processes — The microstructure, properties, or appearance of the workpiece are altered without changing the original shape of the workpiece, e.g., heat treatment and surface hardening.

Joining and assembly processes — Smaller objects are put together to achieve a desired geometry, structure, and/or property. There are two general types: (1) consolidation processes which use mechanical, chemical, or thermal energy to bond the objects (e.g., welding and diffusion bonding) and (2) strictly mechanical joining (e.g., riveting, shrink fitting, and conventional assembly).

Unit Process Selection

Each component being manufactured has a well-defined geometry and a set of requirements that it must meet. These typically include

- Shape and size
- Bill-of-material
- Accuracy and tolerances
- Appearance and surface finish
- Physical (including mechanical) properties
- Production quantity
- Cost of manufacture

In order to satisfy these criteria, more than one solution is usually possible and trade-off analyses should be conducted to compare the different approaches that could be used to produce a particular part.

Control and Automation of Unit Processes

Every unit process must be controlled or directed in some way. The need for improved accuracy, speed, and manufacturing productivity has spurred the incorporation of automation into unit processes regarding both the translation of part design details into machine instructions, and the operation of the unit process

itself and as a subsystem of the overall production environment. The section of this chapter on computer-aided design/computer-aided manufacturing (CAD/CAM) discusses the technology involved in creating and storing CAD files and their use in CAM. The expectations of precision are continuing to change, as indicated in Figure 13.2.1. This drive for ever-tighter tolerances is helping spur interest in continual improvements in design and manufacturing processses.

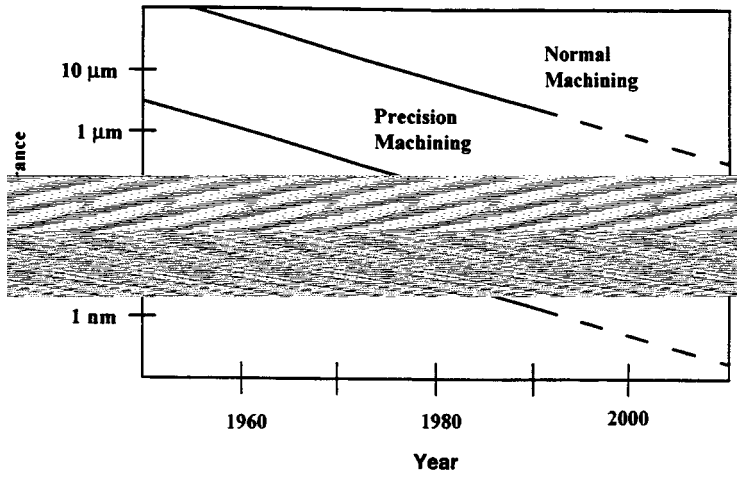

FIGURE 13.2.1 Precision machining domains. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, D.C., 1995, 169. With permission.)

Modern machine tool controls are emphasizing two areas: adaptive control and communication. For *adaptive control* the controller must adapt its control gains so that the overall system remains at or near the optimal condition in spite of varying process dynamics. Expanded *communication* links the data collected by a unit process controller to other segments of the manufacturing operation. Data regarding production time and quantity of parts produced can be stored in an accessible database for use by inventory control and quality monitoring. This same database can then be used by production schedulers to avoid problems and costs associated with redundant databases.

At the factory level, machining operations employing two or more numerically controlled (NC) machine tools may use a separate mainframe computer that controls several machine tools or an entire shop. The system is often referred to as *distributed numerical control* (DNC).

Today many factories are implementing *flexible manufacturing systems* (FMS), an evolution of DNC. An FMS consists of several NC unit processes (not necessarily only machine tools) which are interconnected by an automated materials handling system and which employ industrial robots for a variety of tasks requiring flexibility, such as loading/unloading the unit process queues. A single computer serves as master controller for the system, and each process may utilize a computer to direct the lower-order tasks. Advantages of FMS include:

- A wide range of parts can be produced with a high degree of automation
- Overall production lead times are shortened and inventory levels reduced
- Productivity of production employees is increased
- Production cost is reduced
- The system can easily adapt to changes in products and production levels

Unit Processes

In the following discussion, a number of unit processes are discussed, organized by the effect that they have on workpiece configuration and structure. Many of the examples deal with processing of metals

since that is the most likely material which users of this handbook will encounter. However, other materials are readily processed with the unit processes described in this chapter, albeit with suitable modifications or variations.

Mechanical assembly and material handling are also discussed in this section. On average, mechanical assembly accounts for half of the manufacturing time, and processes have been developed to improve the automation and flexibility of this very difficult task. Material handling provides the integrating link between the different processes — material-handling systems ensure that the required material arrives at the proper place at the right time for the various unit processes and assembly operations.

The section ends with a case study that demonstrates how understanding of the different unit processes can be used to make engineering decisions.

- Material removal (machining) processes
  - Traditional machining
    Drill and reaming
    Turning and boring
    Planing and shaping
    Milling
    Broaching
    Grinding
    Mortality
  - Nontraditional machining
    Electrical discharge machining
    Electrical chemical machining
    Laser beam machining
    Jet machining (water and abrasive)
    Ultrasonic machining
- Phase-change processes
  - Green sand casting
  - Investment casting
- Structure-change processes
  - Normalizing steel
  - Laser surface hardening
- Deformation processes
  - Die forging
  - Press-brake forming
- Consolidation processes
  - Polymer composite consolidation
  - Shielded metal-arc welding
- Mechanical assembly
- Material handling
- Case study: Manufacturing and inspection of precision recirculating ballscrews

Material Removal Processes

These processes, also known as machining, remove material by mechanical, electrical, laser, or chemical means to generate the desired shape and/or surface characteristic. Workpiece materials span the spectrum of metals, ceramics, polymers, and composites, but metals, and particularly iron and steel alloys, are by far the most common. Machining can also improve the tolerances and finish of workpieces previously shaped by other processes, such as forging. Machining is an essential element of many manufacturing systems (ASM, 1989b; Bakerjian, 1992).

Machining is important in manufacturing because

- It is precise. Machining is capable of creating geometric configurations, tolerances, and surface finishes that are often unobtainable by other methods. For example, generally achievable surface roughness for sand casting is 400 to 800 μin. (10 to 20 μm), for forging 200 to 400 μin. (5 to 10 μm), and for die casting 80 to 200 μin. (2 to 5 μm). Ultraprecision machining (i.e., super-finishing, lapping, diamond turning) can produce a surface finish of 0.4 μin (0.01 μm) or better. The achievable dimensional accuracy in casting is 1 to 3% (ratio of tolerance to dimension) depending on the thermal expansion coefficient and in metal forming it is 0.05 to 0.30% depending on the elastic stiffness, but in machining the achievable tolerance can be 0.001%.
- It is flexible. The shape of the final machined product is programmed and therefore many different parts can be made on the same machine tool and just about any arbitrary shape can be machined. In machining, the product contour is created by the path, rather than the shape, of the cutter. By contrast, casting, molding, and forming processes require dedicated tools for each product geometry, thus restricting their flexibility.
- It can be economical. Small lots and large quantities of parts can be relatively inexpensively produced if matched to the proper machining process.

The dominating physical mechanism at the tool/workpiece interface in conventional machining is either plastic deformation or controlled fracture of the workpiece. Mechanical forces are imposed on the workpiece by the application of a tool with sharp edges and higher hardness than the workpiece. However, many new materials are either harder than conventional cutting tools or cannot withstand the high cutting forces involved in traditional machining. Nontraditional manufacturing (NTM) processes can produce precision components of these hard and high-strength materials. NTM processes remove material through thermal, chemical, electrochemical, and mechanical (with high impact velocity) interactions.

Machinability is defined in terms of total tool life, power requirements, and resultant workpiece surface finish. To date, no fundamental relationship incorporates these three factors and thus machinability must be empirically determined by testing.

Process Selection

Machine tools can be grouped into two broad categories:

- Those that generate surfaces of rotation
- Those that generate flat or contoured surfaces by linear motion

Selection of equipment and machining procedures depends largely on these considerations:

- Size of workpiece
- Configuration of workpiece
- Equipment capacity (speed, feed, horsepower range)
- Dimensional accuracy
- Number of operations
- Required surface condition and product quality

For example, Figure 13.2.2 graphically indicates the various tolerance levels that can be typically achieved for common machining unit processes as a function of the size of the workpiece. Such data can help in identifying candidate unit processes that are capable of meeting product requirements.

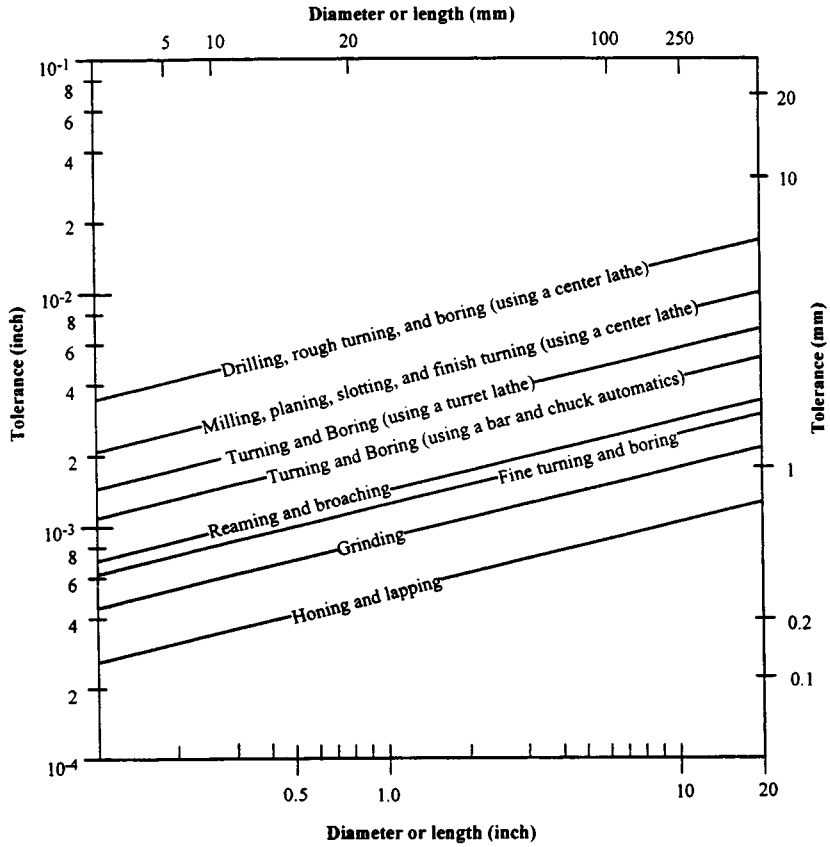

FIGURE 13.2.2 Tolerance vs. dimensional data for machining processes. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, D.C., 1995, 168. With permission.)

Traditional Machining

Steven Y. Liang

Traditional machining processes remove material from a workpiece through plastic deformation. The process requires direct mechanical contact between the tool and workpiece and uses relative motion between the tool and the workpiece to develop the shear forces necessary to form machining chips. The tool must be harder than the workpiece to avoid excessive tool wear. The unit processes described here are a representative sample of the types most likely to be encountered. The reference list at the end of

the section should be consulted for more detailed information on the unit processes discussed below, plus those that are not included here.

Process Kinematics in Traditional Machining. In all traditional machining processes, the surface is created by providing suitable relative motion between the cutting tool and the workpiece. There are two basic components of relative motion: primary motion and feed motion. Primary motion is the main motion provided by a machine tool to cause relative motion between the tool and workpiece. The feed motion, or the secondary motion, is a motion that, when added to the primary motion, leads to a repeated or continuous chip removal. It usually absorbs a small proportion of the total power required to perform a machining operation. The two motion components often take place simultaneously in orthogonal directions.

The functional definitions of turning, milling, drilling, and grinding are not distinctively different, but machining process specialists have developed terminology peculiar to a given combination of functions or machine configurations. Commonly used metal-cutting machine tools, however, can be divided into three groups depending upon the basic type of cutter used: single-point tools, multipoint tools, or abrasive grits.

Dynamic Stability and Chatter. One of the important considerations in selecting a machine tool is its vibrational stability. In metal cutting, there is a possibility for the cutter to move in and out of the workpiece at frequency and amplitude that cause excessive variations of the cutting force, resulting in poor surface quality and reduced life of the cutting tool (Welboum, 1970).

Forced vibrations during cutting are associated with periodic forces resulting from the unbalance of rotating parts, from errors of accuracy in some driving components, or simply from the intermittent engagement of workpiece with multipoint cutters. *Self-excited vibrations* occur under conditions generally associated with an increase in machining rate. These vibrations are often referred to as chatter. All types of chatter are caused by a *feedback loop* within the machine tool structure between the cutting process and the machine frame and drive system. The transfer function of the machine tool, in terms of the stiffness and damping characteristics, plays a critical role in the stability of the overall feedback system. The static stiffness of most machine tools, as measured between the cutting tool and the workpiece, tends to be around 10^5 lb-ft/in. A stiffness of 10^6 lb-ft/in. is exceptionally good, while stiffness of 10^4 lb-ft/in. is poor but perhaps acceptable for low-cost production utilizing small machine tools.

Basic Machine Tool Components. Advances in machine-tool design and fabrication philosophy are quickly eliminating the differences between machine types. Fifty years ago, most machine tools performed a single function such as drilling or turning, and operated strictly stand-alone. The addition of automatic turrets, tool-changers, and computerized numerical control (CNC) systems allowed lathes to become *turning centers* and milling machines to become *machining centers*. These multiprocess centers can perform a range of standard machining functions: turning, milling, boring, drilling, and grinding (Green, 1992).

The machine tool *frame* supports all the active and passive components of the tool — spindles, table, and controls. Factors governing the choice of frame materials are: resistance to deformation (hardness), resistance to impact and fracture (toughness), limited expansion under heat (coefficient of thermal expansion), high absorption of vibrations (damping), resistance to shop-floor environment (corrosion resistance), and low cost.

Guide ways carry the workpiece table or spindles. Each type of way consists of a *slide* moving along a track in the frame. The slide carries the workpiece table or a spindle. The oldest and simplest way is the *box way.* As a result of its large contact area, it has high stiffness, good damping characteristics, and high resistance to cutting forces and shock loads. Box slides can experience stick-slip motion as a result of the difference between dynamic and static friction coefficients in the ways. This condition introduces positioning and feed motion errors. A *linear way* also consists of a rail and a slide, but it uses a rolling-element bearing, eliminating stick-slip. Linear ways are lighter in weight and operate with less friction,

so they can be positioned faster with less energy. However, they are less robust because of the limited surface contact area.

Slides are moved by hydraulics, rack-and-pinion systems, or screws. *Hydraulic pistons* are the least costly, most powerful, most difficult to maintain, and the least accurate option. Heat buildup often significantly reduces accuracy in these systems. Motor-driven *rack-and-pinion* actuators are easy to maintain and are used for large motion ranges, but they are not very accurate and require a lot of power to operate. Motor-driven screws are the most common actuation method. The screws can either be lead screws or ballscrews, with the former being less expensive and the latter more accurate. The *recirculating ballscrew* has very tight backlash; thus, it is ideal for CNC machine tools since their tool trajectories are essentially continuous. A disadvantage of the ballscrew systems is the effective stiffness due to limited contact area between the balls and the thread. (*Note:* a case study at the end of this section discusses the manufacture of precision ballscrews.)

Electric motors are the prime movers for most machine tool functions. They are made in a variety of types to serve three general machine tool needs: spindle power, slide drives, and auxiliary power. Most of them use three-phase AC power supplied at 220 or 440 V. The design challenge with machine tools and motors has been achieving high torque throughout a range of speed settings. In recent years, the operational speed of the spindle has risen significantly. For example, conventional speeds 5 years ago were approximately 1600 rpm. Today, electric motors can turn at 12,000 rpm and higher. Higher speeds cause vibration, which makes use of a mechanical transmission difficult. By virtue of improvement in motor design and control technology, it is now possible to quickly adjust motor speed and torque. Mechanical systems involving more than a three-speed transmission are becoming unnecessary for most high-speed and low-torque machines. Spindle motors are rated by horsepower, which generally ranges from 5 to 150 hp (3.7 to 112 kW) with the average approximately 50 hp (37 kW). Positioning motors are usually designated by torque, which generally ranges from 0.5 to 85 lb-ft (0.2 to 115 Nm).

The *spindle* delivers torque to the cutting tool, so its precision is essential to machine tool operation. The key factors influencing precision are bearing type and placement, lubrication, and cooling.

Cutting Tool Materials. The selection of cutting tool materials is one of the key factors in determining the effectiveness of the machining process (ASM, 1989b). During cutting, the tool usually experiences high temperatures, high stresses, rubbing friction, sudden impact, and vibrations. Therefore, the two important issues in the selection of cutting tool materials are hardness and toughness. *Hardness* is defined as the endurance to plastic deformation and wear; hardness at elevated temperatures is especially important. *Toughness* is a measure of resistance to impact and vibrations, which occur frequently in interrupted cutting operations such as milling and boring. Hardness and toughness do not generally increase together, and thus the selection of cutting tool often involves a trade-off between these two characteristics.

Cutting tool materials are continuously being improved. Carbon steels of 0.9 to 1.3% carbon and tool steels with alloying elements such as molybdenum and chromium lose hardness at temperatures above 400°F (200°C) and have largely been replaced by *high-speed steels* (HSS). HSS typically contains 18% tungsten or 8% molybdenum and smaller amounts of cobalt and chromium. HSSs retain hardness up to 1100°F (600°C) and can operate at approximately double the cutting speed with equal life. Both tool steels and HSS are tough and resistive to fracture; therefore, they are ideal for processes involving interrupted engagements and machine tools with low stiffness that are subject to vibration and chatter.

Powder metallurgy (P/M) high-speed tool steels are a recent improvement over the conventionally cast HSSs. Powder metallurgy processing produces a very fine microstructure that has a uniform distribution of hard particles. These steels are tougher and have better cutting performance than HSS. Milling cutters are becoming a significant application for these cutting tool materials.

Cast cobalt alloys, popularly known as Stellite tools, were introduced in 1915. These alloys have 38 to 53% cobalt, 30 to 33% chromium, and 10 to 20% tungsten. Though comparable in room temperature hardness to HSS tools, cast cobalt alloy tools retain their hardness to a much higher temperature, and they can be used at 25% higher cutting speeds than HSS tools.

Cemented carbides offered a four- or fivefold increase in cutting speeds over conventional HSS. They are much harder, but more brittle and less tough. The first widely used cemented carbide was tungsten carbide (WC) cemented in a ductile cobalt binder. Most carbide tools in use now are a variation of the basic WC-Co material. For instance, WC may be present as single crystals or a solid solution mixture of WC-TiC or WC-TiC-TaC. These solid solution mixtures have a greater chemical stability in the cutting of steel. In general, cemented carbides are good for continuous roughing on rigid machines, but should avoid shallow cuts, interrupted cuts, and less rigid machines because of likely chipping.

A thin layer of TiC, TiN, or Al_2O_3 can be applied to HSS or carbide substrate to improve resistance to abrasion, temperature, friction, and chemical attacks. The *coated tools* were introduced in the early 1970s and have gained wide acceptance since. Coated tools have two or three times the wear resistance of the best uncoated tools and offer a 50 to 100% increase in speed for equivalent tool life.

Ceramic tools used for machining are based on alumina (Al_2O_3) or silicon nitride (Si_3N_4). They can be used for high-speed finishing operations and for machining of difficult-to-machine advanced materials, such as superalloys (Komanduri and Samanta, 1989). The alumina-based materials contain particles of titanium carbide, zirconia, or silicon carbide whiskers to improve hardness and/or toughness. These materials are a major improvement over the older ceramic tools. Silicon nitride–based materials have excellent high-temperature mechanical properties and resistance to oxidation. These materials also have high thermal shock resistance, and thus can be used with cutting fluids to produce better surface finishes than the alumina tools.

These tools can be operated at two to three times the cutting speeds of tungsten carbide, usually require no coolant, and have about the same tool life at higher speeds as tungsten carbide does at lower speeds. However, ceramics lack toughness; therefore, interrupted cuts and intermittent application of coolants can lead to premature tool failure due to poor mechanical and thermal shock resistance.

Cermets are titanium carbide (TiC) or titanium carbonitride particles embedded in a nickel or nickel/molybdenum binder. These materials, produced by the powder metallurgy process, can be considered as a type of cemented carbide. They are somewhat more wear resistant, and thus can be used for higher cutting speeds. They also can be used for machining of ferrous materials without requiring a protective coating.

Cubic boron nitride (CBN) is the hardest material at present available except for diamond. Its cost is somewhat higher than either carbide or ceramic tools but it can cut about five times as fast as carbide and can hold hardness up to 200°C. It is chemically very stable and can be used to machine ferrous materials.

Industrial *diamonds* are now available in the form of polycrystalline compacts for the machining of metals and plastics with greatly reduced cutting force, high hardness, good thermal conductivity, small cutting-edge radius, and low friction. Recently, diamond-coated tools are becoming available that promise longer-life cutting edges. Shortcomings with diamond tools are brittleness, cost, and the tendency to interact chemically with workpiece materials that form carbides, such as carbon steel, titanium, and nickel.

Wear of Cutting Tool Materials. Cutting tools are subjected to large forces under conditions of high temperature and stress. There are many mechanisms that cause wear.

- Adhesion. The tool and chip can weld together; wear occurs as the welded joint fractures and removes part of the tool material, such as along a tool cutting edge.
- Abrasion. Small particles on the wear surface can be deformed and broken away by mechanical action due to the high localized contact stresses; these particles then abrade the cutting tool. Typically, this is the most common wear mode.
- Brittle fracture. Catastrophic failure of the tool can occur if the tool is overloaded by an excessive depth of cut and/or feed rate.
- Diffusion. Solid-state diffusion can occur between the tool and the workpiece at high temperatures and contact pressures, typically at an area on the tool tip that corresponds to the location of

maximum temperature, e.g., cemented carbide tools used to machine steel. High-speed machining results in higher chip temperatures, making this an increasingly important wear mode.

- Edge chipping.
- Electrochemical. In the presence of a cutting fluid, an electrochemical reaction can occur between the tool and the workpiece, resulting in the loss of a small amount of tool material in every chip.
- Fatigue.
- Plastic deformation.

Single-Point Cutting Tool Geometry. Figure 13.2.3 depicts the location of various angles of interest on a single-point cutting tool. The most significant angle is the *cutting-edge* angle, which directly affects the shear angle in the chip formation process, and therefore greatly influences tool force, power requirements, and temperature of the tool/workpiece interface (ASM, 1989a). The larger the positive value of the cutting-edge angle, the lower the force, but the greater the load on the cutting tool. For machining higher-strength materials, negative rake angles are used. *Back rake* usually controls the direction of chip flow and is of less importance than the side rake. Zero back rake makes the tool spiral more tightly, whereas a positive back rake stretches the spiral into a longer helix. *Side rake* angle controls the thickness of the tool behind the cutting edge. A thick tool associated with a small rake angle provides maximum strength, but the small angle produces higher cutting forces than a larger angle; the large angle requires less motor horsepower.

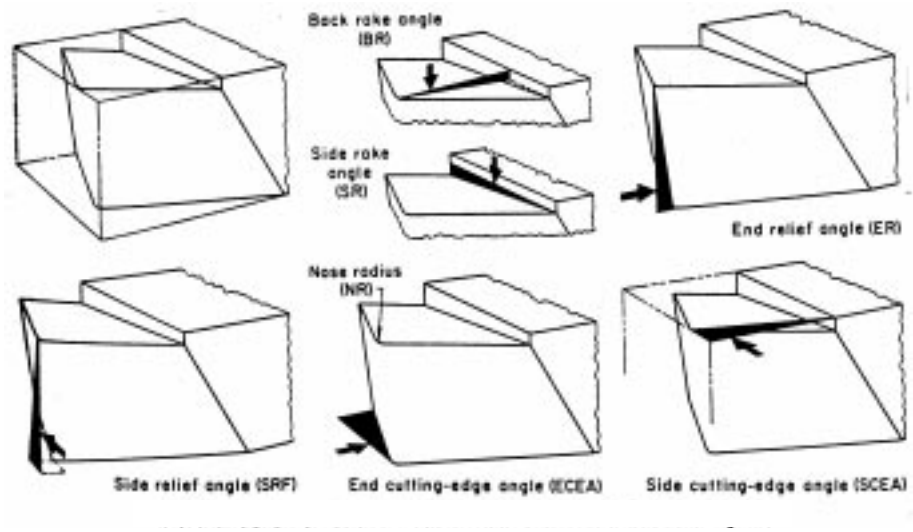

FIGURE 13.2.3 Standard nomenclature for single-point cutting tool angles. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 141. With permission.)

The *end relief angle* provides clearance between the tool and the finished surface of the work. Wear reduces the angle. If the angle is too small, the tool rubs on the surface of the workpiece and mars the finish. If the angle is too large, the tool may dig into the workpiece and chatter, or show weakness and fail through chipping. The *side relief angle* provides clearance between the cut surface of the work and the flank of the tool. Tool wear reduces the effective portion of the angle closest to the workpiece. If this angle is too small, the cutter rubs and heats. If the angle is too large, the cutting edge is weak and the tool may dig into the workpiece. The *end cutting-edge angle* provides clearance between the cutter and the finished surface of the work. An angle too close to zero may cause chatter with heavy feeds, but for a smooth finish the angle on light finishing cuts should be small.

Machinability. Optimum speed and feed for machining depend on workpiece material, tool material, characteristics of the cut, cutting tool configuration, rigidity of setup, tolerance, and cutting fluid. Consequently, it is not possible to recommend universally applicable speeds and feeds.

Drilling and Reaming

Description and Applications. *Drilling* is the most widely used process for making circular holes of moderate accuracy. It is often a preliminary step to other processes such as tapping, boring, or reaming. *Reaming* is used to improve the accuracy of a hole while increasing its diameter. Holes to be reamed are drilled undersize.

Key System Components. Drills are classified by the material from which they are made, method of manufacture, length, shape, number and type of helix or flute, shank, point characteristics, and size series (Table 13.2.1). Selection of drill depends on several factors (ASM, 1989b):

TABLE 13.2.1 Common Drill Types

Drill Type	Description	Application
Core	Has large clearance for chips	Roughing cuts; enlarging holes
General-purpose (jobber)	Conventional two-flute design; right-hand (standard) or left-hand helix. Available with flute modification to break up long chips	General-purpose use, wide range of sizes
Gun	Drill body has a tube for cutting fluid; drill has two cutting edges on one side and counter-balancing wear pads on the other side	Drill high-production quantities of holes without a subsequent finishing operation
High helix	Wide flutes and narrow lands to provide a large bearing surface	Soft materials, deep holes, high feed rates
Low helix	Deep flutes facilitate chip removal	Soft materials, shallow holes
Oil hole	Has holes through the drill body for pressurized fluid	Hard materials, deep holes, high feed rate
Screw-machine	Short length, short flutes, extremely rigid	Hard materials; nonflat surfaces
Step	Two or more drill diameters along the drill axis	Produce multiple-diameter holes, such as for drilling/countersinking
Straight flute	Flutes parallel to the drill axis minimize torquing of the workpiece	Soft materials; thin sheets

- Hardness and composition of the workpiece, with hardness being more important
- Rigidity of the tooling
- Hole dimensions
- Type of drilling machine
- Drill application — originating or enlarging holes
- Tolerances
- Cost

The most widely used drill is the general-purpose twist drill, which has many variations. The flutes on a twist drill are helical and are not designed for cutting but for removing chips from the hole. Typical twist drills are shown in Figure 13.2.4.

Machining forces during *reaming* operations are less than those of drilling, and hence reamers require less toughness than drills and often are more fragile. The reaming operation requires maximum rigidity in the machine, reamer, and workpiece.

Most *reamers* have two or more flutes, either parallel to the tool axis or in a helix, which provide teeth for cutting and grooves for chip removal. The selection of the number of flutes is critical: a reamer with too many flutes may become clogged with chips, while a reamer with too few flutes is likely to chatter (Table 13.2.2).

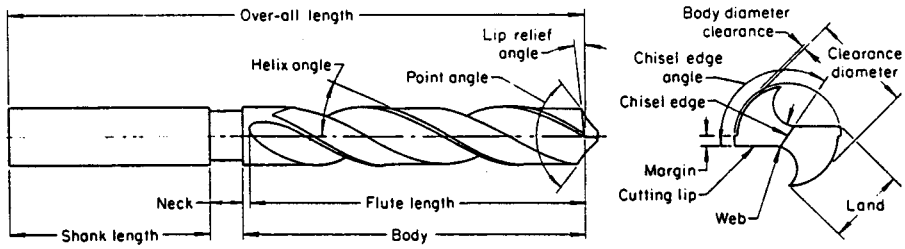

FIGURE 13.2.4 Design features of a typical straight-shank twist drill. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 218. With permission.)

TABLE 13.2.2 Common Reamer Types

Reamer Type	Description	Application
Adjustable	Tool holder allows adjustment of the reamer diameter to compensate for tool wear, etc.	High-rate production
End-cutting	Cutting edges are at right angles to the tool axis	Finish blind holes, correct deviations in through-holes
Floating blade	Replaceable and adjustable cutting edges to maintain tight tolerances	High-speed production (workpiece rotated, tool stationary)
Gun	Hollow shank with a cutting edge (e.g., carbide) fastened to the end and cutting fluid fed through the stem	High-speed production (workpiece rotated, tool stationary)
Shell	Two-piece assemblies, mounted on arbors, can be adjusted to compensate for wear	Used for finishing operations (workpiece rotated, tool stationary)
Spiral flute	Flutes in a helix pattern, otherwise same as straight-flute reamer	Difficult to ream materials, and holes with irregularities
Straight flute	Flutes parallel to the tool axis, typically pointed with a 45° chamfer	General-purpose, solid reamer

Machining Parameters. The optimal speed and feed for drilling depend on workpiece material, tool material, depth of hole, design of drill, rigidity of setup, tolerance, and cutting fluid. For *reaming* operations, hardness of the workpiece has the greatest effect on machinability. Other significant factors include hole diameter, hole configuration (e.g., hole having keyways or other irregularities), hole length, amount of stack removed, type of fixturing, accuracy and finish requirements, size of production run, and cost. Most reamers are more easily damaged than drills; therefore, the practice is to ream a hole at no more than two thirds of the speed at which it was drilled.

Capabilities and Process Limitations. Most drilled holes are $^1/_8$ to 1 in. (3.2 to 40 mm) in diameter. However, drills are available for holes as small as 0.001 in. (0.03 mm) (microdrilling), and special drills are available as large as 6 in. (150 mm) in diameter. The range of length-to-diameter (L/D) of holes that can be successfully drilled depends on the method of driving the drill and the straightness requirements. In the simplest form of drilling in which a rotating twist drill is fed into a fixed workpiece, best results are obtained when L/D is <3. But by using special tools, equipment, and techniques, straight holes can be drilled with L/D = 8 or somewhat greater. Nonconventional machining processes can also generate high-aspect-ratio holes in a wide variety of materials.

Reaming and boring are related operations. Hole diameter and length, amount of material to be removed, and required tolerance all influence which process would be most efficient for a given application (ASM, 1989b). Most holes reamed are within the size range of $^1/_8$ to 1 inch (3.2 to 40 mm), although larger and smaller holes have been successfully reamed. For most applications with standard reamers, the length of a hole that can be reamed to required accuracy ranges from slightly longer to much shorter than the cutting edges of the reamer, but there are many exceptions to this general rule-of-thumb. Tolerances of 0.001 to 0.003 in. (0.03 to 0.08 mm) with respect to the diameter are readily

achievable in production reaming operations. Surface finish for annealed steels can be held within the range of 100 to 125 µin. (2.50 to 3.20 µm), but a surface as smooth as 40 µin. (1 µm) can be obtained under appropriate processing conditions (ASM, 1989b).

Turning and Boring

Description and Applications. *Turning* produces external cylindrical surfaces by removing material from a rotating workpiece, usually with a single-point cutting tool in a lathe. *Boring* is this same process applied for enlarging or finishing internal surfaces of revolution.

Key System Components. The basic equipment for turning is an *engine lathe* that consists of a bed, a headstock, a carriage slide, a cross slide, a tool holder mounted on the cross slide, and a source of power for rotating the workpiece (Table 13.2.3). Engine lathes are often modified to perform additional types of machining operations through the use of attachments. Most turning machines can also perform boring operations, but boring machines may not be able to perform turning operations. Sizes of lathes range from fractional horsepower to greater than 200 hp.

TABLE 13.2.3 Typical Lathes Used for Turning

Lathe	Description	Applications
Bench lathe	An engine lathe that can be placed on a workbench	Small workpieces and prototype parts
Engine lathe	Has a leadscrew that moves the slide uniformly along the bed; available with chucking or centering headstock	Chucking type allows centering and clamping for rotation, e.g., holding castings or forgings Centering type secures workpiece between pointed centers, e.g., for turning long workpieces, such as shafts
Gap-frame lathe	Modified engine lathe for turning larger diameter parts	Workpieces requiring off-center mounting or irregular protuberances
Numerically controlled lathe	Uses a computer program to control the lathe to generate the desired shape	Produces consistent parts in a CAD/CAM environment
Tracer-controlled lathe	A duplicating lathe that uses a stylus moving over a template to control the cutting tool	Manufacture of prototype parts and low-rate production

TABLE 13.2.4 Typical Machines Used for Boring

Boring Machine	Description	Applications
Bar (screw) machine	Modified turret lathe to handle bars and tubes	Parts made from bars or tubes
Engine lathe	Versatile machine; essentially same machine as used for turning	Bores one hole at a time in a single part; limitations regarding workpiece size and configuration
Horizontal boring mill	Workpiece remains stationary and tool rotates	Wide variety of parts; cost-effective for a relatively high production volume
Precision boring machine	Vertical and horizontal models	Parts requiring extreme tolerances
Special-purpose machines	Boring machine modified for specialized application	Single-purpose applications with high production rates
Turret lathe	Has rotating turret on a lathe, tooled for multiple machining operations	More versatile than engine lathe; supports high production rates
Vertical boring mill	Same basic components as a lathe	Very large, heavy, or eccentric workpieces
Vertical turret lathe	Same features as vertical boring mill; may also have a second vertical head	Flexible machine, useful in CAD/CAM environment; simultaneous multiple machining operations possible

Machines used for boring are noted for their rigidity, adaptability, and ability to maintain a high degree of accuracy (Table 13.2.4). For extremely large workpieces, weighing thousands of pounds, the boring cutting tool is rotated and the workpiece is fixed.

Machine Tool and Machining Parameters. In turning and boring operations, a single-point tool is traversed longitudinally along the axisymmetric workpiece axis parallel to the spindle. A tangential force is generated when the cutting tool engages the rotating work. This force is generally independent of the cutting speed and directly proportional to the depth of cut for a particular material, tool shape (particularly side rake angle), and feed rate. That force, when multiplied by the surface speed of the workpiece, estimates the net horsepower required to remove material. The extent to which workpiece material affects required machining power is illustrated in Figure 13.2.5. Moving the tool longitudinally requires much less power (ASM, 1989b).

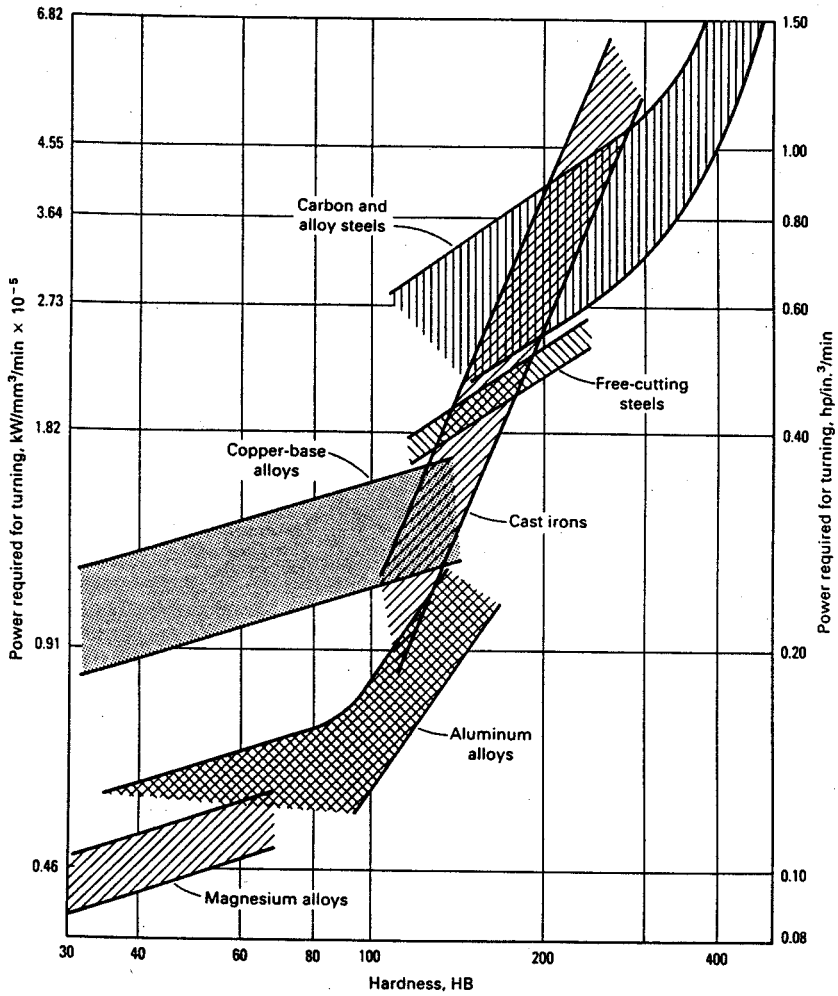

FIGURE 13.2.5 Effect of workpiece composition and hardness on power required for turning. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 136. With permission.)

To minimize the number of cuts required, the depth of cut should be as great as possible, which is limited by the strength of the part and the fixturing, and the power output of the machine tool. The feed rate is a function of the finish desired and the strength and rigidity of the part and machine tool.

Capabilities and Limitations. Components that range in size from those used in watches up to large steel propeller shafts more than 80 ft (24 m) long are regularly turned. Aluminum parts over 10 ft (3 m) in diameter have been turned. In practice, the weight of the workpiece per unit of volume determines the size of the workpiece that is practical to turn. Large, heavy parts can be turned in a vertical boring machine. Irregular-shaped parts, such as crankshafts, may require the use of counter-weighting to achieve dynamic balance for vibration-free turning.

For both turning and boring, the rotation speed, feed, and depth of cut determine the rate of material removal and resulting surface quality. Feed rate for most applications falls between 0.005 and 0.020 in./rev (0.13 and 0.51 mm/rev). Finishing cuts have a significantly lower feed rate (e.g., 0.001 in./rev, 0.03 mm/rev), and roughing cuts are made at a significantly higher feed rate (e.g., 0.25 in./rev, 6.35 mm/rev). Boring is not limited by the L/D ratio of a hole — this ratio can be as great as 50 if the tool bar and workpiece are adequately supported.

There are many potential sources of tolerance error in turning and boring operations. The more common errors are summarized in Tables 13.2.5 and 13.2.6.

TABLE 13.2.5 Factors Affecting Dimensional Accuracy in Turning

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diametrical roundness	Lathe spindle runout	Preload angular bearings to eliminate side and end movement
Diameter variation (taper)	Parallelism of spindle to longitudinal travel	Establish true parallelism between the axis of rotation of the workpiece and the longitudinal travel of the cutting tool
Face flatness	Lack of true normality of cross slide to axis of rotation	Precision align cross slide to axis of rotation
Length dimensions parallel to the axis of rotation	Improper positioning of longitudinal slide	Adjust positioning of longitudinal slide
Diameter accuracy	Inadequate gauging	Employ proper measurement technique

TABLE 13.2.6 Factors Affecting Dimensional Accuracy in Boring

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diameter accuracy	Inadequate gauging, or heat generated by the machining action	Employ proper measurement techniques; use cutting fluid to control temperature
Taper of the cylindrical bore	Deflection of the boring bar	Reduce the boring bar unsupported length; use a higher-stiffness material for the boring bar
Roundness, as determined by the variation in radius about a fixed axis	Finish cut is not concentric with the previous cut; or out-of-balance workpiece or holder	Begin with a semifinish cut, followed by a finish cut; carefully balance the initial setup
Concentricity of one surface with another	Too great a clamping force on the workpiece	Redesign clamping fixture, or use a precision boring machine
Squareness and parallelism of holes in relation to other features of the work	Dimensional changes in machine components	Maintain constant ambient temperature; maintain cutting fluid at constant temperature; or stabilize oil temperature

Planing and Shaping

Description and Applications. *Planing* is a widely used process for producing flat, straight surfaces on large workpieces. A variety of contour operations and slots can be generated by use of special attachments. It is often possible to machine a few parts quicker by planing than by any other method. *Shaping* is a process for machining flat and contour surfaces, including grooves and slots.

Principle of Operation. *Planers* develop cutting action from straight-line reciprocating motion between one or more single-point tools and the workpiece; the work is reciprocated longitudinally while the tools

are fed sideways into the work. Planer tables are reciprocated by either mechanical or hydraulic drives, with mechanical drives predominating.

Shapers use a single-point tool that is supported by a ram which reciprocates the tool in a linear motion against the workpiece. The workpiece rests on a flat bed and the cutting tool is driven toward it in small increments by ram strokes. Shapers are available with mechanical and hydraulic drives, with mechanical drives predominating.

Machine Tool and Machining Parameters. Planing and shaping are rugged machining operations during which the workpiece is subjected to significant cutting forces. These operations require high clamping forces to secure the workpiece to the machine bed.

In general, it is advisable to plane steel with as heavy a feed and as high a speed as possible to promote good chip-formation conditions so that chip breakers are not needed. Carbide cutters allow cutting speed to be increased from 225 to 300 surface feet per minute (sfm) (70 to 90 m/min). For best results, uniform cutting speed and feed are maintained throughout the entire stoke (ASM, 1989b).

In general, speeds are related to workpiece material characteristics and associated machinability. Feeds are influenced by the workpiece machinability, but also by ram speed, depth of cut, and required dimensional accuracy and surface finish. Common practice in shaping is to make roughing cuts at as high a feed and slow a speed as practical, and make finishing cuts at a low feed rate and high speed (ASM, 1989b). For low carbon steel, a typical speed for a roughing cut is 50 sfm (15 m/min), while for a finishing cut it is 80 sfm (25 m/min) using a conventional cutting tool. Similarly for aluminum, a roughing cut of 150 sfm (45 m/min) is typically followed by a finishing cut of 200 sfm (60 m/min).

There is a practical lower bound on minimum feed rate. Feed rates that are too low will cause the tool to chatter; feed rates less than 0.005 in. (0.125 mm) are seldom used in shaping. Similarly, shallow cuts (less than 0.015 in., 0.38 mm) will cause chatter during shaping.

Key System Components. Planers are available in a wide range of sizes (Table 13.2.7). Tools are available in a variety of configurations for undercutting, slotting, and straight planing of either horizontal or vertical surfaces (ASM, 1989b).

TABLE 13.2.7 Types of Planers

Planer Type	Description	Application
Double housing	Two vertical uprights support the crossrail which in turn supports the tools	Rigid machine; restricts the width of workpiece
Open side	A single upright column supports a cantilevered crossrail; less rigid than the double-housing type	Accommodates wide workpieces which can overhang one side of the table without interfering with the planer operation

Shapers are available in a large variety of sizes (Table 13.2.8), ranging from small models with a maximum stroke length of less than 6 in. (150 mm) to large machines with a maximum stroke of 36 in. (914 mm). On each machine, the length of stroke can be varied from its maximum to slightly less than 1 in. (25 mm) for the largest machine, and to $^1/_8$ in. (3.2 mm) for the smallest machine.

TABLE 13.2.8 Types of Shapers

Shaper Type	Description	Application
Horizontal	The ram drives the tool in the horizontal direction; uses plane or universal table (rotates on three axes)	Gears, splined shafts, racks, and so on; not used for rate production
Vertical	The ram operates vertically, cutting on the downstroke	Slots, grooves, keyways; matching die sets, molds, fixtures; not used for rate production

Capabilities and Process Limitations. Planing is a precision process in which flatness can be held within 0.0005 in. (0.013 mm) total indicated runout (TIR) on workpieces up to 4 ft^2 (0.4 m^2). Although planing is most widely used for machining large areas, it is also used for machining smaller parts, although 12 in. is about the minimum distance for a planing stoke. Size of the workpiece that can be planed is limited by the capacity of the planing equipment.

Shaping is a versatile process in which setup time is short and relatively inexpensive tools can be used. Under good conditions, a shaper can machine a square surface of 18 in. on a side (0.2 m^2) to a flatness within 0.001 in. (0.025 mm); under optimum conditions this can be improved to 0.0005 in. (0.013 mm). The size of the workpiece that can be shaped is limited by the length of the stoke, which is usually about 36 in. (914 mm). Shaping should be considered for machining flat surfaces in these instances:

- Required flatness cannot be achieved by another method
- Production quantity is insufficient to justify the tooling costs of milling or broaching

Planing and shaping are interrupted cutting processes, and are comparatively inefficient means of metal removal; for example, shaping costs five times that of milling, exclusive of the tooling and setup costs.

Milling

Description and Applications. Milling is a versatile, efficient process for metal removal. It is used to generate planar and contour surfaces through the action of rotating multiple-tooth cutters. Surfaces having almost any orientation can be machined because both the workpiece and cutter can move in more than one direction at the same time.

Principle of Operation. Cutters with multiple cutting edges rotate in a spindle. The machining process is interrupted as the teeth of the milling cutter alternately engage and disengage from the workpiece.

Key System Components. Most milling is done in machines designed for milling (Table 13.2.9). Milling can also be done by any machine tool that can rigidly hold and rotate a cutter while feeding a workpiece into the cutter. Milling machines are usually classified in terms of their appearance: knee-and-column, bed-type, planar-type, and special purpose. The knee-and-column configuration is the simplest milling machine design. The workpiece is fixed to a bed on the knee and the tool spindle is mounted on a column, as depicted in Figure 13.2.6. For very large workpieces, gantry or bridge-type milling machines are used. Machines having two columns can provide greater stability to the cutting spindle(s). Special-purpose machines are modifications of the three basic models.

The usual power range for knee-and-column machines is 1 to 50 hp (0.75 to 37 kW). Bed-type machines are available in a wide range of sizes, up to 300 hp (225 kW). Planar-type machines are available from 30 to 100 hp (22 to 75 kW).

There is a wide variety of milling cutters, using the full range of cutting tool materials; there are three basic constructions (ASM, 1989b):

- Solid — Made from a single piece of HSS or carbide; cutters can be tipped with a harder material; teeth can designed for specific cutting conditions; low initial cost.
- Inserted blade — Usually made from HSS, carbide, or cast alloy; individual blades can be replaced as they wear out, saving replacement cost; ideal for close-tolerance finishing.
- Indexable insert — Cutter inserts are made from carbide, coated carbide, ceramic, or ultrahard material such as diamond; each insert has one or more cutting edges; as inserts wear, they are repositioned to expose new cutting surface or indexed to bring another cutting insert on line. These inserts, widely used in computer-controlled machines due to their performance and flexibility, can produce a rougher surface than the other tool constructions and require somewhat higher cutting forces to remove metal.

TABLE 13.2.9 Types of Milling Machines

Milling Machine	Description	Application
Knee-and-column	Six basic components: • Base — the primary support • Column — houses spindle and drive • Overarm — provides support for the arbor-mounted cutting tools • Knee — supports the table, saddle, and workpiece; provides vertical movement • Saddle — provides 1° of horizontal motion • Table — directly supports the workpiece and provides a second degree of horizontal motion	Widely used for low production milling; provides three-axis movement; primary drawback is lack of rigidity due to the number of joints
Bed-type	Table and saddle mounted on a bed in fixed vertical position; vertical motion obtained by movement of the spindle carrier; available with horizontal or vertical spindle	Very rigid machine; permits deep machining cuts and close dimensional control
Planar-type (adjustable rail)	Can accommodate almost any type of spindle for driving cutters and boring bars; utilizes several milling heads	Use for mass-production milling; can perform simultaneous milling and boring operations
Special purpose	Many possible configurations involving major modifications or combinations of the basic types of milling machines; adapted for automated control	Optimized for high-volume production; includes profilers and machining centers; these machines are capable of performing multiple simultaneous machining operations

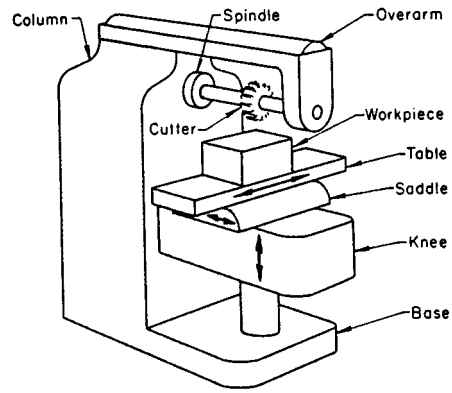

FIGURE 13.2.6 Principal components of a plain knee-and-column milling machine with a horizontal spindle. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 304. With permission.)

Milling cutters are also described by the location of the cutting edges, as described in Table 13.2.10. Several cutters are depicted in Figure 13.2.7.

Machine Tool and Machining Parameters. The angular relationships of the cutting edge greatly influence cutting efficiency, analogous to single-point cutting tools. A milling cutter should have enough teeth to ensure uninterrupted contact with the workpiece, yet not so many so as to provide too little space between the teeth to make chip removal difficult.

Milling speed varies greatly depending on workpiece material composition, speed, feed, tool material, tool design, and cutting fluid. Speeds as low as 20 sfm (6.1 m/min) are employed for milling low machinability alloys, while speeds as high as 20,000 sfm (6100 m/min) have been reported for milling aluminum (ASM, 1989b). If the setup is sufficiently rigid, carbide or carbide-tipped cutters can be operated three to ten times faster than HSS cutters; top speed is usually constrained by onset of tool chatter.

TABLE 13.2.10 Types of Milling Cutters

Milling Cutters	Description	Application
Peripheral mills	Cutting is primarily done by teeth on the periphery of the cutting tool; mounted on an arbor having its axis parallel to the machined surface	Removing metal from simple flat surfaces; milling contoured surfaces and surfaces having two or more angles or complex forms
Face mills	Machining action is accomplished by the bevel cutting edge located along the circumference of the mill; driven by a spindle on an axis perpendicular to the surfaced being milled	Can be more efficient at removing material than peripheral milling; very rigid tool setup possible; can achieve tight tolerances
End mills	Incorporate cutting edges on both the face and the periphery; can be used for face cuts and periphery cuts	Allow multiple operations without changing cutters; cutters can have difficulty in maintaining dimensional accuracy due to long unsupported length
Special mills	Can be almost any design	Optimized for a particular task

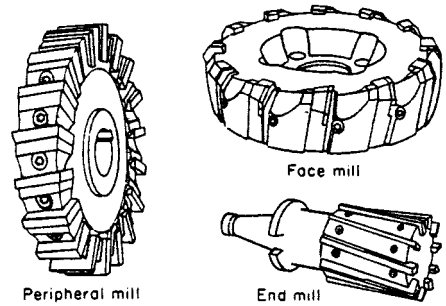

FIGURE 13.2.7 Three typical milling cutters. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 311. With permission.)

For highest efficiency in removing metal while minimizing chatter conditions, the feed per tooth should be as high as possible. The optimum feed rate is influenced by a number of factors (ASM, 1989b): type of cutter, number of teeth on the cutter, cutter material, workpiece machinability, depth of cut, width of cut, speed, rigidity of the setup, and machine power. The surface finish obtainable by milling can be quite good. A finish of 125 μin. (3.2 μm) can be readily achieved under normal circumstances with HSS mills, and finishes of 63 μin. (1.6 μm) are common if carbide tools are used. With careful selection of cutters and stringent control of process conditions, a finish of 10 min (0.25 mm) can be produced.

Process Limitations. The initial cost of a milling machine is considerably greater than that of a planar or a shaper that can machine workpieces of similar size to similar finishes. Milling tools usually cost up to 50 times as much as tools for planers and shapers, and the setup time is usually longer. However, milling is far more efficient in removing material, and milling machines are commonly highly automated. Therefore, milling is preferred for production operations.

Grinding is often preferred to milling when the amount of metal to be removed is small and the dimensional accuracy and surface finish are critical. Milling and grinding are frequently used in combination.

Broaching

Description and Applications. Broaching is a precision machining process. It is very efficient since both roughing cuts and finishing cuts are made during a single pass of the broach tool to produce a smooth surface, and further finishing is usually not necessary. Consequently, close tolerances can be readily achieved at a reasonable cost for high rates of production.

Broaches are expensive multitoothed cutting tools. Thus, the process is usually employed for low or high production when broaching is the only practical method to produce the required dimensional tolerance and surface quality. An example of the latter case is the dovetail slots in jet engine turbine disks.

Principle of Operation. Broaching is a machining process similar to planing. A broach is essentially a tapered bar into which teeth are cut, with the finishing teeth engaging last on the end with the larger diameter. A single broach has teeth for rough cutting, semifinishing, and finishing. Broaching involves pushing or pulling a broach in a single pass through a hole or across a surface. As the broach moves along the workpiece, cutting is gradual as each successive tooth engages the workpiece, removing a small amount of material. Overall machining forces are much greater than that of other machining methods, and consequently broaching is considered to be the most severe of all machining operations.

Key System Components. Broaching machines are categorized as horizontal or vertical, depending on the direction of broach travel. Industry usage is almost evenly divided between these two categories. The selection of machine type depends heavily on the configuration of the workpiece and available space in the factory, considering both floor space and vertical clearance requirements.

Broaches can be categorized by the method through which they are actuated (push or pull), by type of cut (internal or external), and by the construction of the broach body. Figure 13.2.8 depicts typical internal and external broaching operations. Table 13.2.11 describes broaches according to their construction.

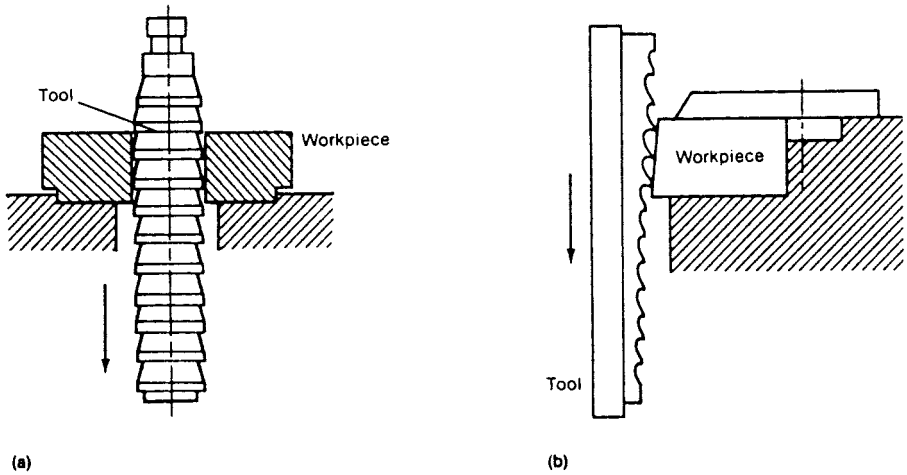

FIGURE 13.2.8 Internal (a) and external (b) broaching. (From *ASM Handbook, Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 195. With permission.)

TABLE 13.2.11 Types of Broaches

Broaches	Description	Application
Solid	One-piece broach produced from tapered bar stock; repair of broken teeth is difficult	Parts which require high dimensional accuracy and concentricity
Shell	Multipiece broach consisting of a main body, an arbor section over which a removable shell fits, and a removable shell containing the cutting edges; worn or damaged sections can be replaced	Internal and selected external broaching; sacrifices some accuracy and concentricity as the tool is not as stiff as a solid broach
Insert-type	Effectively a tool holder with inserts to perform the actual cutting; inserts are typically made from HSS or carbides; worn or damaged inserts can be readily replaced	Broaching large, flat surfaces

Machine Tool and Machining Parameters. Length and depth of cut have the most influence on determining the required broaching tool length. For internal cutting operations, as the cut length increases, more chip storage capacity must be provided between the cutting edges for the same amount of tooth advance. Cutting fluids are useful in preventing the work metal from adhering to the broach, and thus result in higher-quality surface finishes and increased broach life.

The primary consideration in the selection of optimum broaching speed is the trade-off between speed and wear rate. In general, steels are broached at 10 to 30 sfm (3 to 9 m/min); the harder the steel, the slower the broach speed (ASM, 1989b).

Capabilities and Process Limitations. Broaching can maintain tight tolerances during long production runs since metal-cutting operations are distributed among the different roughing and finishing teeth. Also, broach teeth can be repeatedly sharpened, allowing cutting efficiency and accuracy to be maintained.

Broaching is an extremely fast, precise machining operation. It is applicable to many workpiece materials over a wide range of machinability, can be accomplished in seconds, is readily automated, and can easily be done manually. For example, for low-carbon steels, tolerances of 0.002 in. (0.05 mm) can be readily attained with a surface finish of 60 μin. (1.55 μm); if desired, tighter tolerances and surface finishes of 30 μin. (0.8 μm) are possible without much additional effort. For difficult-to-machine superalloys, tolerances of 0.001 in. (0.025 mm) and surface finishes of 30 μin. (0.8 μm) are commonly achieved in production (ASM, 1989b).

Broaching is rarely used for removing large amounts of material since the power required would be excessive. It is almost always more effective to use another machining method to remove the bulk of material and use broaching for finishing.

Since a broach moves forward in a straight line, all surface elements along the broach line must be parallel to the direction of travel. Consequently, the entire surface of a tapered hole cannot be broached. Also, cutting is done sequentially with the finishing teeth engaging last. Therefore, a blind hole can be broached only if a sufficiently long recess is provided to permit full travel of the broach.

The direction of travel of the broach cannot realistically be changed during a broaching stroke, except for rotating the tool. Thus, surfaces having compound curves cannot be broached in a single operation. On external surfaces, it is impossible to broach to a shoulder that is perpendicular to the direction of broach movement.

Grinding

Trevor D. Howes, John Webster, and Ioan Marinescu

Description and Applications. Grinding, or abrasive machining, refers to processes for removing material in the form of small chips by the mechanical action of irregularly shaped abrasive grains that are held in place by a bonding material on a moving wheel or abrasive belt (Green, 1992). In surface-finishing operations (e.g., lapping and honing) these grains are suspended in a slurry and then are embedded in a roll-on or reference surface to form the cutting tool. Although the methods of abrasion may vary, grinding and surface-finishing processes are used in manufacturing when the accuracy of workpiece dimensions and surface requirements are stringent and the material is too hard for conventional machining.

Grinding is also used in cutoff work and cleaning of rough surfaces, and some methods offer high material-removal rates suitable for shaping, an area in which milling traditionally has been used.

Grinding is applied mainly in metalworking because abrasive grains are harder than any metal and can shape the toughest of alloys. In addition, grinding wheels are available for machining plastics, glass, ceramics, and stone. Conventional precision metal and ceramic components and ultraprecision electronic and optical components are produced using grinding.

Mechanics of Grinding. Three types of energy are involved in grinding (Andrew et al., 1985). *Rubbing energy* is expended when the grains (cutting edges) of the grinding wheel wear down. As they wear,

they cut less and produce increasing friction, which consumes power but removes less material. *Plowing energy* is used when the abrasive does not remove all of the material but rather plows some of it aside plastically, leaving a groove behind. *Chip-formation energy* is consumed in removing material from the workpiece as the sharp abrasive grain cuts away the material (or chip) and pushes it ahead until the chip leaves the wheel.

The grinding wheel experiences *attritious wear* as the abrasive grains develop wear flats from rubbing on the workpiece, or when grains break free from the bond material. Attritious wear gives rise to rubbing energy resulting from friction, and thus can lead to thermal damage as power consumption increases without an increase in material removal rate. The wheel can wear through *fracture*, predominating at relatively high in-feed rates. In this case, pieces of the abrasive grain break free and expose a new, sharp surface.

Materials can be classified as either easy to grind or difficult to grind. For *easy-to-grind materials*, most of the power consumption becomes invested in chip formation; thus, rubbing and plowing energy are minimal. *Difficult-to-grind materials* involve considerable rubbing and plowing energy since the force required to remove chips is comparatively high.

Types of Grinding. In *surface grinding*, the grinding wheel traverses back and forth across the workpiece. Grinding can take place by using either the periphery or side face of the wheel. The table holding the part may also reciprocate. Surface grinding is done most commonly on flat surfaces and surfaces with shapes formed of parallel lines, e.g., slots.

Creep-feed grinding is a form of surface grinding in which the wheel feeds into the workpiece at a low rate (0.4 to 40 in./min, 10 to 1000 mm/min) while grinding at a large depth of cut (0.04 to 0.4 in., 1 to 10 mm, or deeper). A large amount of material can be removed with one pass of the wheel, compared with conventional surface grinding in which the wheel makes many quick passes over the workpiece at slight depths of cut. This process is limited by the large amount of heat generated at the grinding arc which can result in thermal damage (grinding "burn"). Application of coolant is critical in creep-feed operations. CBN wheels, with their good heat transfer property, can also reduce the severity of burn (King and Hahn, 1986).

Cylindrical grinding produces round workpieces, such as bearing rings, although some machines can also grind tapered parts. The workpiece is mounted to a spindle and rotates as the wheel grinds it. The workpiece spindle has it own drive motor so that the speed of rotation can be selected. Both inner surfaces (internal cylindrical grinding) and outer (external cylindrical grinding) can be worked, although usually the same machine cannot do both.

There are three variants for *external grinding*:

- *Plain grinding* — the wheel carriage is brought to the workpiece on its spindle and in-feeds until the desired dimensions are reached
- *Traverse grinding* — the rotating workpiece is mounted on a table that reciprocates under the wheel; the grinding wheel is stationary except for its downward feed into the workpiece
- *Plunge grinding* — the table with the rotating workpiece is locked while the wheel moves into the workpiece until the desired dimensions are attained

Centerless grinding is a form of cylindrical grinding. In this method workpieces are not held in a centering chuck but instead rotate freely between a support, regulating wheel, and the grinding wheel. The force of the rotating grinding wheel holds the workpiece against the support. The supports are usually stationary and so a flow of lubricant is required to reduce friction between workpiece and support. An example of centerless grinding is shown in Figure 13.2.9.

Abrasive belt machines use a flexible fabric coated with an abrasive stretched between two rollers, one of which is driven by a motor. Usually, the abrasive coating is aluminum oxide for steels and bronzes and silicon carbide for hard or brittle materials. In the metal industries, common use of such machines is for dry grinding of metal burrs and flash and polishing of surfaces. However, some fabrics permit use

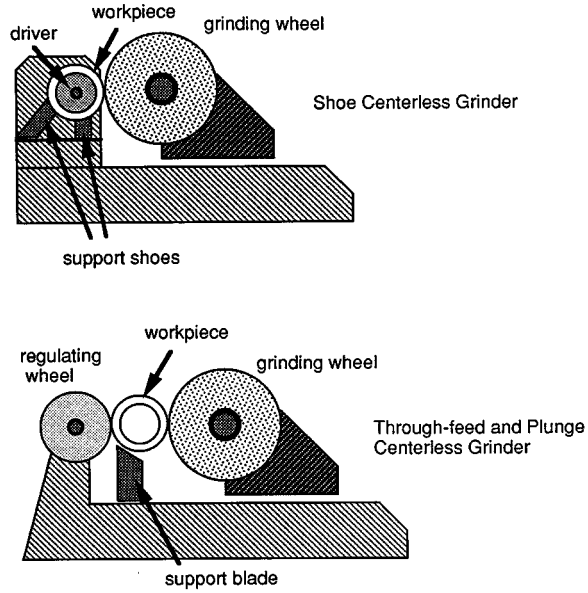

FIGURE 13.2.9 Through-feed and plunge centerless grinding. (Courtesy of T. D. Howes, John Webster, and I. Marinescu.)

of grinding fluids to enhance chip removal and provide cooling and lubrication, which results in better cutting action and longer belt life.

Honing, lapping, and polishing use abrasives to improve the accuracy of the form of a workpiece or the surface finish beyond the capabilities of grinding.

- *Honing* is a low-surface-speed operation, usually performed on an internal, cylindrical surface but possible also on external ones. Stock is removed by the shearing action of abrasive grains: a simultaneous rotary and reciprocating motion of fixed abrasive in the form of a stone or stick. Finishes range from under 1 to 50 μin. (0.025 to 1.3 μm). The development of CBN has revolutionized the honing process because this material easily outperforms conventional abrasives such as aluminum oxide, lasting up to 100 times longer.
- *Superfinishing*, like honing, uses fixed abrasives in the form of a stone. Unlike honing, which has a helical motion inside a bore, superfinishing uses high-speed, axial reciprocation combined with slow rotation of the outside diameter of the cylindrical component being processed. The geometry produced by a previous operation generally is not improved.
- *Lapping* is a fine-finishing, abrasive machining process used to obtain superior finish and dimensional accuracy. Lapping is unlike other finishing processes because some of the abrasive is loose rather than bonded. In general, lapping occurs when abrasive grains in a liquid vehicle (called a slurry) are guided across a workpiece by means of a rotating plate.
- *Polishing* uses free abrasive, as in lapping, but requires a soft support unlike the relatively hard support used in lapping. The total depth of cut during polishing can be as little as nanometers where chemical interactions will play a stronger role than mechanical or physical interactions. When the depth of cut is greater than 1 μin. (0.025 μm), the interactions are usually of a mechanical nature. Many industrial components, especially electronic and optical, required highly polished surfaces.

Key System Components. A *grinding wheel* consists of thousands of small, hard grains of abrasive material held on the surface in a matrix of bond material (Table 13.2.12). The bond material is matched to the characteristics of the grain to retain the grain sufficiently to maximize its use before shedding it.

TABLE 13.2.12 Common Grinding Wheel Abrasives

Abrasive	Characteristic	Grinding Application
Aluminum oxide	Friable	Steel: soft or hardened, plain or alloyed
Seeded gel aluminum oxide	More friable and expensive than aluminum oxide	Steel: soft or hardened, plain or alloyed; use at higher stock removal rates
CBN	Tough; increased life at higher speeds; high accuracy and finish	Hardened steels; tough superalloys
Synthetic diamond	Hardest of all abrasives; can be friable; seldom need dressing/truing	Grinding hardened tool steels, cemented carbides, ceramics, and glass; cutting and slicing of silicon and germanium wafers
Silicon carbide	Friable	Cast iron; nonferrous metals; nonmetallics

The structure of the wheel formed by specific types of grains and bonds determines its characteristics. The grains are spaced apart depending on the cutting required. Widely spaced grains (open structure) cut aggressively, which is useful for hard materials or high rates of material removal, but which tends to produce coarse finishes. Closely packed grains (dense structure) make fine and precise cuts for finish grinding.

Grain spacing is also important for temporary storage of chips of material removed from the workpiece. An open structure is best for storing chips between the grains, which are then released after wheel rotation moves the grains away from the workpiece. An open structure also permits more coolant to enter the spaces to dissipate heat.

The bonding material is important to grinding performance. This material is weaker than the cutting grains so that ideally, during grinding, the grain is shed from the wheel surface when it becomes dull, exposing new sharp grains. For instance, wheels with friable abrasives that fracture to expose new, sharp grains must retain the grains longer to maximize the use of the abrasive; these wheels use stronger bonding materials. The four types of bond material are vitrified, resinoid, rubber, and metal. Table 13.2.13 shows their properties and uses.

TABLE 13.2.13 Characteristics of Grinding Wheel Bonds

Bond Type	Characteristic	Application
Rubber	Relatively flexible	Wet cut-off wheels; high-finish work; regulating wheels for centerless grinding
Resinoid (thermoplastic)	Relatively flexible	Rough grinding; portable grinders
Vitrified (glasslike)	Endure high temperatures; resist chemical effects of coolants; sensitive to impacts	Most widely used of all bonding materials
Metal	Electrodeposited nickel or sintered metal powder often used to bond CBN and diamond abrasives; has long wheel life; electrically conductive	Aggressive cutting operations such as creep-feed and deep grinding; electrically conductive grinding (e.g., electrochemical methods)

Grinding wheels must be resharpened on occasion. *Dressing*, not always required, sharpens the grains before grinding. *Truing* operations ensure the wheel conforms to the required cutting shape and will rotate concentrically to its spindle.

Because grinding wheels have relatively high mass and high operating speed, they must be *precisely balanced*. Imbalance causes vibrations that reduce the quality of the workpiece, hasten the wear of the spindle and bearings of the machine, affect other devices mounted on the grinder, and possibly transmit vibration from the grinder through the shop floor to other machines. Mounting of the wheel on the spindle and subsequent wheel wear can degrade the balance of the rotating system. Wheels are balanced by moving counterweights on balancing flanges. Some machines have an automatic balancer that shifts internal counterbalance masses.

Coolants are usually sprayed on the grinding zone to cool the wheel and workpiece, lubricate the surface to reduce grinding power, and flush away the chips. Excessive heat can damage both the wheel and workpiece by inducing undesirable physical changes in materials, such as metallurgical phase changes or residual stresses, or softening of the bond material in the grinding wheel. Coolant application is especially important in creep-feed grinding where the wheel-to-workpiece contact arc is long, heat generation is high, and the chips produced and abrasive lost from the wheel must be flushed away.

Selecting the type of *coolant system* depends on many factors, including the grinding wheel speed, material removal rate, depth of cut, and wheel/workpiece materials. The type of fluids used in this system requires consideration of both physical and environmental issues. Use of oil fluids can favor the formation of preferred residual stress patterns and better surface finish, and these oils can be recycled for long periods. However, oils present health risks, potential for groundwater contamination, and fire risks (especially with high-sparking superalloys). Water-based fluids offer far fewer environmental problems. Disadvantages of water-based fluids lie in their limited life expectancy of 3 to 12 months. Also, the relatively low viscosity of a water-based fluid at high velocity promotes a dispersed jet which reduces cooling capacity.

Capabilities and Process Limitations. Surface grinding can be a cheaper, faster, and more precise method than milling and planing operations. For profiled shapes, the grinding wheel can be dressed with less cost and inconvenience than changing milling setups for different parts. Grinding can be used as a high-stock-removal process; for example, creep-feed grinding has a depth of cut more typical of milling operations (0.1 in., 2.54 mm, and deeper). Creep-feed grinding is used for machining materials that are too difficult to work by other machining methods.

High-speed grinding can be extremely efficient. CBN abrasive allows high rates of material removal because CBN transfers heat away from the grinding zone due to its relatively high thermal conductivity, and CBN does not react with steel.

Considerable effort has been expended on modeling and testing the thermal limitations of grinding (Malkin, 1989). Nearly all models depend on a fundamental model which depends on sliding contact theory. All models confirm the following guidelines for grinding with conventional abrasives when burn is a limitation: decrease wheel speed, increase workpiece speed, use softer-grade wheels.

Grinding operations can be limited by two types of vibration:

- *Forced vibration.* Typical causes are out-of-balance wheels, nonuniform wheels, couplings, belts, noise from hydraulic systems, bearing noise, and forces transmitted from the floor to the grinding machine.
- *Self-excited vibration.* Typical causes are wheel wear, workpiece surface error regeneration, wheel loading, and wear flats. Typical solutions include softer grinding wheels, flexible (for dampening) wheel structures, and stiffer machine structures.

Nontraditional Machining

K. P. Rajurkar and W. M. Wang

The processes described below are representative of the types most likely to be encountered. The references listed at the end of the section contain detailed information on these processes, plus those that are not described here.

Electrical Discharge Machining (EDM)

Description and Applications. The EDM process machines hard materials into complicated shapes with accurate dimensions. EDM requires an electrically conductive workpiece. Process performance is unaffected by the hardness, toughness, and strength of the material. However, process performance is a function of the melting temperature and thermal conductivity. EDM is currently widely used in aerospace, machinery, and die and mold industries.

There are two types of EDM processes:

- Die-sinking EDM uses a preshaped tool electrode to generate an inverted image of the tool on the workpiece; commonly used to generate complex-shaped cavities and to drill holes in different geometric shapes and sizes on hard and high-strength materials.
- Wire EDM (WEDM) uses a metal wire as the tool electrode; it can generate two- or three-dimensional shapes on the workpiece for making punch dies and other mechanical parts.

Principle of Operation. EDM removes workpiece materials by harnessing thermal energy produced by pulsed spark discharges across a gap between tool and workpiece. A spark discharge generates a very small plasma channel having a high energy density and a very high temperature (up to 10,000°C) that melts and evaporates a small amount of workpiece material. The spark discharges always occur at the highest electrical potential point that moves randomly over the machining gap during machining. With continuous discrete spark discharges, the workpiece material is uniformly removed around the tool electrode. The gap size in EDM is in the range of 400 μin. to 0.02 in. (0.01 to 0.5 mm), and is determined by the pulse peak voltage, the peak discharge current, and the type of dielectric fluid.

EDM Power System. The discharge energy during EDM is provided by a direct current pulse power generator. The EDM power system can be classified into RC, LC, RLC, and transistorized types. The transistorized EDM power systems provide square waveform pulses with the pulse on-time usually ranging from 1 to 2000 msec, peak voltage ranging from 40 to 400V, and peak discharge current ranging from 0.5 to 500 A. With the RC, LC, or RLC type power system, the discharge energy comes from a capacitor that is connected in parallel with the machining gap. As a result of the low impedance of plasma channel, the discharge duration is very short (less than 5 msec), and the discharge current is very high, up to 1000 A. The peak voltage is in the same range of transistorized power systems.

The transistorized power systems are usually used in die-sinking EDM operations because of their lower tool wear. Capacitive power systems are used for small hole drilling, machining of advanced materials, and micro-EDM because of higher material removal rate and better process stability. WEDM

power generator usually is a transistor-controlled capacitive power system that reduces the wire rupture risk. In this power system, the discharge frequency can be controlled by adjusting the on-time and off-time of the transistors that control the charging pulse for the capacitor connected in parallel with the machining gap.

Key System Components. The machining gap between tool and workpiece during EDM must be submerged in an electrically nonconductive *dielectric fluid*. In die-sinking EDM, kerosene is often used as a dielectric fluid because it provides lower tool wear, higher accuracy, and better surface quality. Deionized water is always used as a dielectric fluid in WEDM to provide a larger gap size and lower wire temperature in order to reduce the wire rupture risk. This fluid also serves to flush debris from the gap and thus helps maintain surface quality.

Copper and graphite are commonly used as die-sinking *EDM tool materials* because of the high electrical conductivity and high melting temperature and the ease of being fabricated into complicated shapes. The wire electrode for WEDM is usually made of copper, brass, or molybdenum in a diameter ranging from 0.01 to 0.5 mm. Stratified copper wire coated with zinc brass with diameter of 0.25 mm is often used.

In the traditional die-*sinking EDM process*, the tool is fabricated into a required shape and mounted on a ram that moves vertically. The spark discharges can only occur under a particular gap size that determines the strength of electric field to break down the dielectric. A servo control mechanism is equipped to monitor the gap voltage and to drive the machine ram moving up or down to obtain a dischargeable gap size and maintain continuous sparking. Because the average gap voltage is approximately proportional to the gap size, the servo system controls the ram position to keep the average gap voltage as close as possible to a preset voltage, known as the servo reference voltage.

In a WED machine, the wire electrode is held vertically by two wire guides located separately above and beneath the workpiece, with the wire traveling longitudinally during machining. The workpiece is usually mounted on an *x-y* table. The trajectory of the relative movement between wire and workpiece in the *x-y* coordinate space is controlled by a CNC servo system according to a preprogrammed cutting passage. The CNC servo system also adjusts the machining gap size in real time, similar to the die-sinking EDM operation. The dielectric fluid is sprayed from above and beneath the workpiece into the machining gap with two nozzles.

The power generators in WED machines usually are transistor-controlled RC or RLC systems that provide higher machining rate and larger gap size to reduce wire rupture risks. In some WED machines, the machining gap is submerged into the dielectric fluid to avoid wire vibration to obtain a better accuracy. The upper wire guide is also controlled by the CNC system in many WED machines. During machining, the upper wire guide and the *x-y* table simultaneously move along their own preprogrammed trajectories to produce a taper and/or twist surface on the workpiece.

Machining Parameters. The polarity of tool and workpiece in EDM is determined in accordance with the machining parameters. When the discharge duration is less than 20 μsec, more material is removed on the anode than that on the cathode. However, if the discharge duration is longer than 30 μsec, the material-removal rate on the cathode is higher than that on the anode. Therefore, with a transistorized power system, if the pulse on-time is longer than 30 μsec, the tool is connected as anode and the workpiece is connected as cathode. When the on-time is less than about 20 μsec, the polarity must be reversed. With an RC, LC, or RLC power system, since the discharge duration is always shorter than 20 μsec, the reversed polarity is used.

With transistorized EDM power systems, the machining rate and surface finish are primarily influenced by the peak current. The machining rate increases with the peak current. The relationship between the machining rate and pulse on-time is nonlinear, and an optimal pulse on-time exists. Reducing peak current improves the surface finish, but decreases the machining rate.

Capabilities and Process Limitations. Die-sinking ED machines with transistorized power systems under good gap-flushing conditions can attain a material-removal rate as high as 12 mm^3/min/amp (for

a steel workpiece). The wire cut EDM process can cut ferrous materials at a rate over 100 mm^2/min. A surface roughness value of 0.01 in. (0.2 mm) can be obtained with a very low discharge current. The tool wear ratio can be controlled within 1% during rough machining and semifinishing with the transistorized power generator. Dimensional tolerance of ±118 μin. (3 μm) and taper accuracy of 20 to 40 μin. (0.5 to 1 μm/mm) with both die-sinking and WEDM can be obtained.

EDM can machine materials having electrical conductivity of 10^{-2} W^{-1} cm^{-1} or higher. An average current density more than 4 A/cm^2 tends to cause substantial tool wear and unstable machining, and may lead to dielectric fire. This factor largely limits the productivity of EDM. During machining a deep cavity using die-sinking EDM under difficult flush condition, arc discharges occur, and the resultant thermal damage on workpiece substantially limits the productivity and the machined surface quality. Dielectric properties also impose additional constraints.

Electrical Chemical Machining (ECM)

Description and Applications. The ECM process uses the electrochemical anodic dissolution effect to remove workpiece material. Like die-sinking EDM, the tool electrode of ECM is preshaped according to the requirements of the workpiece. During machining, the inverted shape of the tool is gradually generated on the workpiece. ECM machines complex contours, irregular shapes, slots, and small, deep, and/or noncircular holes. Typical applications of ECM include machining nickel-based superalloy turbine blade dovetails, slots in superalloy turbine disks, engine castings, gun barrel rifles, and forging dies. ECM is also used for deburring, surface etching, and marking.

Principle of Operation. Electrolyte fluid is forced through the gap between tool and workpiece during ECM. A low-voltage and high-current DC power system supplies the machining energy to the gap. The tool electrode of ECM must be connected as cathode and the workpiece must be connected as anode. The electrochemical anodic dissolution phenomenon dissolves workpiece surface material into metal ions. The electrolyte fluid flushes the metal ions and removes heat energy generated by the deplating actions. The gap size in ECM is in the range of 0.004 to 0.04 in. (0.1 to 1 mm). ECM process performance is independent of the strength, hardness, and thermal behavior of workpiece and tool materials.

Key System Components. Copper, brass, stainless steel, and titanium are commonly used as *ECM tool electrode materials* due to their good electrical conductivity, resistance to chemical erosion, and ease of being machined into desired shapes. The geometric dimensions of the machined surface generated by ECM depend on the shape of tool and the gap size distribution.

The structure of an EC machine varies with the specific applications. An ECM must have a tool feed system to maintain the machining gap, a power system to supply the power energy, and a fluid-circulating system to supply the electrolyte and to flush the machining gap. The power system used in ECM is a DC power source with the voltage ranging from 8 to 30 V and a high current in the range of 50 to 50,000 A, depending on the specific design of the power system.

The *electrolyte* is the medium enabling the reaction of electrochemical dissolution occurring on the anode. The electrolyte can be classified into categories of aqueous and nonaqueous, organic and nonorganic, alkaline and neutral, mixed and nonmixed, and passivating and nonpassivating, and acidic. The electrolyte is selected according to the type of workpiece material, the desired accuracy, surface finish requirements, and the machining rate. Neutral salts are used in most cases. Acid electrolytes are used only for small hole drilling when the reaction products must be dissolved in the electrolyte.

Machining Parameters. ECM performance is mainly influenced by electrical parameters, electrolyte, and geometry of tool and workpiece. The electrical parameters include machining current, current density, and voltage. ECM systems with 50 to 50,000 A and 5 to 30 V DC are available, and the current density can be in the range of 10 to 500 A/cm^2. Key electrolyte parameters consist of flow rate, pressure, temperature, and concentration. Important parameters of tool and workpiece geometry are contour gradient, radii, flow path, and flow cross section. When the tool feed rate equals the machining rate, an equilibrium gap size is obtained; this is critical to maintaining shaping accuracy.

The electrolyte selection also plays an important role in ECM dimension control. In this regard, the sodium nitrate solution is preferable because the metal-removal rate at smaller gap size locations is higher than at other places. Therefore, the characteristics of current efficiency in ECM influence the uniformity of the gap size distribution. ECM accuracy has recently been shown to improve with pulsed voltage (instead of continuous voltage) and an appropriate set of pulse parameters (on-time, off-time, etc.).

Capabilities and Process Limitations. ECM is capable of machining any electrically conductive metallic material, and the process is generally unaffected by the hardness, strength, and thermal behaviors of materials. This process can be used to machine parts with low rigidity such as parts with thin walls. Machining rates of 2 to 2.5 cm^3/min/1000 A current, surface roughness of 4 to 50 μin. (0.1 to 1.2 μm), and accuracy of 400 μin. to 0.01 in. (10 to 300 μm) can be achieved with ECM. The available ECM equipment can machine a 0.04 to 80 in. (1 to 2000 mm) long workpiece. The typical energy consumption is 300 to 600 J/mm^3.

The machining rate and surface finish with ECM are much higher than that with EDM due to higher allowable current density and the molecular level of material removal. The machining accuracy, however, is substantially lower than EDM and is much more difficult to control.

The gap size distribution is influenced by many factors including the type of electrolyte, electrolyte flow rate and flow pattern, electrolyte temperature, current density of machining, etc. Therefore, the gap size distribution is not uniform in most cases and is difficult to determine analytically. The shape of machined surface by ECM will not be a perfect mirror image of the tool electrode. In order to achieve an acceptable accuracy, the tool shape must be modified by using trial-and-error method in test machining before machining of actual workpieces.

ECM cannot machine materials with electrical conductivity less than 10^3 W^{-1} cm^{-1}. ECM cannot produce very sharp corners (less than 800 μin., 0.02 mm, radius). The machining rate is limited by the electrolytic pressure (less than 5 MPa) and boiling point as well as the applied current (less than 50,000 A). The gap size which determines the final shape and accuracy is limited to 800 μin. to 0.004 in. (0.02 to 0.1 mm).

ECM generates a large amount of sludge and spent electrolyte. This waste requires significant processing before it can be safely disposed of.

Water and Abrasive Jet Machining

Description and Application. *Water jet machining* (WJM) and *abrasive water jet machining* (AWJM) are used in many applications. In the WJM process, relatively soft workpiece materials are cut by a high-velocity water jet; e.g., food, wood, paper, plastic, cloth, rubber, etc. The AWJM process uses the fine abrasive particles mixed in the water jet to machine harder workpiece materials. The AWJM is used for drilling, contour cutting, milling, and deburring operations on metal workpieces, as well as for producing cavities with controlled depths using multipass and non-through-cutting methods. The cutting path of the WJM and AWJM can be controlled by a CNC system according to a preprogrammed program.

Principle of Operation and Machine Structures. During WJM, the workpiece material is removed by the mechanical energy generated by the impact of a high-velocity water jet. In a water jet machine, a high-pressure pumping system increases the pressure of water in the pipe system, and the pressurized water is sprayed from a nozzle with a small diameter to generate a high-velocity water jet.

In the AWJM process, pressurized water is sprayed from an orifice in the nozzle body into a mixing chamber to generate a negative pressure that absorbs the abrasive particles (supplied by an abrasive feed hose) into the water jet. The water jet/abrasive grain mixture is then sprayed through a tungsten carbide nozzle. The abrasive grains in the high-velocity water jet provide small cutting edges that remove material. The relative distance between water jet nozzle and workpiece is controlled by a two- or three-dimensional CNC system. This process can be used to generate a complicated shape.

Process Parameters and Limitations. The key parameters are the water and/or abrasive flow velocity, abrasive grain size, and mixing tube (nozzle) length and diameter. The typical water flow velocity is in the range of 2000 to 3000 ft/sec (600 to 900 m/sec) as determined by the water pressure. The water pressure in WJM and AWJM is very high, up to 2.7×10^6 psi (400 MPa), and the nozzle diameter is in the range of 0.003 to 0.08 in. (0.8 to 2 mm). The abrasive flow rate is governed by the water flow rate and the mixing density, and can be controlled up to 10 g/sec. Abrasive particles are usually in the range of 60 to 150 mesh size. Increasing water jet flow velocity increases cutting depth. The taper error of cutting is determined by the traverse rate that describes the ratio between the material removal and the cutting depth and width. This parameter is influenced by the water and abrasive velocity and cutting speed. Proper selection of AWJ parameters is essential for the elimination of burrs, delaminations, and cracks.

Limitations of the process include stray cutting and surface waviness, high equipment costs, hazard from the rebounding abrasive, high noise levels, and short nozzle lifetimes due to wear and abrasion.

Ultrasonic Machining

Description and Applications. *Ultrasonic machining* (USM) is a process that uses the high velocity and alternating impact of abrasive particles on the workpiece to remove material. The abrasive particles are mixed in a slurry that fills the machining gap between the tool and workpiece. The alternating movement of abrasive particles is driven by the vibration of the frontal surface of tool at an ultrasonic frequency. The ultrasonic machining process can machine hard and brittle materials.

USM is often used for machining of cavities and drilling of holes on hard and brittle materials including hardened steels, glasses, ceramics, etc. Rotary ultrasonic machining (RUM) is a new application that uses a diamond grinding wheel as the tool for drilling, milling, and threading operations. During RUM, the tool is rotating at a high speed up to 5000 rpm and vibrating axially at ultrasonic frequency. This process is able to drill holes with diameter from 0.02 to 1.6 in. (0.5 to 40 mm) at depths up to 12 in. (300 mm). The material removal rate of 6 mm^3/sec can be obtained with the RUM process. The tolerance of ±300 μin. (±0.007 mm) can be easily achieved with both conventional and rotary ultrasonic processes.

Principle of Operation. In the USM process, the machining gap between tool and workpiece is filled with an abrasive slurry composed of an oil mixed with abrasive particles, with the frontal surface of the tool vibrating at ultrasonic frequency to provide the machining energy. The inverted shape of the tool is gradually generated on the workpiece. Material removal by the USM process is very complex. When the machining gap is small, the material may be removed as the frontal surface of the tool moves toward the workpiece, hitting an abrasive particle that impacts the workpiece surface. Material can also be removed by the impact of the abrasive particles when the machining gap is relatively large. In this case, the abrasive particles are accelerated by the pressure of slurry due to the ultrasonic vibration of the frontal surface of the tool. Also, ultrasonic-induced alternating pressure and cavitation in the slurry assist material removal.

Key System Components. The ultrasonic vibration in USM is generated by an *ultrasonic generator.* The ultrasonic generator consists of a signal generator, a transducer, and a concentrator. The signal generator produces an electrical signal whose voltage and/or current is changing at an ultrasonic frequency to drive the transducer. The frequency of the electrical signal can be adjusted in the range of 10 to 40 kHz.

The transducer converts the electrical voltage or current into the mechanical vibration. Two types of transducers are commonly used in USM: magnetostrictive and piezoelectric.

- The *magnetostrictive transducer* was extensively used prior to 1970. This transducer is constructed by surrounding a number of sheets of magnetostrictive material with a coil. When the strength of the electric current in the coil changes at an ultrasonic frequency, a mechanical ultrasonic vibration is generated in the magnetostrictive material. This transducer has a low energy conversion efficiency, usually less than 30%.

- The *piezoelectric ultrasonic transducer* is commonly used today. The geometrical dimensions of this transducer vary with the change in the applied electric field. A mechanical ultrasonic vibration is generated when the strength of the electric voltage applied across the transducer material changes at an ultrasonic frequency. This transducer has an extremely high energy conversion efficiency, up to 95%. The amplitude of the ultrasonic vibration generated directly by the transducer is very small, about 400 μin. (0.01 mm). A concentrator is used for amplifying the amplitude into a level that is acceptable for USM. The transducer is mounted on the larger end of the concentrator; the tool is mounted on the smaller end.

In the ultrasonic machine, the ultrasonic generator is held vertically on the ram that moves vertically, and the workpiece is mounted on an *x-y* table that determines the relative position between tool and workpiece. During machining, a force providing pressure between the tool and workpiece is added through the ram mechanism.

Process Parameters and Limitations. The material-removal rate during USM increases with an increase in the amplitude of ultrasonic vibration, grain size of the abrasive particles, and pressure between the tool and workpiece. The surface finish is essentially determined by the grain size for a given workpiece material; i.e., the smaller the grain size, the better surface finish. The abrasive grains used in USM are usually in the range of 100 to 900 mesh number.

The USM process is limited by the softness of the material. Workpiece materials softer than Rockwell C40 result in prohibitively long cycles. The best machining rate can be obtained on materials harder than Rockwell C60.

Phase-Change Processes

Phase-change processes produce parts from materials originally in the liquid or vapor phase. These include processes such as metal casting and injection molding of polymers. The two most commonly used metal-casting processes are described below. The references listed at the end of the section contain detailed information on all phase-change unit processes.

Advantages and Applications of Metal Casting

Metal casting is one of the primary methods of producing bulk shapes. Very complex shapes can be cast from nearly every metal, making casting an extremely versatile process. Castings are made in sizes that range from fractions of an ounce to hundreds of tons.

The selection of the best molding and casting process for an application can be complex, and is governed by many factors which include casting size, variation in thickness of the casting sections, required mold strength, required surface finish and dimensional accuracy, production rates, environmental factors (e.g., reclamation of the sand and type of sand binder), and cost. Casting processes can be considered to fall into five categories (Kanicki, 1988):

- Conventional molding processes — green sand, shell, flaskless
- Precision molding and casting processes — investment, permanent mold, die casting
- Special molding and casting processes — vacuum molding, evaporative pattern casting, centrifugal casting

- Chemically bonded self-setting sand molding — no-bake, sodium silicate
- Innovative molding and casting processes — unbonded sand molding (Patz and Piwonka, 1988), rheocasting, squeeze casting, electroslag casting

This section discusses the most widely used conventional molding process, green sand, and the most widely used precision molding and casting process, investment casting. The reference list at the end of the section should be consulted for detailed information on all casting processes.

Casting Defects and Design Considerations

Properly designed and manufactured castings provide many advantages, and are competitive with other unit process methods. Success with casting processes, as with every process, requires design and process engineers knowledgeable regarding the advantages and limitations of casting processes so that appropriate design and process choices can be made that avoid or minimize the occurrence of defects.

Table 13.2.14 summarizes the most common defects that occur during casting and suggests design and process changes that can avoid or reduce the effect of the defects. However, the suggested mitigation strategies may introduce different casting defects or the evolution of other problems, so each change should be carefully evaluated with regard to the system as a whole.

Green Sand Casting Processes

Description and Applications. Sand-mold casting is adaptable to a very wide range of alloys, shapes, sizes, and production quantities. Hollow shapes can be produced in these castings through the use of cores. Sand-mold casting is by far the most common casting process used in industry; some estimates are that as many as 90% of industrial castings use the sand-mold casting process (O'Meara et al., 1988). Green sand molding is currently the most widely used of all sand casting methods, although dry sand methods are preferred for very large castings. "Green" sand refers to the fact that water is added to activate the clay binder. In dry sand molding, the moisture is removed prior to casting.

Green sand-mold casting involves mixing sand with a suitable clay binder (usually a bentonite clay) and other additives, and packing the sand mixture tightly around a pattern that is constructed from the part design, but the pattern is not an exact replica of the part since various dimensional allowances must be made to accommodate certain physical effects. After extracting the pattern from the sand mold, a cavity is left behind that corresponds to the shape of the pattern. Next, molten metal is poured into this cavity and solidifies into a cast replica of the desired part. After the casting cools, the sand is readily removed from the casting and may be reclaimed for further use.

Key System Components. A *mold pattern* is constructed from the casting design with suitable modifications. Depending on the complexity of the part, CAD/CAM programs are able to design patterns that require very little adjustment to achieve desired solidification control and dimensional accuracy in the resulting casting (Berry and Pehlke, 1988). The computation is complex and cannot be easily done for complex shapes. The principal adjustments that must be made to translate a part design to a mold design result from many considerations (ASM, 1988). One needs to

- Compensate for shrinkage of the sand during the drying/curing operations
- Compensate for expansion of the sand caused by the rapid introduction of the molten metal into the mold
- Compensate for contraction of the liquid metal during freezing
- Allow easy extraction of the pattern from the packed sand through a taper on the vertical sides of the pattern
- Add a gating network to allow molten metal to smoothly flow into the cavity
- Add risers (including size), as required in key locations to continue feeding molten metal into the solidifying casting
- Add provisions for core prints, as required, to anchor cores that produce internal cavities which could not be directly molded from the pattern

TABLE 13.2.14 Typical Casting Defects and Mitigation Strategy

Casting Defect	Description and Cause	Mitigation Strategy
Cold shuts	Appear as folds in the metal — occurs when two streams of cold molten metal meet and do not completely weld Possible causes: • Interruption in the pouring operation • Too slow a pouring rate • Improperly design gating	Pour as quickly as possible Design gating system to fill entire mold quickly without an interruption Preheat the mold Modify part design Avoid excessively long thin sections
Hot tears and cracks	Hot tears are cracklike defects that occur during solidification due to overstressing of the solidifying metal as thermal gradients develop Cracks occur during the cooldown of the casting after solidification is complete due to uneven contraction	Fill mold as quickly as possible Change gating system; e.g., use several smaller gates in place of one large gate Apply thermal management techniques within the mold (e.g., chills or exothermic material) to control solidification direction and rate Insulate the mold to reduce its cooling rate Modify casting design: • Avoid sharp transitions between thin and thick sections • Taper thin sections to facilitate establishment of appropriate solidification gradients • Strengthen the weak section with additional material, ribs, etc.
Inclusions	Presence of foreign material in the microstructure of the casting Typical sources: • Furnace slag • Mold and core material	Modify gating system to include a strainer core to filter out slag Avoid metal flow turbulence in the gating system that could cause erosion of the mold Improve hardness of the mold and core
Misruns	Incomplete filling of the mold cavity Causes: • Too low a pouring temperature • Too slow a pouring rate • Too low a mold temperature • High backpressure from gases combined with low mold permeability • Inadequate gating	Control mold and metal temperature Increase the pouring rate Increase the pouring pressure Modify gating system to direct metal to thinner and difficult-to-feed sections quicker
Porosity	Holes in the cast material Causes: • Dissolved or entrained gases in the liquid metal • Gas generation resulting from a reaction between molten metal and the mold material	Pour metal at lowest possible temperature Design gating system for rapid but uniform filling of the mold, providing an escape path for any gas that is generated Select a mold material with higher gas permeability
Microshrinkage	Liquid metal does not fill all the dendritic interstices, causing the appearance of solidification micro-shrinkage	Control direction of solidification • Design gating system to fill mold cavity so that solidification begins at the extremities and progresses toward the feed gate • Lower the mold temperature and increase the pouring temperature • Add risers, use exothermic toppings to maintain temperature longer • Control cooling rate using chills, insulators, etc. in selected portions of the mold

There are basically three types of molding methods which are categorized by the resulting hardness or density of the sand mold (O'Meara et al., 1988; Brown, 1988):

Low-density molding

- *Hand-ramming* is the oldest, slowest, and most variable method for packing sand around the pattern. It is rarely used for production, but can be employed for prototypes or very limited production runs.
- *Jolt* machines operate with the pattern mounted on a table which is attached to the top of an air piston. Typically, a flask is placed on the table with the pattern centered in the flask cavity. The flask is filled with sand. Compressed air lifts the piston, and then the air is released, allowing the entire assembly to fall with a sharp jolt. The sequence can be repeated. The sand is compacted by its own weight and is densest at the pattern plate.
- *Jolt-squeeze* molding machines employ the same pattern equipment as the jolt machines but after the jolting operation, the sand is squeezed by hydraulic pressure to improve the packing uniformity in the mold.

Medium-density molding

- *Rap-jolt machines* are improved versions of the low-pressure machines, capable of exerting higher pressure to compact the sand.
- *Sand slingers* direct sand into a mold from a rotating impeller. Sand-packing density is a function of the centrifugal velocity of the impeller. This method is particularly useful for large molds.

High-pressure molding

- *Pressure wave* methods allow the sand to gravity fill the mold. Then, the top of the mold is sealed and a high-pressure wave is created by a controlled explosion of a combustible gas or by the rapid release of air pressure.
- *Horizontal flaskless molding* utilizes a pattern carrier to support the top half (cope) and bottom half (drag) of the mold pattern. The cope and drag are spaced apart in the carrier, and the space is evacuated. The molding setup is depicted in Figure 13.2.10. Vents in the pattern cause sand to be drawn into the mold. When the mold is filled, it is tightly squeezed.

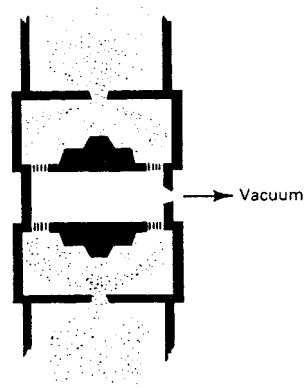

FIGURE 13.2.10 High-pressure vacuum-fill squeeze machine. (From *ASM Handbook, Machining*, Vol. 15, 9th ed., ASM International, Metals Park, OH, 1989, 343. With permission.)

The details of the *metal pouring* operation vary quite a bit depending on the metal, the material specification, the furnace type, and the foundry layout. A ladling method using gravity pressure is commonly used to transfer the molten metal, which may be alloyed, degassed, etc. immediately before it is discharged into the poring basin that feeds the gating system of the castings.

A *gating system* must allow complete fill of a mold cavity without causing flow turbulence that can entrap loose sand or slag and feed shrinkage as the liquid metal within the mold cools. The gating system should be designed to promote progressive solidification from the point most distant from the gate toward the gate.

A *riser* is a reservoir of molten metal that is attached to the casting. It feeds the voids that develop within the casting as the liquid metal cools and begins to solidify. A thin skin of frozen metal first forms in a shell around the outer part of the mold cavity immediately after the metal is poured. This rigid shell serves as a mold for the remainder of the casting. The volume lost by the shrinkage of the metal as it solidifies within this shell must be replaced from a liquid metal source, such as a riser or a feeding gate, to prevent internal porosity. Risers are subsequently removed from the casting.

Management of thermal gradients within the solidifying casting is essential to minimize shrinkage. The solidification of risers can be slowed by the use of an *exothermic material* placed on top of a riser. The heat generated by this material can allow the riser to continue to feed the casting until it is solidified. *Chills* can be used to reduce the local temperature at the mold-casting interface, and thus accelerate freezing in selected locations, thereby establishing the solidification direction. Chills are usually metal inserts strategically placed in the mold. The mold can also be *insulated* to reduce the overall cooling rate of the casting if necessary to reduce residual stresses, but the metallurgical effect must be carefully considered.

In most cases, *electric furnaces* are used for melting, and *pouring* is nonpressurized.

Influence of Process on Part Design. Properly designed gating systems and risers should produce completely solid castings. A number of design rules for the gating and risering system have been developed for casting various metals to achieve continuous feeding of the solidifying casting. These rules are embedded in computer programs that aid design of casting molds and layouts.

It may be less expensive and easier to change the design than to develop a complex thermal management system within the mold. Typical design changes to evaluate include

- Thickening thin sections that feed heavier, more remote sections
- Reducing the mass of the remote thick section
- Adding a riser to feed separately the remote thick section

Process Limitations. Each production step contributes to *dimensional variations* in a sand casting. For instance, dimensions are affected by the sand-packing density, by the process of withdrawing the pattern from the sand, by the moisture content of the sand, and by both the temperature of the molten metal and the speed with which it enters the mold cavity. The result is that sand casting is not inherently a precision process.

The surface finishes of sand castings are controllable only within rather wide limits (ASM, 1988). Normally, the maximum allowable surface roughness is specified, and any smoother surface is acceptable. For instance, casting steel in green sand can have a surface roughness varying from 500 to 2000 μin. (12 to 50 μm), and aluminum from 125 to 750 μin. (3 to 20 μm). These values can be improved in certain instances through the application of coatings on the sand mold.

Porosity cannot be prevented in all cases. Changes to the part design and postcasting processing, such as hot isostatic pressing (HIP), should be considered.

Investment Casting

Description and Applications. Investment castings are noted for their ability to reproduce extremely fine details and conform to very tight tolerances. As a result, these castings are used in critical, demanding structural applications, such as superalloy turbine airfoils and works of art.

The investment casting process employs a mold produced by enclosing an expendable pattern with a refractory slurry that is then hardened. The pattern, usually made from wax or plastic, is subsequently removed (e.g., by melting, dissolving, or burning), creating the desired mold cavity. The expendable

patterns are themselves cast in a permanent pattern die. Ceramic cores can create internal passages within the casting.

Key System Components. Shell investment and solid investment processes are used in the production of investment castings (Horton, 1988). The two processes differ in the method of mold preparation, not in pattern preparation or pattern assembly. In the *shell investment process*, the pattern assembly is precoated, dipped in a coating slurry, and covered with granulated refractory until the shell is built up to desired thickness, usually less than 0.5 in. (20 μmm); the thickness depends on the casting size and weight, cluster size, and type of ceramic and binder. As thin a shell as possible is specified to maximize mold permeability. Ceramic shell molds are used for the investment casting of carbon and alloy steels, stainless steels, heat-resistant alloys, and other alloys with melting points above 1100°C (2000°F).

The *ceramic material* used in shell investments is often silica, zircon (zirconium orthosilicate), an aluminum silicate, or alumina (Horton, 1988). *Silica glass* (fused silica) is desirable because it is readily available, but it has a high coefficient of thermal expansion and an abrupt phase transition, and it cannot be used in vacuum casting because the silica decomposes at low vapor pressures, leading to severe metal–mold reaction. *Zircon* is readily available, is resistant to wetting by molten metal, and has a high refractoriness. Its use is limited to prime coats though, because it is not available in large grain sizes. *Aluminum silicates*, such as mullite, can be manufactured to a range of pellet sizes and over a range of compositions. *Alumina* is more refractory than silica or mullite and is not very reactive with many metals.

The *binders* most often employed in shell investments are colloidal silica, ethyl silicate, and sodium silicate. *Colloidal silica* is an excellent general-purpose binder, and is the most widely used binder. Its primary disadvantage is that it is slow to dry. *Ethyl silicate* produces a bond between the refractory material that is very similar to that of colloidal silica. It dries much faster, but poses a fire hazard and is more expensive. Liquid *sodium silicate* forms a strong, glassy bond. The material is inexpensive but its refractoriness is poor, and the bond deteriorates in the presence of steam used to remove the wax pattern.

In the *solid investment process*, the pattern assembly is placed in a flask, which is filled with a refractory mold slurry. This slurry hardens in air, forming a solid mass in which the pattern assembly is encased. The types of bonding materials and refractories differ depending on the pouring temperature of the metal. For nonferrous alloys, pouring temperature is usually below 2000°F (1100°C). In these cases, *alpha gypsum* is commonly used as both the refractory and the binder, with other refractories such as silica added to improve mold permeability. The process is primarily used for making dental and jewelry castings.

For extremely limited production and for the development of production process parameters, investment mold patterns can be directly machined from an expendable material, such a plastic. For production-level investment casting, however, the patterns are produced by injecting wax or plastic into *permanent pattern molding dies*. The dimensional tolerance of these permanent dies must be closely controlled.

A mixture of paraffin and microcrystalline *wax* is widely used for making investment casting patterns (Horton, 1988). Waxes are strong, stiff, and provide adequate dimensional control during pattern making. They are easy to remove with pressurized saturated steam or elevated temperatures. *Plastic* patterns have several advantages compared with wax: higher strength, less subject to handling damage, can withstand automatic ejection from the pattern mold, and can reproduce thinner sections, finer definition, sharper corners, and better surface finish. But a major disadvantage is that certain plastics, such as polystyrene, expand during burnout and can crack ceramic shell molds.

Some investment castings require complex internal cavities (e.g., holes and air passages). For complicated shapes, the pattern-die *cores* are used to form portions of the pattern that cannot be withdrawn after the pattern is made. The cores must subsequently be dissolved or etched out from the casting.

As much *gating* as possible is included in the wax patterns. This allows use of standard methods of joining patterns together so that a number of investment castings can be produced during one pouring operation.

Investment casting is done in air and in vacuum. *Gravity pouring* fills the pouring basin from a ladle or directly from a furnace. This method requires low equipment investment, but highly skilled operators. In *pressure pouring* the molds are filled from the furnace with an assist from a pressurized gas to fill rapidly thin sections. With *vacuum-assisted pouring*, a vacuum pump evacuates air from a mold ahead of the stream of molten metal to minimize flow resistance. *Centrifugal casting* uses a spinning mold assembly to develop added pressure to fill the mold.

Capabilities and Process Limitations. Investment castings:

- Produce complex shapes that are difficult to make by other means
- Reproduce fine detail, high dimensional accuracy, and smooth surfaces requiring only minimal finishing
- Adapt to most metal alloys
- Allow control of metallurgical properties such as grain size and grain orientation

A tolerance of ±0.002 in. (0.05 mm) can be held on investment castings for each inch in its maximum dimension; however, a tolerance of ±0.005 in. (0.13 mm) is more typical (Horton, 1988). A surface finish of 125 min. (3 mm) can be readily achieved, and surface finishes as smooth as 30 to 40 min. (0.8 to 1.0 mm) can be produced with suitable process control.

The size and weight of castings that can be investment cast are usually limited by physical and economic considerations. Generally, the process can be applied cost-effectively to casting weighing up to 10 lb (4.5 kg); investment castings weighing 50 lb (22.5 kg) are not unusual, and castings as large as 1000 lb (450 kg) are feasible. The initial tooling costs of investment casting can be high.

Structure-Change Processes

Structure-change processes alter the microstructure of a workpiece. These changes can be achieved through thermal treatment involving heating and cooling (quenching) under controlled conditions, sometimes in combination with mechanical forces, in order to effect desired solid-state phase transformations. These processes include those that diffuse selected species into a surface layer to modify its composition or to create a thin layer of material that does not increase the dimensions of the workpiece.

The two structure-change processes described here are representative examples. *Normalization of steel* is a process that changes bulk properties of a workpiece. *Laser surface hardening* of steel only changes its surface properties; it does not affect the bulk properties. Even though both examples relate to ferrous

materials, structure-change processes are used to impart desired properties to many material systems; e.g., age hardening of aluminum alloys. The references listed at the end of this section contain detailed information on structure-change processes.

Normalizing Steel

Description and Applications. Normalizing is a heat-treating process that results in a relatively uniform steel microstructure. Essentially all the standard carbon steels can be normalized. The resulting phases and their size/distribution depend heavily on the carbon content of the steel. Normalization treatments are performed for a variety of reasons (Ruglic, 1991):

- Refine the dendritic grain structure remaining from casting
- Eliminate severe texture (and hence anisotropic properties) that results from forging and rolling operations
- Reduce residual stresses
- Improve the response of a steel to further processing, such as machining or surface hardening
- Improve mechanical properties by precipitating desirable phases

Principle of Operation. The steel workpiece must be heated sufficiently high to transform the entire structure to austenite, a face-centered cubic phase which essentially solutionizes all the carbon (at room temperature iron exists as ferrite, a body-centered cubic phase which has a very low carbon solubility). Diffusion-controlled solid-state phase transformations require time at temperature to occur. Therefore, the workpiece must be held at temperature long enough for austenite to dissolve the carbon.

The workpiece is then cooled slowly enough to avoid trapping the carbon in a supersaturated solution as the iron transforms back from austenite to ferrite. A time–temperature-transformation curve depicts which phase transformations will occur for different cooling gradients. A typical T-T-T curve is shown in Figure 13.2.11, which depicts the difference between a normalizing cool rate and that for annealing. For the normalization treatment to be successful, the regions in the microstructure with a carbon content of 0.8% carbon precipitate fine lamellae of ferrite and iron carbide (Fe_3C) on cooling, known as pearlite. Those areas low in carbon content should precipitate ferrite grains during the initial phase of the cooling cycle, followed by pearlite precipitation. The regions high in carbon should precipitate iron carbide in the austenite grain boundaries, followed by pearlite precipitation (Ruglic, 1990).

The end result of normalization is a microstructure, and hence the mechanical properties characteristic of the composition of the steel (primarily governed by carbon content) as opposed to a microstructure that was principally shaped by its previous thermomechanical processing.

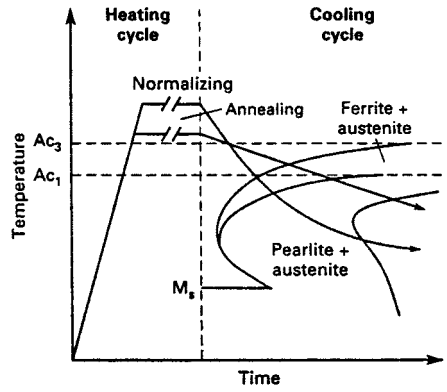

FIGURE 13.2.11 Time–temperature-transformation curve for normalizing compared to annealing. (From *ASM Handbook, Heat Treating*, Vol. 4, 10th ed., ASM International, Metals Park, OH, 1991, 35. With permission.)

Key System Components. Conventional heat-treating furnaces are used for normalization, such as batch or continuous furnaces (Ruglic, 1991). The rate of heating is not critical. The furnaces must be able to heat the component to about 100°F (55°C) into the austenitizing region — this temperature depends on the composition of the steel.

Control of the cooling rate is critical. In the usual case, a workpiece can be removed from the furnace and allowed to air cool uniformly until the diffusion-controlled phase transformations are completed.

Process Limitations. The ability to normalize the microstructure of steel is governed by thermodynamics. Phase stability and kinetics of the phase transformations are crucial. But heat transfer considerations also play a major role. For instance, it may not be possible to achieve the desired cooling gradient in the center of a thick section, and hence the properties of such sections will not be uniform.

For complex shapes or for those workpieces having a high degree of residual stresses, some distortion will occur during the normalization process. The extent of distortion can be reduced by appropriate fixturing, but it cannot be eliminated. Hence, some tolerance allowance must be made.

Laser Surface Hardening

Description and Applications. Laser surface hardening is used as an alternative to flame hardening and induction hardening ferrous materials. The rapid heating rate achievable by the laser minimizes part distortion and can impart surface hardness to low-carbon steels. The ability to locate the laser some distance from the workpiece can also be advantageous. The entire operation can be performed in air. This process is used to harden selected areas of machine components, such as gears, cylinders, bearings, and shafts.

Laser surface hardening imparts wear resistance and strength to the surface of a component without affecting its overall dimensions or changing its bulk properties. It is applied to selected areas which can be accessed by a laser beam. The process relies on rapid laser heating, followed by rapid quenching, to effect the necessary degree of hardening through phase transformation. The result is a very fine grain structure that is extremely hard. Typical case depth is a function of the composition of the ferrous material, but it will usually not exceed 0.1 in. (0.25 cm). For low- and medium-carbon steels, the case depth will range from 0.01 to 0.05 in. (0.03 to 0.13 cm), with the case depth increasing as the carbon content increases (Sandven, 1991).

Principle of Operation. An industrial laser rapidly heats a thin surface layer into the austenite phase region (austenite is a face-centered cubic allotropic phase of iron that has a high solubility for carbon). The interior of the workpiece is unaffected. When the laser beam is moved, the heated surface quickly cools. Consequently, the carbon does not have time to diffuse as the iron attempts to transform back to its ferrite (body-centered cubic) structure. The resulting microstructure is extremely hard since the trapped carbon atoms distort the iron crystal structure into a highly strained body-centered tetragonal form, known as martensite.

Key System Components. The majority of *industrial metalworking lasers* are either solid-state Nd:YAG or carbon dioxide type. Either pulsed or continuous mode can be used for surface treatment. The power output range for YAG lasers is 50 to 500 W. Carbon dioxide lasers are available in much higher power levels, up to 25 kW.

The surface to be hardened is usually *coated* to improve its ability to absorb laser radiation. A typical coating is manganese phosphate. *Paints* containing graphite, silicon, and carbon are also used. These coatings/paints can increase the absorption of laser energy to 80 to 90% (Sandven, 1991).

The output beam of the laser must be shaped and directed by an *optical system* to generate a laser spot of desired shape and size at the correct location on the workpiece surface. Reflective optical components are used since they are sturdy and easily adapted to an industrial environment.

Process Parameters. Many factors affect the end result of laser surface hardening. Important is the hardenability of the workpiece material which is affected by its composition and prior thermomechanical

history. For the laser process, the key parameters are beam power density, uniformity of the beam, and processing speed. Following are some general processing guidelines (Sandven, 1991).

- The range of usable power densities for laser surface hardening is 3200 W/in.^{2} (500 W/cm^2) to 32,000 W/in.^{2} (5000 W/cm^2) with beam dwell times ranging from 0.1 to 10 sec; higher power levels would melt the surface.
- Alloys with high hardenability can be processed at low speed with low power density to produce relatively thick cases.
- Alloys with low hardenability should be processed at high speed with high power density; the result is a shallow case.
- Beam configuration can be rectangular, square, or round; uniform energy density within the beam is very important.
- Maximum achievable surface temperature is proportional to the square root of the processing speed; thus doubling the beam power density requires the processing speed to be increased by a factor of four to maintain the equivalent maximum surface temperature.
- Smaller workpieces are not as effective a heat sink as larger workpieces, and hence self-quenching may have to be assisted by quenching media.

Process Limitations. The depth of hardness that can be practically achieved is limited by the surface melting point. Because of the high beam energy density, heat flow on complex-shaped surfaces, particularly those involving sharp corners or edges, can cause unexpected surface melting. Therefore, power density and process conditions must be carefully controlled.

It may be necessary to overlap passes of the laser beam, such as at the end of a complete pass around a cylinder. As a result, some tempering of the area already hardened occurs. The slower the processing speed, the greater the degree of tempering.

Deformation Processes

Deformation processes change the shape of an object by forcing material to flow plastically from one shape into another shape without changing mass or composition (Table 13.2.15). The initial shape is usually simple. This shape is plastically deformed between tools or dies to obtain the final desired geometry, properties, and tolerances. A sequence of such processes is generally used to progressively form material. Deformation processes, along with casting and machining, have been the backbone of modern mass production.

In addition to shape change, forming processes alter the microstructure of the workpiece and can improve material properties. Deformation processes are normally considered when (Semiatin, 1988):

- Part geometry is moderately complex
- Component properties and structural integrity are important

TABLE 13.2.15 Significant Factors in Modeling a Deformation Process

Process Component	Characteristics
Input material	Flow stress; workability; surface condition
Output material	Geometry; mechanical properties; dimensional accuracy and tolerances; surface finish
Deformation zone	Deformation mechanics; stress state; temperature
Tooling	Material and geometry; surface conditions; temperature
Tool/material interface	Friction and lubrication; heat transfer
Process equipment	Speed and production rate; power range; precision

- Sufficient production volume can amortize tooling costs

Deformation processes can be classified (Semiatin, 1988) as bulk forming processes and sheet forming processes.

Bulk forming processes (e.g., rolling, extrusion, and forging) are characterized by

- Input material form is a billet, rod, or slab
- Workpiece undergoes a significant change in cross section during forming

Sheet metal forming processes (e.g., stretching, flanging, and drawing) are characterized by

- Input material is a sheet blank
- Workpiece is deformed into a complex three-dimensional form without appreciably changing the cross section

The key to attaining desired shape and properties is controlling metal deformation (Altan et al., 1983). The direction of the metal flow, the magnitude of the deformation, the rate of deformation, and the processing temperatures greatly affect the properties of the formed part. Design of the end product and the required deformation process consists of these steps:

- Predict metal flow by analyzing kinematic relationships (e.g., shape, velocities, strain rates, and strains) between the deformed and undeformed part configurations
- Establish producibility limits
- Select the process equipment and tooling capable of operating within the producibility limits

A bulk forming process (forging) and a sheet forming process (bending) are described below as representative examples of deformation processes. The references listed at the end of the section should be consulted for further information on these unit processes.

Die Forging

Talyan Altan

Description and Applications. Forging involves the controlled plastic deformation of metals into useful shapes (ASM, 1988c). Deformation may be accomplished by means of pressure, impact blows, or a combination. In order to reduce the flow stress, forging is usually accomplished at an elevated temperature. Forging refines the microstructure of a metal and can improve its mechanical properties, especially in preferred directions. Forging can also be used for other purposes, such as to consolidate powder preforms by welding grains, eliminate porosity in castings, break up long inclusions in forgings, and demolish the dendritic structure resulting from casting (Altan, 1988a).

Forgings are generally considered when strength, reliability, fracture toughness, and fatigue resistance are important. Forgings are used in critical, high-load applications, such as connecting rods, crankshafts, transmission shafts and gears, wheel spindles, and axles. Military and commercial aircraft are major users of forgings for numerous critical items, such as bulkheads, beams, shafts, landing gear cylinders

and struts, wheels, wing spars, and engine mounts. Similarly, jet engines depend on forgings for disks, blades, manifolds, and rings.

Types of Forging Processes. There are two broad categories of forging processes: closed-die forging and open-die forging. *Closed-die forging*, also known as *impression die forging*, employs precision-machined, matching die blocks to forge material to close dimensional tolerances. Large production runs are generally required to justify these expensive dies. During forging, the die cavity must be completely filled. In order to ensure this, a slight excess of material is forged. Consequently, as the dies close, the excess metal squirts out of the cavity in a thin ribbon of metal, called flashing, which must be trimmed.

Isothermal forging in heated superalloy dies minimizes the die quenching effect, preventing the rapid cooling of the workpiece in cold dies. This allows complete die fill and the achievement of close dimensional tolerances for difficult to process materials, such as superalloys.

Open-die forgings are the least refined in shape, being made with little or no tooling (Klare, 1988). These forgings are large, relatively simple shapes that are formed between simple dies in a large hydraulic press or power hammer. Examples are ship propeller shafts, rings, gun tubes, and pressure vessels. Since the workpiece is always larger than the tool, deformation is confined to a small portion of the workpiece at any point in time. The chief deformation mode is compression, accompanied by considerable spreading in the lateral directions.

Key System Components. There are two major classes of forging equipment as determined by their principle of operation: forging hammer, or drop hammer, which delivers rapid impact blows to the surface of the metal, and forging press, which subjects the metal to controlled compressive force. Each of these classes of forging equipment needs to be examined with respect to load and energy characteristics, its time-dependent characteristics, and its capability for producing parts to dimension with high accuracy.

Forging hammers generate force through a falling weight or ram (Altan, 1988b). These machines are energy restricted since the deformation results from dissipating the kinetic energy of the ram. The forging hammer is an inexpensive way to generate high forging loads. It also provides the shortest contact time under pressure, ranging from 1 to 10 msec. Hammers generally do not provide the forging accuracy obtainable in presses.

Forging presses are either mechanical or hydraulic (Altan, 1988c). *Mechanical forging presses* are stroke-restricted machines since the length of the press stroke and the available load at various positions of the stroke represent their capacity. Most mechanical presses utilize an eccentric crank to translate rotary motion into reciprocating linear motion of the press slide. The blow of the press is more like a squeeze than an impact of a hammer. Because of this, dies can be less massive and die life is longer than with a hammer. *Hydraulic presses* are load-restricted machines in which hydraulic pressure actuates a piston that squeezes the die blocks together. Full press load is available at any point during the stroke of the ram. A hydraulic press is relatively slow, resulting in longer process time; this may cause undesirable heat loss and die deterioration.

Design Considerations. Preform design is the most difficult and critical step in forging design. Proper preform design assures defect-free flow, complete die fill, and minimum flash loss. Although metal flow consists only of two basic types, extrusion (flow parallel to die motion) and upsetting (flow perpendicular to the direction of die motion), in most forgings both types of flow occur simultaneously, leading to a very complex flow field. An important step in understanding metal flow is to identify the neutral surfaces. Metal flows away from the neutral surface in a direction perpendicular to the die motion. Ideally, flow in the finishing step should be lateral toward the die cavity without additional shear at the die–workpiece interface. This type of flow minimizes forging load and die wear. A milestone in metalworking is the use of CAD in establishing the proper design for preforming and finishing dies in closed-die forging (Gegel and Malas, 1988). Figure 13.2.12 illustrates the relationships between forging process variables and those of a forging press that must be understood in order to estimate process performance for a hot-forging operation.

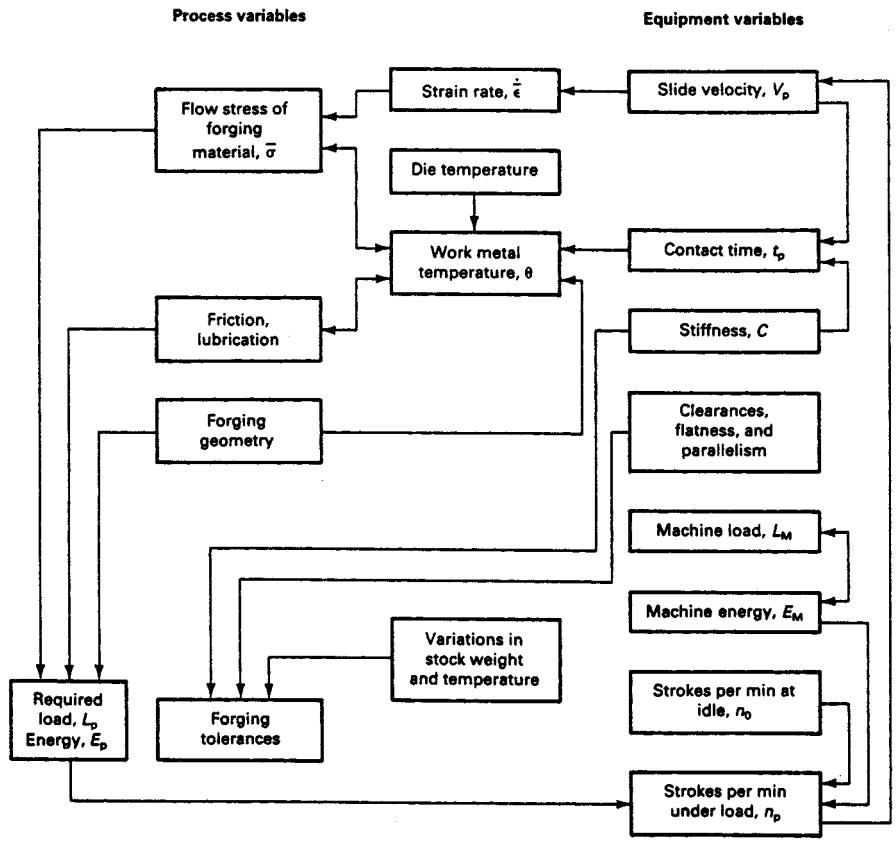

FIGURE 13.2.12 Relationships between process and machine variables in hot-forging processes conducted in presses. (From *ASM Handbook, Forming and Forging*, Vol. 14, 9th ed., ASM International, Metals Park, OH, 1988, 36. With permission.)

Designing a mechanical component that is to be made by forging together with the optimum geometry for the forging dies requires analysis of many factors (Altan, 1988a), including

- Design rules
- Workpiece material specification, and its critical temperatures
- Flow stress of the material at the process conditions (e.g., temperature, temperature gradient, strain rate, total strain)
- Workpiece volume and weight
- Frictional conditions in the die
- Flash dimensions
- Number of preforming steps and their configuration (flow field for the material)
- Load and energy requirements for each forging operation
- Equipment capability

In closed-die forging, it is particularly difficult to produce parts with sharp fillets, wide thin webs, and high ribs. Moreover, dies must be tapered to facilitate removal of the finished piece; draft allowance is approximately 5° for steel forgings (see Table 13.2.16).

TABLE 13.2.16 Typical Forging Defects and Mitigation Strategies

Defect	Description and Cause	Mitigation Strategy
Surface cracking	Fine cracks in the surface of the forging Possible causes: • Excessive working of the surface at too low a temperature • Brittle or low melting phases in the grain boundaries • Cracking at the die parting line	Increase the amount of preheating of the forging billet and forging die Change material specification Change furnace atmosphere to avoid diffusion of unwanted elements Increase the flash thickness Relocate the die parting line to a less critical location Stress relieve the forging prior to flash removal
Cold shut	Appears as a fold; occurs when two surfaces of metal fold against each other without welding Possible causes: • Poor metal flow in the die • Excessive chilling during forging • Poor die lubrication	Redesign forging die and/or forging preform to improve plastic flow of the metal during the forging operation Redesign the forging to avoid areas which are difficult to fill Increase the amount of preheating of the forging billet and forging die Improve die lubrication
Underfill	Incomplete forging in which all details are not produced Possible causes: • Debris residue in die • Scale on forging billet • Billet too small to completely fill die	Clean die thoroughly Completely descale the billet Redesign preform
Internal cracks	Cracks not visible from the surface, but detected during inspection and/or exposed during metal removal Possible causes: • Scale embedded in the internal structure of the forging • High residual tensile stresses	Completely descale the billet For open-die forgings, use concave dies Redesign for closed-die forging Use a hydraulic press and heated dies to avoid formation of excessive tensile stresses during forging

Press-Brake Forming

Description and Applications. Press-brake forming is a process used for bending sheet metal; the workpiece is placed over an open die and then pressed into the die by a punch that is actuated by a ram known as a press brake (ASM, 1988b). The main advantages of press brakes are versatility, ease and speed with which new setups can be made, and low tooling costs.

Press-brake forming is widely used for producing shapes from ferrous and nonferrous metal sheet and plate. Although sheet or plate 0.250 in. (10 mm) thick or less is commonly formed, metals up to 1 in. (25 mm) thick are regularly formed in a press brake. The length of a sheet is limited only by the size of the press brake. Forming can be done at room or elevated temperature. Low-carbon steels, high-strength low-alloy steels, stainless steels, aluminum alloys, and copper alloys are commonly formed in a press brake. Press-brake forming is applicable to any metal that can be formed by other methods, such as press forming and roll forming.

Press-brake forming is considered for bending sheet metal parts when the production quantities are small, dimensional control is not critical, or the parts are relatively long. In contrast, press forming would be considered when production quantities are large, tolerances are tight, or parts are relatively small. Contour roll forming would be another option for high-rate production applications (ASM, 1988c).

Principle of Operation. Bending is a method of forming sheet metal by stressing a material beyond its yield strength while remaining below its ultimate strength so that cracking is avoided. In press-brake forming the tooling and setup are relatively simple. A workpiece is placed over a die, typically having a V-shape. The bend angle is determined by the distance the workpiece is pressed into the die by the

punch. The width of the die opening (top of the V) affects the force needed to bend the workpiece. The minimum width is determined by the thickness of the workpiece and the radius of the punch nose.

Key System Components. A *press brake* is basically a slow-speed punch press that has a long, relatively narrow bed and a ram mounted between end housings. Rams are mechanically or hydraulically actuated. Figure 13.2.13 depicts a typical setup for press-brake forming.

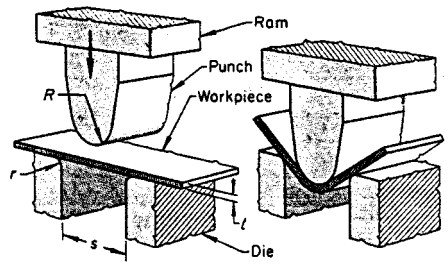

FIGURE 13.2.13 Typical setup for press-brake forming. (From *ASM Handbook, Forming and Forging*, Vol. 14, 9th ed., ASM International, Metals Park, OH, 1988, 533. With permission.)

V-bending dies and their corresponding punches are the tools most commonly used in press-brake forming. The width of the die opening is usually a minimum of eight times the sheet thickness.

Process Parameters. Capacities of commercial press brakes range from 8 to 2500 tons. Required capacity is governed by the size and bending characteristics of the work metal and by the type of bend to be made (ASM, 1988b).

The nose radius of the punch should not be less than the work-metal thickness for bending low-carbon steel, and must be increased as the formability of the workpiece material decreases. The radius of the V-bending die must be greater than the nose radius of the punch by an amount at least equal to the workpiece thickness to allow for the bottoming of the punch in the V.

It is preferable to orient a bend so that it is made across the rolling direction rather than parallel to it. Sharper bends can be made across the rolling direction without increasing the probability of cracking the material. If bends must be made in two or more directions, the workpiece should be oriented on the sheet layout such that none of the bends will be parallel to the rolling direction.

Springback after press-brake bending is considered only when close dimensional control is needed. It can be readily compensated for by overbending. Factors that affect springback include the mechanical properties of the work material, the ratio of the bend radius to stock thickness, the angle of bend, the method of bending, and the amount of compression in the bend zone. A greater amount of overbending is needed to correct for springback on small bend angles than on large bend angles.

Capabilities. The generally accepted tolerance for dimensions resulting from bending of metal sheet in the press brake is ±0.016 in. (±0.4 mm) up to and including 0.125 in. (3 mm) thickness (ASM, 1988b). For heavier gauges, the tolerance must be increased accordingly. Achievable tolerances are influenced by the part design, stock tolerances, sheet metal blank preparation, the condition of the machine and its tooling, and operator skill.

Design Factors. In press-brake forming, as in other forming processes, the metal on the inside portion of the bend is compressed or shrunk, and the metal on the outside portion is stretched. This results in a strain gradient across the thickness of the workpiece in the area of the bend with tensile strain on the outside and compressive strain inside. These residual strains (and resulting stresses) can lead to distortion of the part under loading conditions, heating, or cooling.

The formability of metals decreases as the yield strength approaches the ultimate strength. In press-brake forming, as the yield strength of the work metal increases, power requirements and springback problems also increase, and the degree of bending that is practical decreases.

There are several factors which will make it difficult to establish or maintain accurate placement of a bend line in a press brake. Corrective action may require a design change or change in processing sequence.

- Bends or holes that are located in close proximity to the required bend line can cause the position of the bend line to wander.
- Notches and cutouts located directly on the bend line make it difficult to maintain an accurate bend location.
- Offset bends will shift location unless the distance between bends in the offset is at least six times the thickness of the workpiece material.

If multiple bends must be made on a workpiece, it may not be possible to avoid a bend that is parallel to the rolling direction. Depending on the degree of texture in the sheet and the anisotropy of the material, a change to a higher-strength material may be necessary to achieve the desired geometry.

Consolidation Processes

Consolidation processes fuse smaller objects such as particles, filaments, or solid sections into a single solid part or component to achieve desired geometry, structure, and/or property. These processes use either mechanical, chemical, or thermal energy to bond the objects. Interaction between the material and the energy that produces the consolidation is a key feature of the process.

Consolidation processes are employed throughout manufacturing, from the initial production of the raw materials to final assembly. One group of processes involves the production of parts from powders of metals, ceramics, or composite mixtures. The resultant consolidated products are typically semifinished and require further processing. For instance, the consolidation of powders produces bar, rod, wire, plate, or sheet for upstream processes.

The consolidation of net shape composite structures (i.e., require minimal finishing work) is an increasingly important area. The design of the structural geometry, selection of material, and choice of consolidation processes all act together to provide the required level of performance. There are two types of matrix materials used: themosetting and thermoplastic. The consolidation process of each of these types of resins is different. A unit process described in this section addresses the consolidation of composites using polymeric thermosetting resins.

An important family of consolidation processes includes welding and joining processes used to permanently assemble subcomponents. Historically, welding and joining processes are developed empirically and quickly evaluated for benefit in manufacturing applications, driven by the promise of significant potential benefits. The need for welding and joining is substantial since only monolithic parts can be made without joining. The ideal joint would be indistinguishable from the base material and inexpensive to produce (Eagar, 1993). However, experience indicates that no universal joining process exists that can entirely satisfy the wide range of application needs, and thus design engineers must select the most appropriate joining methods that meet requirements. Shielded metal-arc welding, the most widely-used welding process, is described in this section.

The unit processes described here are a representative sample of the types most likely to be encountered. The references listed at the end of the section should be consulted for detailed information on these unit processes.

Polymer Composite Consolidation

Weiping Wang, Alan Ridilla, and Matthew Buczek

A composite material consists of two or more discrete materials whose combination results in enhanced properties. In its simplest form, it consists of a reinforcement phase, usually of high modulus and strength, surrounded by a matrix phase. The properties of the reinforcement, its arrangement, and volume fraction typically define the principal mechanical properties of a composite material. The matrix keeps the fibers in the correct orientation and transfers loads to the fibers.

Continuous-fiber-reinforced materials offer the highest specific strengths and moduli among engineering materials. For example, a carbon fiber/epoxy structural part in tensile loading has only about 20% of the weight of a steel structure of equal stiffness. Composite parts can integrate component piece parts, such as molded-in rib stiffeners, without the need for subsequent assembly operations and fasteners.

Description and Applications. There are many types of polymer composites in use. Composities are usually identified by their fiber material and matrix material. Fiber materials are necessarily strong, stable materials that can be processed into fiber formats. Typcial fibers are glass, graphite/carbon, aramid, and boron. *Glass* fibers represent the largest volume usage since they have excellent properties and are low cost. *Graphite/carbon* fibers are widely used for advanced composite applications in which stiffness and high performance are critical. These fibers are also expensive. *Aramid* fibers, a type of polyamide, have proved useful in applications where its performance in axial tension can be exploited without incurring too severe a penalty by the material's poor performance under compressive loading. *Boron* filaments have high strength and high modulus, but most applications requiring high performance, such as military aircraft structures, are now using carbon fibers.

Low-cost *polyester* resins are the most widely used matrix material for the general composite industry; the majority of these application use glass as the fiber. Many applications are found in the chemical process, construction, and marine industry. The most widely used polymers are *epoxy* resins, which are used with carbon, aramid, and boron fibers for many advanced applications, such as in aircraft structure and rocket motor fuel tanks. *Polyimides* are polymer resins that provide more temperature performance than is possible from the epoxy-based material, and these are used in advanced aircraft structures and jet engine components where heating of the structure will occur.

Principle of Operation. Each of the constituent materials in advanced composites acts synergistically to provide aggregate properties that are superior to the materials individually. The functional effectiveness

of composites is principally due to the anisotropy of the materials and the laminate concept, where materials are bonded together in multiple layers. This allows the properties to be tailored to the applied load so that the structure can be theoretically more efficient than if isotropic materials were used. The reinforcements come in a variety of formats. Unidirectional tapes with all fibers along a common axis, woven fabrics constructed with fibers along both axes in the *x-y* plane, and multidimensional architectures with reinforcements in more than one axial direction are just a few of the available formats.

Consolidation in composites can be considered to occur at two levels: the fibers are infiltrated with the matrix to form a lamina or ply, and the individual laminae are consolidated together to form the final structure. In the prepreg process, these two levels are distinctly separated, since the fiber/matrix consolidation process forms the prepreg, which is then laid up to form the laminate or final component. In other processes, such as resin transfer molding, fiber/matrix infiltration and the consolidation of the final part are done in a single stage. Single-stage consolidation processes are attractive because they eliminate the additional cost associated with prepreg production; however, two-stage consolidation processes have major advantages that often outweigh the benefits of single-stage consolidation. These include flexibility in part geometry, high fiber content, excellent fiber wet-out, and better control of fiber volume fraction distribution. Because of these advantages, prepreg processing is firmly entrenched in high-value products, such as aerospace applications, in spite of its high cost.

Fabrication Methods. Typical steps in manufacturing continuous-fiber composites involve *preform fabrication* and consolidation/curing (Advani, 1994). Preform fabrication creates the structure by positioning material close to the final part shape (Table 13.2.17). The material comes in either the *dry fiber* (without resin) form or with resin included, called prepreg. Dry fibers are used in filament winding, weaving, braiding, and pultrusion. The resin can be introduced in the operation or downstream molding. *Prepreg*, at a higher material cost, eliminates the step of resin addition and provides the adhesion to hold the material together. Consolidation/curing involves compacting the preform to remove entrapped air, volatiles, and excess resins while developing the structural properties by increasing the polymer chain length and cross-linking.

Process Parameters. Thermosetting polymeric materials will not soften and flow upon reheating after polymerization because of the formation of a cross-linked polymer network. Hence, thermosetting polymer matrices must be cured *in situ* with the fibers to form the composite structure. The goals of a successful cure are good consolidation with low porosity and high conversion of initial monomeric constituents to polymer.

The challenge of the cure process is to manage the interactions of temperature distribution, degree of cure, laminate thickness, and void content by manipulating the applied temperature, pressure (or displacement), and vacuum. Temperature must be controlled so that resin temperature stays within limits. Both the duration and the magnitude of pressure application are important as excessive resin flow results in a resin-starved laminate. Similarly, pressure application too soon in the process can entrap volatiles in the material. Materials can also exhibit lot-to-lot variability. The problem is further complicated when processing a complex-shaped part or multiple parts of different geometry.

Composite cure processes are typically performed in an autoclave or in a heated press. An *autoclave* is essentially a heated pressure vessel. Nitrogen gas is normally used for pressurization. The temperature, pressure, and vacuum are controlled vs. time to effect the cure. Recent advancements in *intelligent processing* use sensors to determine the state of cure in real time, and make appropriate control adjustments to optimize the cure cycle (NRC, 1995). Figure 13.2.14, which plots data from an actual implementation, depicts the potential that intelligent processing has in reducing autoclave processing time and cost.

Press molding uses a high-pressure press and matched metal tools to form a part. The main components of a press-molding system include the tools, the ram, and the heated platens. Again, release materials must be applied to the tools to avoid laminate adhesion. Advantages of press molding include improved surface finish (since both sides are tooled) and the elimination of the vacuum bagging systems. However, the pressure inside the mold is not necessarily uniform and volatiles are not easily removed. Hence,

TABLE 13.2.17 Methods of Composite Preform Fabrication

Method	Description	Application
Weaving	Process of interlacing yarns to form a stable fabric construction that is flexible Less frequent interlacing results in better composite strength	Closely conforms to surfaces with compound curvature
Braiding	Intertwines parallel strands of fiber A tubular braid consists of two sets of yarn which are intertwined in "maypole dance" fashion; produced with varying diameter or circumferential size	Sporting equipment Good torsional stability for composite shafts and couplings Geometric versatility and manufacturing simplicity
Pultrusion	Reinforcing fibers pulled from a series of creels through a resin impregnating tank; preformed to the shape of the profile to be produced; enters a heated die and is cured to final shape	Produce constant cross-section pieces at high production rates
Filament winding	Pulling roving (unlisted bundles of fibers) over a mandrel by rotating the mandrel about a spindle axis; can cure on the mandrel	Cylindrical parts Can be low cost
Tube rolling	Material cut from prepreg tapes and laid on a flat surface; plies of different orientations joined together; a cylindrical mandrel is rolled on the material; curing is typically done on the mandrel	Low-cost method for making tubular structures or tapered tubes, e.g., golf shafts
Manual layup	Plies of different fiber orientations are cut from flat sheets of the prepreg material and laid up on a tool; bagging materials are applied and sealed to the tool for subsequent consolidation Flexible in producing complicated features at low start-up/tooling cost; building a curved, variable-thickness part can be complicated	Most common method used in the aerospace industry
Automatic tape layup	Computer-controlled machine tools or robots with a material delivery system • Automated tape layup machine uses prepreg tape, typically 3 to 12 in. wide, suitable for large surface of gentle contours • Fiber placement employs multiple tows for more complex surfaces	Provides lower cost and variability over manual layup, but requires higher capital investment

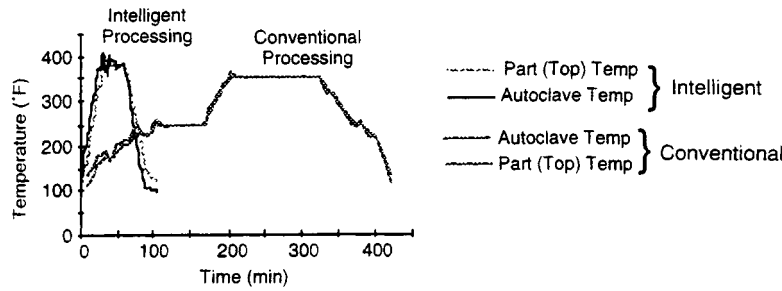

FIGURE 13.2.14 Intelligent processing of composites. (From NRC, *Expanding the Vision of Sensor Materials*, NMAB-470, National Academy Press, Washington, D.C., 1995, 39. With permission.)

press molding is generally suitable for composite systems which do not generate a significant amount of volatiles.

Shielded-Metal Arc Welding

Description and Applications. Bonding is achieved in fusion welding by interposing a liquid of substantially similar composition as the base metal between the surfaces to be joined (Eagar, 1993). The need for welding and joining is substantial since only monolithic parts can be made without joining. Traditional welding processes have unique advantages, which make them the processes of choice for a large number of applications. For example, in the fabrication of heavy structures, arc welding will dominate other assembly processes because of the inherent flexibility and economy of welding.

Principle of Operation. In the majority of arc-welding methods, the workpiece is made part of the electric welding circuit, which has as its power source a welding generator or transformer. To start a weld, an arc is struck by touching the workpiece with the tip of the electrode. The welder guides the electrode by hand in welding a joint, and controls its direction and traveling speed. The welder maintains arc voltage by controlling arc length (the distance between the end of the electrode and the work surface). Because an electric arc is one of the hottest sources of heat, melting occurs instantaneously as the arc touches the metal. Arc welding is a highly popular process because of its flexibility and relatively low cost (ASM, 1993).

In shielded-metal arc welding, an arc is struck between the workpiece and a covered (or coated) metal electrode. Filler metal is provided by the consumable electrode. Combustion and decomposition of the electrode covering from the heat of the welding arc produce a gaseous shield that excludes the oxygen and nitrogen in the atmosphere from the weld area; these gases would otherwise cause excessive porosity and poor ductility in the weld. Welds by this method are of very high quality (Juers, 1993). Figure 13.2.15 depicts the components of the shielded-metal arc welding process.

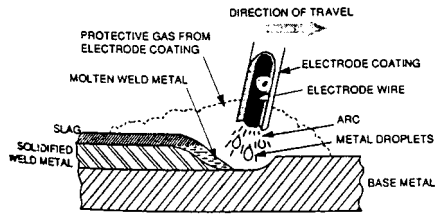

FIGURE 13.2.15 Shielded-metal arc-welding process. (From *ASM Handbook, Welding, Brazing, and Soldering*, Vol. 6, 10th ed., ASM International, Metals Park, OH, 1993, 175. With permission.)

Key System Components. For shielded-metal arc welding, the metallurgical properties of a weld depend greatly on the type of electrode and its covering. The *electrode coverings* contain shielding gas formers that exclude atmospheric gases from the weld area. Electrode coverings offer additional capabilities (Juers, 1993):

- Deoxidizers and nitrogen absorbers to purify the depositing metal
- Slag formers to protect the weld from oxidation
- Ionizing elements to stabilize the arc
- Alloying elements to produce higher-strength welds
- Iron powder to increase metal deposition rate

Selection of the proper electrode is based on many considerations (Juers, 1993):

- Base metal strength
- Base metal composition
- Welding attitude (position)
- Welding current
- Joint design and fit
- Base metal thickness and shape
- Service conditions
- Production efficiency and conditions

Many types and sizes of *power supplies* are used. Supplies can be either direct current (DC) or alternating current (AC) types; combination AC/DC power supplies are widely used. In general, power supplies are required that produce controllable levels of constant-current output. The rate of metal deposition is determined by the output current from the power supply.

Capabilities. Shielded-metal arc welding is the most widely used welding process for joining metal parts, principally because of its versatility. Also, the welding equipment is less complex, more portable, and less costly than for other arc-welding processes.

Shielded-metal arc welding is generally very useful in joining components of complex structural assemblies. Joints in virtually any position that can be reached with an electrode can be welded, even if directly overhead. Joints in blind areas can be welded using bent electrodes. Welding in positions other than flat require the use of manipulative techniques and electrodes that cause faster freezing of the molten metal to counteract gravity. Shielded-metal arc welding can be done indoors or outdoors.

Metals welded most easily by the shielded-metal arc process are carbon and low-alloy steels, stainless steels, and heat-resistant alloys. Cast iron and high-strength steels can also be welded but preheating and postheating may be required. Shielded-metal arc-welding electrode materials are available for matching the properties of most base metals; thus, the properties of a joint can match those of the metals joined.

Design Considerations. Joint design (shape and dimension) is determined by the design of the workpiece, metallurgical considerations, and established codes or specifications.

Welds should preferably be located away from areas of maximum stress. Poorly placed welds can result in undesirable, and unplanned, stress concentrations that can cause early failure of the joint.

Poor joint fit-up increases welding time and is often the cause of poor welds.

Process Limitations. Metals with a low melting point, such as zinc, lead, and tin, cannot be welded by electric arc methods.

Limitations of shielded-metal arc welding compared with other arc-welding methods are related to metal deposition rate and deposition efficiency. Consumable electrodes have a fixed length, usually 18 in. (460 mm), and hence welding must be stopped periodically to replace the electrode. Another limitation is the requirement to remove the slag covering that forms on the weld after each welding pass.

There is a minimum gauge of sheet that can be successfully welded without burn-through. Generally 0.060 in. (1.5 mm) is the minimum practical sheet thickness for low-carbon steel sheet that can be welded by a welder possessing average skill (Juers, 1993).

Special techniques are required when welding pieces of unequal thickness because of their different heat dissipation characteristics. Solutions include

- Placing a copper backing plate against the thinner section to match the heat dissipation from the thick section
- Redesigning the component so that the thick and thin sections taper at the joint to approximately the same size

Distortion is unavoidable in welding because of residual stresses that arise from nonuniform heating and cooling. Various procedures can be used to minimize distortion, such as clamping the workpieces. But straightening of the workpiece may be required to achieve the required dimensional accuracy.

Mechanical Assembly

S. H. Cho

Total labor involved in the assembly processes in the U.S. varies from 20% (farm machinery) to almost 60% (telecommunications equipment). On average, assembly tasks occupy 53% of manufacturing time, and 10 to 30% of total production cost of most industrial products. Use of improved assembly methods and technologies is essential to reduce overall manufacturing costs.

Assembly Methods and Systems

Assembly systems are classified in several different ways (Table 13.2.18). Figure 13.2.16 indicates the types of automated systems that could be cost-effective based on assembly part count and production volume.

Generally, *automatic assembly systems* consist of three major components:

- *Transfer system* to move work carriers with in-process subassemblies between workstations;
- *Parts feeding device* to supply parts to be assembled into the appropriate position, where the parts are loaded by the handling/placing mechanism;
- *Parts handling/placing mechanisms* to pick parts and perform assigned assembly tasks such as placing, inserting, and screwing.

TABLE 13.2.18 Classification of Assembly Systems

Type of Assembly System	Classification Basis	Description
Manual	Level of automation	Assembly tasks completed manually
Automatic	Level of automation	Adopts mechanized devices or industrial robots with supplementary equipment for handling and assembling parts
Semiautomatic system	Level of automation	Manual workers and mechanized devices cooperate to complete assembly tasks
Cell-type system	Configuration	Very flexible integrated assembly workstation; assembly completed by various equipment, such as robots or pick-and-place units, parts feeders, parts tray, magazines, automatic tool changer, and auxiliary jig/fixtures
Line-type system	Configuration	Assembly tasks divided into subtasks which are completed at workstations connected by transfer systems; handles large parts, cycle-time variation, and gripper change
Dedicated system	Degree of flexibility	Not flexible — can assemble only one product of a single model; generally economical for large production volumes
Flexible system	Degree of flexibility	Accommodates different products; economical for medium-size and mixed-model production

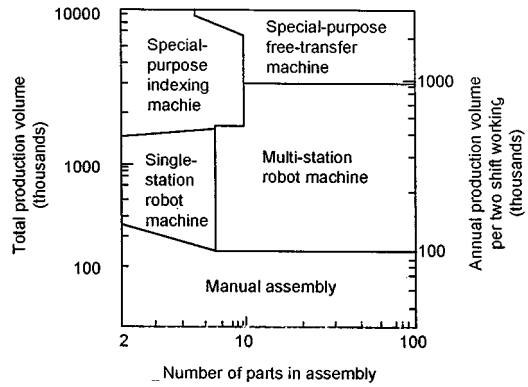

FIGURE 13.2.16 Conditions for economic application of various assemby systems. (Courtesy of S. H. Cho.)

The *transfer system* can be continuous or intermittent according to the transfer method. In the *intermittent transfer system*, assembly tasks in a workstation are performed during a stationary period of the work carriers, which are transferred to the subsequent workstation after completion of the assembly tasks. *Continuous transfer systems* have a problem of not being able to assure positioning accuracy between an in-process subassembly and the tools of a workstation; thus, the intermittent type is usually used (Boothroyd, 1992).

There are two modes of *intermittent transfer:* in-line and rotary. For the *in-line* mechanisms, the walking beam, the shunting work carrier, and the chain-driven work carrier are commonly used. The *rotary* type employs mechanisms such as rack and pinion, ratchet and pawl, Geneva mechanism, and mechanical cam drives. Currently, free-transfer conveyors with stopping and positioning mechanisms are widely used in flexible assembly lines.

Most *feeding systems* have devices to orient parts supplied by the following means (Yeong and Vries, 1994):

- *Bulk supply,* for parts that are easily separated, fed, and oriented automatically. Bulk supply usually adopts various part feeders, e.g., vibratory bowl feeders and various nonvibratory mechanical feeders for small parts. These feeders usually only handle one type of part and cannot be applied to assembly systems which require flexible part-feeding devices.

- *Organized supply* uses special pallets such as a kit or a magazine for parts that cannot easily be separated, fed, and oriented.

Parts-handling/placing mechanisms include pick-and-place units and various types of industrial robots. To load and assemble parts, the mechanism usually employs various assembly wrists: jaw-type gripper, vacuum suction pad, magnetic chuck, screwdriver, nut runner, and others. A number of different wrists are required when automatically assembling different parts in a workstation. To accommodate this assembly situation, a multifunctional gripper, a tool-changing system, and a universal gripper have been developed and widely used in robotic assembly systems.

Selection of Assembly Systems

The placement of a part in its assembled position and part mating impose tight constraints on the positioning mechanism and on part properties such as clearances and geometry. These constraints are more severe for assembly systems mating a variety of precision products that must adapt to frequent design changes. The assembly systems of this type must possess the adaptability to changing assembly environments, thus requiring *flexible automatic assembly* (Boothroyd, 1984).

A typical *flexible robotic assembly system* uses an industrial robot for part handling, part positioning, and part mating. These systems are limited by positioning and orientation misalignment caused by the low positioning accuracy of robots, uncertainty in part handling, and variation in the location of parts.

Various approaches are available that take into consideration uncertainty in orientation and parts properties variation. Figure 13.2.17 depicts various types of assembly wrists that are in use. In general, wrists can be classified into three basic configurations:

- Passive accommodation;
- Active accommodation;
- Passive-active accommodation.

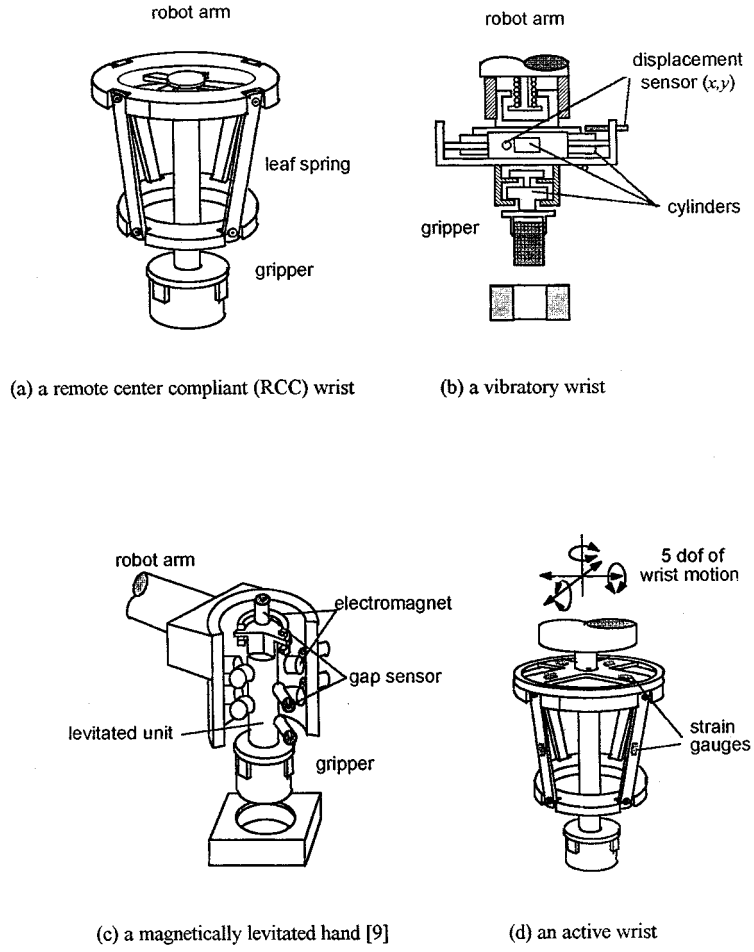
There are two types of *passive wrist methods:*

- Wrist accommodates misalignments by deforming its structure elastically under the influence of the contact forces generated during the assembly of the misaligned parts. A *mechanically compliant structure* is needed for either the robot wrist or the assembly worktable, which can be deformable according to the reaction force acting on the mating parts. Remote center compliant wrist is one of such typical wrists; this method usually requires part chamfering (Cho et al., 1987).
- Wrist corrects misalignment by *applying external forces* or torques to the misaligned parts in a prescribed manner or a random way. For instance, a vibratory wrist utilizes pneumatic actuators controlled by a pulse width modulation controller to generate desirable vibration; this method does not require part chamfering.

Active wrist methods employ sensor-controlled wrists and compensate misalignments by controlling the fine motion of the assembly wrist or the work table based upon sensory feedback. Advances have been made in the area of sensing technique, gripper and actuating mechanism design, and the related control algorithms. Sensors for these wrists are needed prior to contact (vision, range, displacement, proximity), during contact (touch, slip), and after contact (force, moment). Based upon the force sensor signals and the associated algorithms, the wrist motion can be corrected to reduce misalignment.

The *passive–active accommodation method* is achieved by combination of the “passive and active” techniques. The basic strategy is that the part mating is continued within some allowable forced moments, while beyond this the insertion method is switched from the passive to active to reduce the mating force by using sensors with compliant structures.

The *sensor-based assembly* is similar to the method employing the active wrist. Both rely on sensory information for fine-motion control. The principal difference is that the former utilizes robot motion, while the latter relies on wrist motion.



(a) a remote center compliant (RCC) wrist (b) a vibratory wrist

(c) a magnetically levitated hand [9] (d) an active wrist

FIGURE 13.2.17 Various assembly wrists. (Courtesy of S. H. Cho.)

Reaction forces (*force/torque information*) that occur during part mating can represent the status of the contact between mating parts. Among the approaches are pattern classifiers that determine the contact state at which the assembly parts are contacting each other, position error recovery via fuzzy logic, heuristic search with fuzzy pattern matching, and learning of nonlinear compliance using neural network.

Visual/optical information is critical to compensate for positioning and orientation error occurring due to misalignment. Visual information is often combined with other data, such as force/torque, pressure, and displacement, because a rather longer time is required for image processing, object recognition and error calculation and because visual information is sensitive to external environmental conditions such as illumination.

Assembly Line

An assembly line usually consists of a set of workstations that perform distinct tasks linked together by a transfer mechanism. Each task is an assembly operation, while each workstation represents a location along the line where the tasks are processed. A buffer storage is placed between workstations for reducing the effect of a workstation failure on the throughput.

Line balancing is essential for designing a cost-effective assembly system (Groover, 1980). The time required for the completion of a task is known as the process time, while the sum of the process times

of the tasks assigned to a station is the station time. The total task processing times for assembling all the parts is the work content. When *assembly sequences* are generated without considering line balancing, the sequences may not guarantee the minimum number of workstations. Therefore, line balancing must be concurrently considered in defining the assembly sequences.

Design for Assembly

Approximately 80% of manufacturing cost is determined at the conceptual design stage. Design for assembly (DFA) is crucial during early design. The objective of the DFA is to facilitate the manufacturing and assembly of a product. DFA applies to all the assembly operations, such as parts feeding, separating, orienting, handling, and insertion for automatic or manual assembly (Ghosh and Gagnon, 1989).

DFA is directed toward:

- Reducing the number of parts by modularization;
- Easing feeding and minimizing reorientation;
- Easing insertion by self-aligning, self-locating, elimination of part interference, and efficient fastening.

Axiomatic DFA uses design guidelines based on experience of product designs and assembly operations. *Procedural DFA* evaluates the design efficiency based upon the production cost.

Figure 13.2.18 shows results that were obtained using DFA rules to evaluate part designs in consideration of feeding and insertion. Such analysis has great potential in improving assembly operations.

Material Handling

Ira Pence

Material handling provides the right amount of all the required materials at the right place and time to support manufacturing. Properly designed, the material-handling system provides for the acquisition, transportation, and delivery of material such that the minimum cost is incurred considering capital, labor, and expenses. It focuses on obtaining material and supplies, moving them between process steps, and delivering the finished product to the customer. Figure 13.2.19 depicts the elements of a modern materials-handling system which reaches beyond the factory floor, serving as an integrating force for production operations.

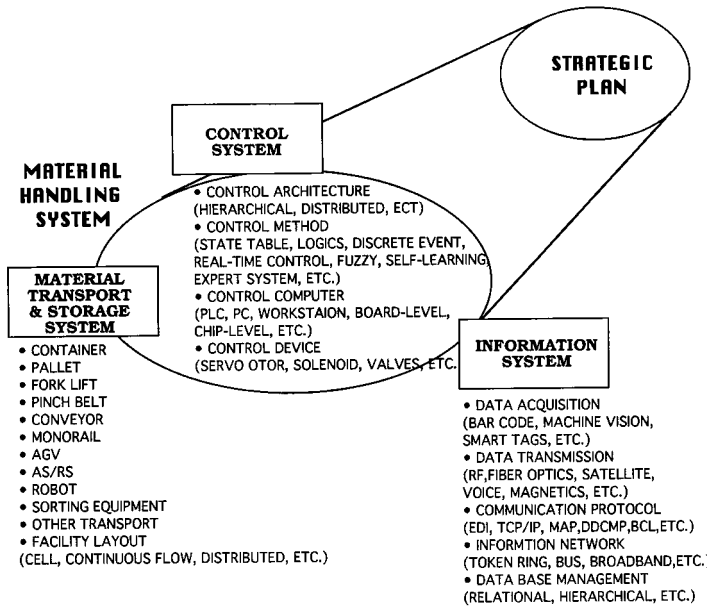

FIGURE 13.2.19 Modern material-handling system. (Courtesy of J. Lee.)

The material-handling system should be analyzed as a single entity so trade-offs in expense in various elements can be made to minimize the total cost. Often, however, the activities are broken into purchasing, transportation, warehousing, and distribution functions which operate independently. Such divisions are arbitrary because the material-handling system is an unbroken chain of activities that start when the suppliers complete their last value-added operation and extend until the product is delivered. Minimum-

cost material handling will not be achieved if the partitioning of material flow into subelements leads to optimization of each subelement at the expense of the entire system.

Planning is crucial to the design of a smoothly functioning materials operation. Planning should be consistent with the strategic plan for the entire manufacturing operation. In formulating the plan, a realistic assessment of the problems and opportunities associated with arranging, controlling, and implementing the material flow must be used. Specific tactics, such as just-in-time delivery, should support the strategic plan. Expensive automation should not be used unless the volume and stability of the product justify its use.

Logistics

The movement of material in a manufacturing enterprise is usually broken into two broad categories, inside the plant and external to it. External movement is generally referred to as "logistics," while the internal flow is known by many different names. Material movement considered logistics is generally marked by a wide geographic scope, diversity of equipment and technology, and some uncertainty in delivery time. But the basic goals are identical to in-plant movement and most of the analysis tools are applicable to both categories.

For large manufacturing enterprises the number of individual components involved in the production of the product, often referred to as SKUs (stock keeping units), can be very large. In the past, it was helpful to treat items of similar size, weight, storage requirements, and delivery times as a single commodity. This simplified manual analysis and was sometimes done by computer programs that analyze logistical information. However, current computer systems make it practical to treat each item individually.

Basic Elements

The basic activities associated with material handling are *moving*, *storing*, and *controlling* materiel. These activities are interrelated with production scheduling and information must flow both ways.

Movement may be over short distances, as from one machining center to another, or long, from one plant to another. In all cases the basic information that must accompany the move includes the part identity, timing, quantity, source, and destination. Each move should be planned and scheduled, taking into account the speed of the basic mechanism as well as allowance for loading, unloading, logging, counting, etc.

Movement can be continuous or in batches, synchronous or asynchronous, horizontal or vertical. Each move should be examined for the characteristics of urgency, safety, size, weight, etc. before selecting the technology to be used to perform the move. Singular instances should be accommodated in the most expeditious manner, and repetitive moves must be made in the most efficient and effective manner.

One of the basic tenets of material handling is to retain *control* of the material. Inventory control generally maintains up-to-date records on the quantity and location of material on hand. However, in a *virtual warehouse*, it is important to know what material has been ordered and the status. Control includes procedures and equipment to properly handle the material.

The *storage* of material should be minimized. Materials are typically stored to compensate for uncertainty in delivery systems and to allow ordering of economic quantities.

Occasionally unexpected changes in production will result in delaying the release of material to the factory floor and that material must be stored until needed. *Just-in-time delivery*, where parts are delivered directly from local suppliers to the assembly line several times a day, has been proved in several industries. Thus, the need for storage due to uncertainty of delivery has been reduced. At the same time, global sourcing has increased. As supply lines lengthen, the uncertainty of delivery increases. The more complex the supply system, the more likely the occurrence of an unexpected delay. In designing a storage system, the trade-off of higher transportation cost but less inventory vs. volume discounts on purchases and transportation, but with storage costs, must be evaluated.

Further Information

The Material Handling Industry produces two catalogs each year. One provides information on the publications available from the MHI, including all the educational material; standards and specifications; operating, maintenance, and safety manuals; and reference works. The other provides a directory of member companies and the products they manufacture. Both are available from the MHI Literature Department (704) 522-8644; FAX (704) 522-7826.

Case Study: Manufacturing and Inspection of Precision Recirculating Ballscrews

Toskiaki Yamaguchi, Yashitsugu Taketomi, and Carl J. Kempf

The precision and quality of the components of mechanical devices used in both industrial and consumer products must meet high performance and durability requirements. The manufacturing challenges that apply to ballscrews, in general, are representative of other components such as gears, shafts, and bearings. This case study on precision ballscrews illustrates how the different unit manufacturing processes presented in this chapter apply to a particular application, and how design and manufacturing engineering decisions are affected by quality and cost considerations.

Many of the processing steps and fundamental techniques discussed in this case apply to the manufacture of many other precision components. The case study also illustrates the rationale for continuously improving production processes and discusses strategies for improvement that benefit from past experience.

Overview of Ballscrew Design and Manufacturing Considerations

Ballscrews convert rotary motion into linear motion. Ballscrews have low friction compared with standard leadscrews, and have enabled precise control of mechanical systems at a relatively low cost. They are used extensively in production machinery, such as milling machines, and are being applied in other fields, such as robotics, inspection equipment, and office automation equipment.

The key components of a ballscrew system consist of a screw shaft with a spiral groove, a nut with a corresponding spiral groove that rides along the shaft, and balls which are captured between the shaft and the nut. A recircultation tube provides a return path for the balls from the end of the nut. Components in this assembly are typically made from steel alloys, chosen to provide a good combination of toughness, surface hardness, and ease of manufacture.

Ballscrews are applied in a variety of ways, but the most common configuration is one in which a rotational input of the shaft imparts a translational motion to the nut. The shaft is normally supported by rotating bearings at both ends, and the translating element attached to the nut is supported by linear guide bearings. Ballscrews range in size from very small units with a shaft diameter on the order of 0.08 in. (2 mm) and a length of about 4 in. (100 mm) to very large units with a shaft diameter on the order of 12 in. (300 mm) and a length of up to 50 ft (16 m). Key dimensional features which are controlled to a high degree of precision for an assembled ballscrew system are shown in Figure 13.2.20.

The main factors in ballscrew performance are accuracy and lifetime. *Accuracy* is determined primarily by the precision of the screw lead, i.e., the linear displacement of the nut which is produced by rotary displacement of the shaft. The measurements used to assess the *precision* of the lead are discussed below. To obtain a *long lifetime*, the shaft must have high surface hardness in order to withstand loads at the shaft/ball and nut/ball interfaces. Since ballscrews may be subject to a variety of loading conditions, the ballscrew must possess good impact strength and toughness.

Secondary design factors include low audible noise, low static and dynamic friction, low friction variation, minimal backlash, high mechanical stiffness, and resistance to dirt and contaminants. Ballscrews are often used in specialized applications, such as operation in vacuum or ultraclean environments, in corrosive or dirty environments, in a thermally controlled environment, and in environments where vibrations must be minimized. To meet these demands, basic ballscrew designs are adapted to

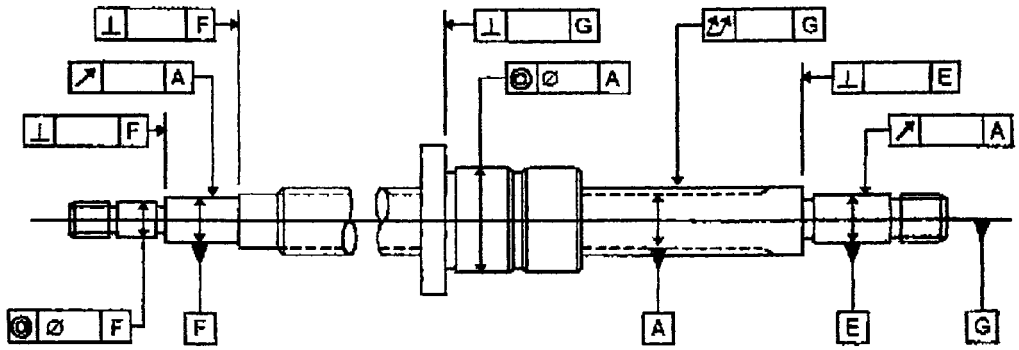

FIGURE 13.2.20 Key ballscrew dimensions. (Courtesy of T. Yamaguchi, Y. Taketomi, and C. J. Kempf.)

use special materials, surface treatments, and to provide features such as hollow shafts for coolant flow or damping materials.

Major steps in production and assembly of traditional ground ballscrews are summarized as a flowchart in Figure 13.2.21.

Initial Machining Operations

A lathe is used to establish the outer diameter of the shaft and cut the groove. In both operations, an allowance is made for material that will be removed in the final grinding operations. For short shafts, the support is provided from the shaft centers and a single cutting tool can be used with multiple passes to produce the desired outside diameter and groove. For long ballscrews, the lateral deflection of the shaft during cutting operations is significant and workpiece supports are necessary to prevent deflection of the shaft.

For long ballscrews, the total processing time can become extremely long using multiple passes with a single-point cutting tool. In such cases, a multiple-point tool that can remove more material on a single cutting pass is more efficient to use. But a multipoint cutter requires more time for setup and adjustment. Thus, there is an economic trade-off between single-point and multipoint cutting techniques.

Because of subsequent heat-treat operations, the shaft will undergo dimensional changes. The design must allow for these dimensional changes. This is an area in which production experience is critical. Statistical analysis of previous manufacturing results, together with modeling of material behavior, is critical to continued design and proceess improvement.

Surface Treatments

In order to withstand the loads at contact points, a very high surface hardness is necessary. A surface hardness of Rockwell C 58-62 with a depth on the order of 0.8 to 1.2 mm is required. For short ballscrews, *carburization* is used to develop the necessary surface hardness. For longer shafts, carburization is impractical because of the size of carburizing furnaces. In this case, an induction hardening process is used.

Electrically heated gas furnaces are used in the carburizing process. The immersion in the carburizing furnace is followed by quenching and tempering. During carburizing, key parameters such as temperature and gas concentrations are continuously monitored and adjusted by a process control system. Because high hardness is needed only in the ball groove, areas of the shaft and nut that will be subject to subsequent machining operations are coated before carburizing. This coating, which is applied like paint, prevents the diffusion of carbon into the material surface.

For longer shafts, a different steel is chosen and an induction hardening process is used. The general trend within the industry is toward induction hardening since it has the advantage of being a continuous process. When using induction hardening, single shafts can be processed immediately after machining. Induction hardening machines require less initial capital than for a carburizing system.

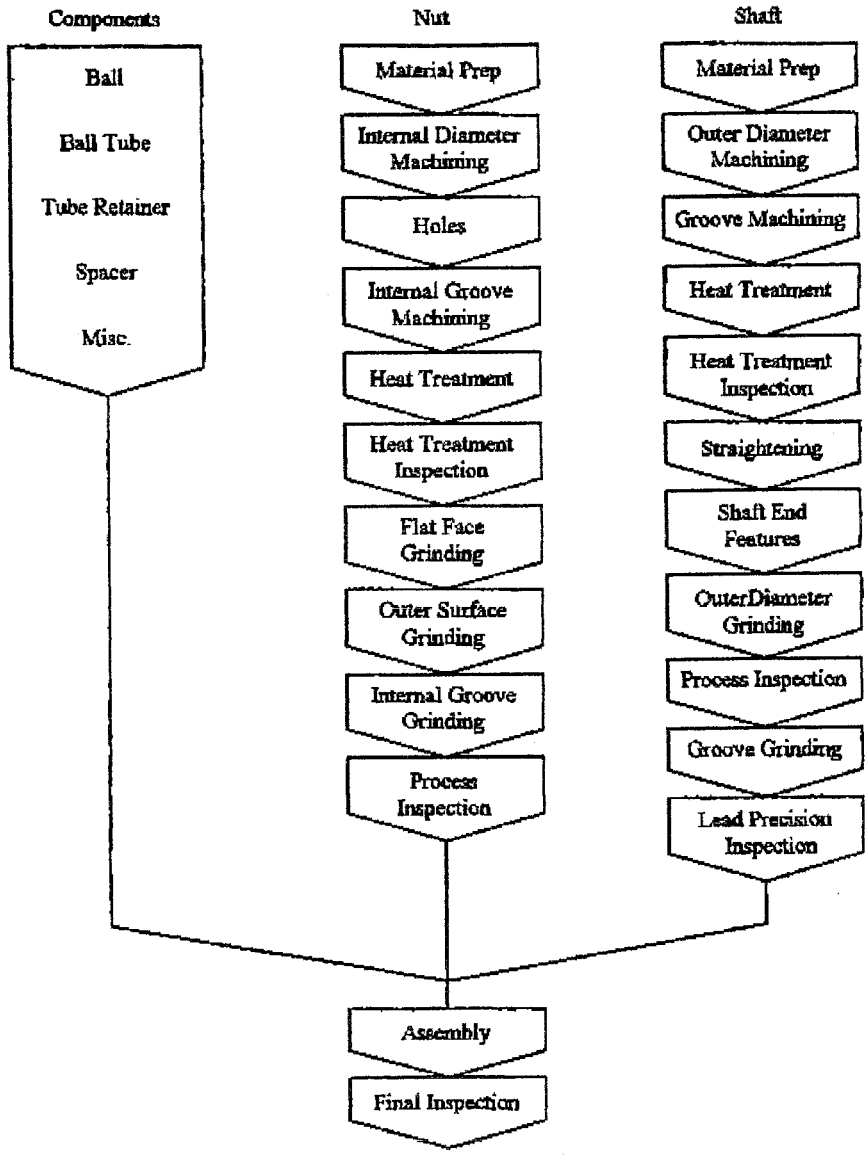

FIGURE 13.2.21 Ballscrew processing flowchart. (Courtesy of T. Yamaguchi, Y. Taketomi, and C. J. Kempf.)

The shaft undergoes dimensional changes as a result of the surface heating, and a *straightening* operation is necessary. Prior to straightening, the shaft is chilled in a carefully controlled manner to sub-zero temperatures to ensure that the solid-state transformations are completed; the result is a more stable microstructure. For straightening, a *specialized press* is used to measure automatically the deviation from perfect straightness; it automatically applies loads along the shaft as necessary to restore the shaft to near-perfect straightness.

Grinding and Finishing Operations

After surface treatment, chilling, and straightening, the outside diameter of the shaft is ground to the final dimensions. Except for very short ballscrews, the grinding cutting forces will cause lateral deflection of the shaft, and thus the centers in the shaft ends cannot be used as datums for final machining operations. Consequently, the outside diameter of the shaft is ground to precise tolerances. Although the outer

diameter of the shaft is not a functional part of the finished ballscrew, it is used as a datum surface when the final grinding of the shaft groove is performed.

Grinding of the shaft can be done on either centerless grinders or cylindrical grinders. Since centerless grinders take a long time to set up, they are generally used for large production runs of shafts having the same diameter. For the case of cylindrical grinders, the shaft is supported at the centers in the shaft ends as well as at workpiece supports along the length of the shaft. By adjusting the work rests, minor variations in taper and bending of the shafts can be corrected. This processing step requires considerable operator skill and experience in order to minimize variations in the outer diameter and residual bending of the shaft.

To maintain precision and finish of the outer diameter, automatic balancing of the grinding wheel is necessary. CBN grinding wheels are used although they are more expensive than traditional abrasive wheels; their long life and low wear rates make them economical.

After turning the external diameter to final size, shaft end features are produced. These features include bearing seats, keyways, flats, and locknut threads. The final finishing operation for the ballscrew generates the ball groove. This is the key processing step in assuring that the ballscrew possesses the required lead accuracy. If this process is not carefully controlled, there will be variation in the lead, depth of the groove, and smoothness of the groove, causing subsequent problems with accuracy, stiffness, running force and noise, and lifetime.

Removal of the outer layer of hardened material during outer diameter grinding can cause minor bending of the shaft as the net residual stresses in the material change. Prior to final cutting of the ball groove, the straightness of the shafts is checked and minor corrections made.

To maintain very high lead precision, the final groove grinding is done in a specially temperature-controlled environment of $68 \pm 2°F$ ($20 \pm 1°C$). Cutting oil is applied liberally to the shaft to minimize thermal effects due to cutting and deviations between the grinding machine and shaft temperature. As in the case of external diameter grinding, automatic balancing is used to minimize vibrations. To further reduce vibrations, each grinding machine is mounted on an individual base to minimize vibration coupling between various machines. The isolation properties of the machine bases are adjusted when a new machine is placed in service and undergo periodic inspection and adjustment during operation.

Since the size and lead of the groove varies from ballscrew to ballscrew, the grinding wheel must be matched to the groove shape. Thus, an inventory of several types of wheels is necessary; traditional abrasives are used since the costs of CBN wheels would quickly become prohibitive.

In general, accuracy in the groove-grinding process requires a combination of modeling and statistical analysis. As in the case of surface treatment, the collection and analysis of past production data allows continuous refinement of the manufacturing process.

Assembly and Inspection

The main factor in ballscrew accuracy is the lead. To facilitate a quantitative measurement of the lead, four fundamental parameters are used. To measure the lead error, precision measurements over a long travel range are made using computer-controlled laser interferometry.

Unacceptable variations in friction, increased running noise, and a reduction in life result from poorly formed grooves. Thus, the depth and cross-sectional profile of the groove must fall within allowable tolerances. Direct measurement of groove cross section is quickly performed on an optical profile projector. Precise measurement of groove depth can be made on selected samples. The screw shaft is supported between two centers and rotated at a fixed speed. A table carrying a contact probe moves along the screw shaft in the axial direction synchronously with the screw rotation. The probe is placed in contact with the groove to measure variations in the groove depth over the entire length of the shaft. By performing a frequency analysis on the groove depth errors and accounting for the rotational speed of the ballscrew during the measurement process, frequencies of unwanted vibrations occurring in the production machinery can be detected and the source of the anomaly eliminated to improve the production process.

Even with good control of the screw shaft and nut groove diameters during production, additional steps are necessary to obtain the desired amount of axial play or preload in the assembled ballscrew. By selecting slightly different ball sizes, required axial play or preload can be achieved. For a given nominal ball diameter, balls usually are grouped in steps of 20 to 40 μin. (0.5 or 1.0 μm). To increase production efficiency, assembly jigs are used.

The majority of precision ballscrews are preloaded in order to remove backlash and achieve the desired axial stiffnes. Two methods of achieving the desired preload are used. The first preloading method increases the ball size until the desired preload is achieved. The second method uses double-nut preloading in which a spacer is inserted between the two nuts to take up the axial play and achieve the desired preload.

The preloaded ballscrew has some running torque when the screw is rotated. The relation between this running torque and the preload has been determined based on both theoretical and experimental studies. Since preload cannot be measured directly, it is estimated based on measurements of the running torque in a specialized torque-measuring machine.

A special machine is used for direct measurement of axial stiffness. In this process, the screw shaft is clamped and an axial load is applied to the nut. A displacement sensor is fixed to the shaft close to the nut and the relative displacement of the nut can be measured when force is applied. The measurements of force and displacement can be plotted on an X-Y recorder to depict the stiffness characteristics of the ballscrew assembly.

13.3 Essential Elements in Manufacturing Processes and Equipment

Sensors for Manufacturing

John Fildes

Introduction

A good modern definition for a sensor must capture the diversity of these devices. A sensor is a device that detects or measures the state or value of a physical or chemical variable and provides the result in a useful way. At the minimum, a sensor contains a transducer that converts the detected or measured quantity to another form of representation. For example, a very simple sensor is an indicator whose color changes upon reaction with a minimum amount of a chemical species. Nonetheless, the sensors that are normally encountered are more complex, containing a transducer, an output display, and possibly supporting electronics for signal conditioning, communications, and logic functions.

Sensor technology is undergoing rapid change because of three developments. One development is the emergence of integrated and smart sensors, wherein transducers have been miniaturized, usually through the use of silicon micromachining, and integrated with electronics for signal conditioning, communications, and logic functions. The second development is the ongoing adaptation of nondestructive evaluation (NDE) measurements and laboratory measurements for on-line use in supervisory and intelligent process control systems. These NDE and laboratory-type measurements require rather complex systems, with extensive signal conditioning and data analysis. The third development is also related to the emergence of supervisory control systems. The data from multiple sensors is comparatively analyzed in a process called data fusion to better identify the state of the system and the occurrence of process faults. Thus, the topic of sensors and sensory systems now encompasses transducers, integration with supporting electronics for communications and logic functions, data analysis techniques, and data fusion methods.

Classification of Sensors

A good taxonomy for sensors is provided by the requirements for different degrees of process control, which is shown in Figure 13.3.1. This taxonomy contains three classes: sensors used in regulatory feedback control loops, process analyzers, and product quality analyzers. In Figure 13.3.2, the basic element of control is the regulatory feedback loop that maintains controllable processing parameters at the desired values. These types of sensors, which usually provide a single value and are relatively generic in their applicability, are used for monitoring variables such as temperature, pressure, flow, level, displacement, proximity, and velocity. For use of sensors in regulatory control, sensitivity, selectivity, simplicity, speed, reliability, and low cost are the critical attributes. Historically, sensors were almost solely used in this function, but this is no longer the case. Sensors, or more properly sensory systems, are now also used as process analyzers and product quality monitors. Sensors of this type, which are used for feedback in supervisory control, are more complex and application specific, and their output tends to be a matrix of values (e.g., a video image or a spectrum). Sensors of this type provide a representation of the process or product that has greater information content, but is more abstract than the representation provided by sensors used in regulatory control. Thus, extensive computations and modeling are needed for process analyzers and product quality sensors, but there is also more ability to correct for deficiencies in sensitivity and selectivity through computational means. In this case, measurement speed is usually less demanding. These differences in the three types of sensors are summarized in Table 13.3.1.

The typical regulatory variables are temperature, pressure, flow, level, humidity, position, and motion. These variables form the basis for many process factors as summarized in Table 13.3.2 and the major sensor technologies for these variables are summarized in Table 13.3.3.

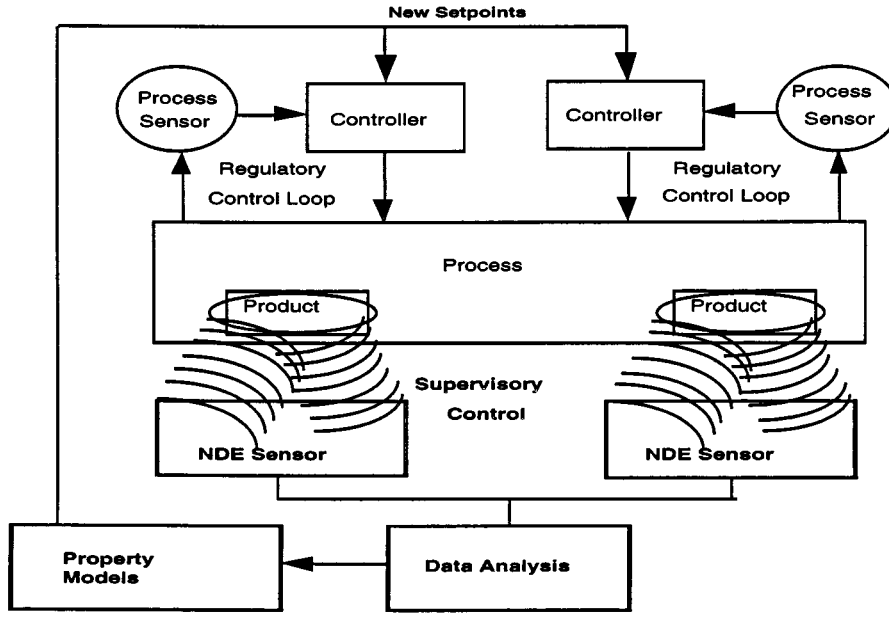

FIGURE 13.3.1 Regulatory and intelligent control.

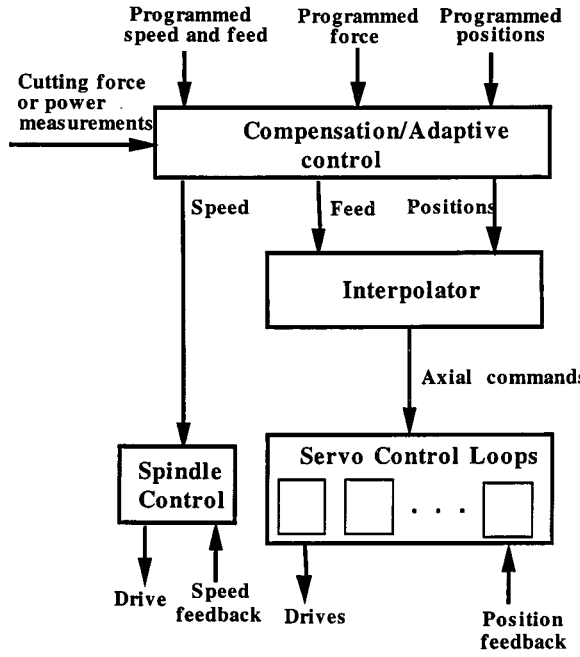

FIGURE 13.3.2 Typical CNC architecture.

Integration refers to inclusion of signal conditioning on the same substrate as the transducer. One of the major advantages of integration is that the integrated sensor can operate with a very small transducer output, which results in significantly smaller sensors. With the advent in telecommunications and the Microelectricalmechanical systems (MEMS) technologies, we can integrate software, hardware, power

TABLE 13.3.1 Characteristics of Regulatory and Intelligent Process Control Sensors

Characteristic	Regulatory Feedback Sensors	Process and Product Sensors
Speed of response	Very fast	Slow
Type of output	Single value	Matrix of values
Relationship of output to system parameter	Simple and direct	Abstract representation
Amount of computation	Little or none	Extensive
Sensitivity	Inherently high	Can be improved by computation and modeling
Selectivity	Inherently high	Can be improved by computation and modeling
Cost	Very low to moderate	High
Size	Small	Large
Applicability	Broad	Application specific

TABLE 13.3.2 Regulatory Processing Variables

Controllable Variable	Influenced Processing Factors
Temperature	Rates of chemical reactions; degree of cure of polymers; degree of softening and viscosity; cooking times; drying times; annealing times; degree of carborization
Pressure	Consolidation density; porosity; concentration of gaseous chemical reactants; forging; bending; injection times in molding
Flow	Mix ratios; quenching time; concentration of chemical reactants; color; pH; humidity
Level	Capacity; mix ratio; concentration of chemical reagents
Humidity	Drying of paper and grains; cooking
Position	Parts handling and placement; machining accuracy
Motion	Assembly; machining accuracy

TABLE 13.3.3 Sensor Technologies for Regulatory Control

Variable	Major Sensor Technologies
Temperature	Thermocouples, thermistors, resistance thermometers, infrared pyrometers, acoustic pyrometers
Pressure	Manometers, bellows and diaphragms, strain gauges, piezoresistive, piezoelectric, capacitive, thermocouple, ionization
Flow	Differential pressure (orifice plate, Venturi, pitot tube); velocity (turbine, vortex, electromagnetic, Doppler ultrasonic, time-of-flight ultrasonic); positive displacement (rotary sliding vane, gear, impeller); mass flow (thermal, coriolis); variable area (rotameters)
Level	Floats, pressure, radio frequency, ultrasonic, microwave, resistance tape, optical
Humidity	Dew point, length of hair, conductivity, capacitive, resonate
Position	Rotary encoder, linear variable differential transformer, potentiometers, magnetostrictive, magnetic, inductive proximity, magnetic, ultrasonic
Motion	Tachometers, pitot tube, anemometers

source, and communications on the same chip. Table 13.3.4 lists the advantages and disadvantages of integrated sensors.

TABLE 13.3.4 Characteristics of Integrated Microsensors

Characteristic	Advantage/Disadvantage
Batch fabrication	Excellent control, low cost, sensor arrays
Loss of modularity	Difficult to package and limitations on materials
On-chip amplification	Better signal-to-noise ratio
On-chip compensation	Better accuracy through compensation for interferences
On-chip feedback	Better linearity
On-chip scaling and conversion	Standardized output
On-chip multiplexing	Sensor arrays, bus addressable

Smart sensors are defined as those that also include logic functions, rather than just signal-conditioning electronics. Smart sensors may also include communications circuitry, diagnostics, and sometimes control outputs so that they can be directly connected to actuators, and documentation and trending functions. Conventional pressure sensors have rather broad accuracy limits, such as 0.25% of span. High-end smart pressure sensors have an accuracy of less than 0.1% of span, and mid-range smart pressure sensors approach this accuracy. Smart pressure transmitters are already available with built-in proportional-integral-derivative control functions, and fuzzy logic capabilities will soon be available. Multivariate measurement is not yet available, but will become so soon. Most likely, pressure and temperature will be the two measurements. Smart sensors are also available for presence detection, positioning, infrared photodetection with triangulation, and flowmeters, specifically magnetic meters, Coriolis mass flowmeters, and ultrasonic flowmeters. Integrated and smart sensor technology is also improving accelerometers, proximity detectors, and tactile sensors. The use of integrated and smart sensors will increase because of the overloading of shared resources and the use of distributed control schemes to solve this problem.

Use of Sensors in Supervisory and Intelligent Control Systems

As shown in Figure 13.3.1, supervisory control augments regulatory control by using process analyzers to better characterize the state of the process and sensors of product characteristics to assess the outcome of the process and to determine corrections for unacceptable deviations. These corrections are then implemented by the regulatory controllers. There are many ways in which supervisory control can be implemented. A common way is to measure important aspects of the process and the product performance, and to use a model to relate variations in processing parameters to variations in product performance.

Process analyzers are central to enabling supervisory control because they allow a more accurate, but abstract, representation of the state of the process. These devices augment regulatory control by monitoring other important variables in the process, but ones which are generally not directly controllable. Use of process analyzers provides improved reliability, flexibility, predictive diagnostics, ease of use, and central data collection with process documentation, trending, recipe handling, and statistical quality assurance. Process analyzers are now used for monitoring important process gases such as oxygen, carbon monoxide and dioxide, oxides of nitrogen and sulfur, and hydrocarbons. For liquids, process analyzers are available for pH, conductivity, redox potential, dissolved oxygen, ozone, turbidity, specific ions, and many organic compounds. The measurement techniques are summarized in Table 13.3.5.

TABLE 13.3.5 Process Analyzers

Process Analyzer Technology	Typical Uses
Electrochemical (potentiometric, amperometric)	Gases such as carbon monoxide and dioxide, oxides of nitrogen and sulfur, and hydrocarbons; species in liquids such as dissolved oxygen, pH, redox potential, specific ions, organic compounds, inorganic compounds
Chromatography (gas and liquid)	Gases such as CO and CO_2; species in liquids such as alcohols, flavors, lipids, polymers, and other organic compounds
Infrared spectroscopy	Near infrared — web processes for thickness, composition, solvent, coating Mid-infrared — chemical and petrochemical processes, polymers, food processes
Ultraviolet/visible	Gases and liquids including all elemental halogens, other inorganics, aromatics, carbonyls, many salts of transition metals

Traditionally, process analyzers have been stand-alone devices with a single sensor and a dedicated operator interface. The trend is toward modularity, multiple sensors, and digital communications so that process analyzers can be incorporated into distributed control systems in an open architecture control environment. Smart sensor technology is also turning conventional sensors into process analyzers. A good example is provided by smart infrared temperature sensors. These sensors provide sample and hold, correction for reflected radiation when the emissivity of the target is less than one and its temperature

is lower than ambient, analog outputs for control, digital outputs, trend analysis, and area sampling with line scanners. This functionality has made temperature mapping of surfaces in furnaces practical and is used in annealing of aluminum, steel reheating, and oven drying of webs such as paper.

Another trend is the use of sensor fusion, where information from multiple sensors is combined to improve the representation of the process. Sensor fusion techniques can use mechanistic models, statistical models, or artificial intelligence techniques, such as neural networks, fuzzy logic, and expert systems. Sensor fusion provides more reliability because the validity of the data of each sensor can be assessed from the other sensors, and if a sensor is faulty, its value can be predicted from the other sensors. Sensor fusion provides a better representation of the process because it captures the interrelationships that often exist between processing variables, which are treated independently without sensor fusion.

As shown in Figure 13.3.1, intelligent control involves the use of product quality sensors. Of the three classes of sensors discussed in this section, these sensors tend to be the most complex and provide the most complete, but abstract, representation of the state of the product. In some cases, the same technologies are used for product quality sensors as for process analyzers. An obvious example would be where chemicals are reacted without a change of state. In other cases, specialized product quality sensors have emerged. Table 13.3.6 lists some of the product quality sensors that are being used or are being experimentally evaluated.

TABLE 13.3.6 Product Quality Sensors

Sensor	Applications
Time-of-flight ultrasound	Either thickness or elastic constants, if the other is known
Electromagnetic acoustic transducer (EMAT)	Either temperature or elastic constants, if the other is known
Eddy currents	Electrical conductivity, magnetic permeability, thickness, temperature, presence of flaws
NMR (high resolution for liquids, low resolution for solids)	Composition of chemicals, petroleum, foods, polymers, fibers
Infrared and Raman spectroscopy	Degree of cure of polymers

Computer Control and Motion Control in Manufacturing

Yoram Koren and M. Tomizuka

Computerized Numerical Control Architecture

A typical architecture of a CNC system consists of three levels, as shown in Figure 13.3.2. At the lowest level are the axial servocontrol loops and the spindle controller. These servoloops are closed at high sampling rate. The interpolator that supplies the axial position commands to the control loops is at the intermediate level of this architecture. At the highest level are the compensation algorithms for the errors of mechanical hardware deficiencies, such as machine geometry errors and thermal deformation of the machine structure. This level also includes adaptive control algorithms that adapt the machine feed and speed to the cutting tool and workpiece material to maximize machine productivity at rough cutting and maintain precision at fine cutting.

CNC Part Programs

The CNC software consists of a control program and part programs. The numerical data which are required for producing a specific part by a CNC machine is called the *part program*. The part program is arranged in the form of *blocks* of information, where each block contains the numerical data required to produce one segment of the workpiece. Each block contains, in coded form, all the information needed for processing a segment of the workpiece: the segment shape and length, its cutting speed, feed, etc. Dimensional information (length, width, and radii of circles) and the contour shape (linear, circular, or other) are taken from an engineering drawing. In NC, dimensions are given separately for each axis of

motion (*X, Y,* etc.). Cutting conditions such as cutting speed, feed rate, and auxiliary functions (coolant on and off, spindle direction, clamp, gear changes, etc.) are programmed according to surface finish and tolerance requirements.

The part program contains the required positions of each axis, its direction of motion and velocity, and auxiliary control signals to relays. The controller generates an internal signal indicating that the previous segment is completed and that the new block of the part program should be read. The controller also operates the drives attached to the machine leadscrews and receives feedback signals on the actual position and velocity of each one of the axes.

In CNC systems the part dimensions are expressed in the part programs by integers. Each unit corresponds to the position resolution of the axes of motion and is referred to as the *basic length-unit* (BLU). The BLU is also known as the "increment size" or "bit-weight," and in practice it corresponds approximately to the accuracy of the system. To calculate the position command that the computer sends to the CNC machine, the actual length is divided by the BLU value. For example, in order to move 0.7 in. in the positive *X* direction in a system with BLU = 0.001 in., the position command is *X* + 700.

In the first generations of CNC systems, dimension were given in part programs by BLUs, as in NC. In new CNCs, however, dimensions, or desired cutter positions, are given in a normal way, as to a regular computer. The command *X* – 0.705, for example, will move the *X* axis the negative direction by 0.705 in. The resolution by which the dimension commands are given depends on the system BLU.

In addition to cutter positions, the part programmer must program the machining parameters such as tool diameter, cutting speed (*n*), feed (*s*), and depth of cut (*d*). The task of the part programmer is to convert the machining parameters *n* and *s* to NC control variables — spindle speed (*N*) and feed rate (*f*), as shown in Figure 13.3.3.

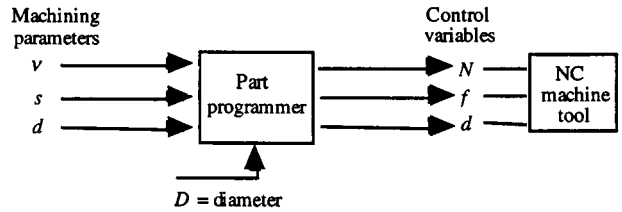

FIGURE 13.3.3 Conversion of machining parameters to control variables.

Point-to-Point and Contouring Axes of Motion

CNC systems consist of two functional types: point to point (e.g., drilling machine) and contouring or continuous path (e.g., milling machine).

Point-to-Point Systems. The simplest example of a point-to-point (PTP) CNC machine tool is a drilling machine. In a drilling machine the workpiece is moved along the axes of motion until the center of the hole to be drilled is exactly beneath the drill. Then the drill is automatically moved toward the workpiece (with a spindle speed and feed which can be controlled or fixed), the hole is drilled, and the drill moves out in a rapid traverse feed. The workpiece moves to a new point, and the above sequence of actions is repeated.

In a PTP system, this system requires only position counters for controlling the final position of the tool upon reaching the point to be drilled. The path from the starting point to the final position is not controlled. The data for each desired position is given by coordinate values. However, in high-speed drilling applications, such as the task of single-spindle drilling of an engine block, a control loop is needed to control the acceleration and deceleration of the motion. The digital signal processing technique has been used to control the settling time of the motion system for very fast PTP motion profile (1 to 4 g) so that the spindle could perform drilling operations without breaking the drill. A linear motor-based machine tool has been built and demonstrated by Anorad Corp. (Hauppauge, NY) for Ford Motor's engine machining line.

Contouring Systems. In contouring, or continuous-path, systems, the tool is cutting while the axes of motion are moving, as, for example, in a milling machine. All axes of motion might move simultaneously, each at a different velocity. When a nonlinear path is required, the axial velocity changes, even within the segment. For example, cutting a circular contour requires a sine-rate velocity change in one axis, while the velocity of the other axis is changed at a cosine rate.

In contouring machines, the position of the cutting tool at the end of each segment together with the ratio between the axial velocities determines the desired contour of the part, and at the same time the resultant feed also affects the surface finish. Since, in this case, a velocity error in one axis causes a cutter path position error, the system has to contain continuous-position control loops in addition to the end point position counters. Consequently, each axis of motion is equipped with both a position loop and a position counter. Dimensional information is given in the part program separately for each axis and is fed to the appropriate position counter. Then, an *interpolator*, in the controller, determines the proper velocity commands for each axis in order to obtain the desired tool feed rate.

Interpolators. In contouring systems the machining path is usually constructed from a combination of linear and circular segments. It is only necessary to specify in the part program the coordinates of the initial and final points of each segment and the feed rate. The operation of producing the required shape based on this information is termed *interpolation*, and the corresponding software algorithm in CNC is the *interpolator.* The interpolator coordinates the motion along the machine axes, which are separately driven, to generate the required machining path. The two most common types of interpolators are the linear and circular. Parabolic interpolators are also available in a few CNC systems which are used in the aircraft industry.

Linear interpolator: The ability to control the movement along a straight line between given initial and final coordinates is termed *linear interpolation.* Linear interpolation can be performed in a plane (two dimensional), using two axes of motion, or in space (three dimensional), where the combined motion of three axes is required. In this chapter only two-dimensional linear interpolators are discussed. To illustrate the interpolator function, consider a two-axis system, where a straight cut is to be made. Assume that the X axis must move p units at the same time that the Y axis moves q units. The contour formed by the axis movement has to be cut with a feed rate of V length-units per second (e.g., mm/sec). The numerical data of p, q, and V are contained in the part program and are fed into the interpolator. The interpolator then generates two velocity signals V_x and V_y, where

$$V_x = \frac{pV}{\sqrt{p^2 + q^2}}$$

and

$$V_y = \frac{qV}{\sqrt{p^2 + q^2}}$$

The position reference inputs to the axial control loops are

$$R_x = V_x t$$

and

$$R_y = V_y t$$

As seen, the two-dimensional linear interpolator supplies velocity commands simultaneously to the two machine axes and maintains the ratio between the required incremental distances.

Circular interpolator: The two most common interpolators in CNC systems are linear and circular. The *circular interpolator* eliminates the need to define many points along a circular arc. Only the initial and final points and the radius are required to generate the arc. The circular interpolator divides the arc into straight lines with a contour error smaller than one BLU. It operates on an iterative basis, where

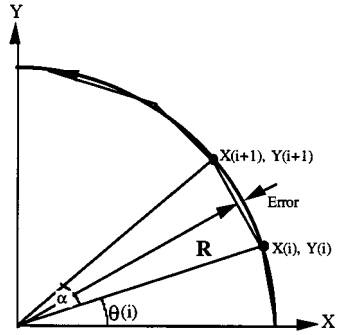

FIGURE 13.3.4 A circular interpolator divides the arc to straight lines.

for a given point, $x(i),Y(i)$, a small incremental angle is added to calculate the next point, as shown in Figure 13.3.4.

Both the linear and circular interpolators are based on generating incremental positions every T seconds, where T is the sampling period of the CNC system. Typically, CNC systems operate on one common sampling period for both the interpolator and the control loops. In these systems a typical T may be between 1 and 10 msec. Some other CNC systems utilize a separate computer for the interpolation and another one or several microprocessors for closing the control loops.

Motion Control Systems

Control Loops. A typical closed loop of a CNC machine is shown in Figure 13.3.5. The computer compares the command and the feedback signals and gives, by means of a digital-to-analog converter, a signal representing the position error of the system, which is used to drive the DC servomotor. The feedback device, which is an incremental encoder in Figure 13.3.4, is mounted on the leadscrew and supplies a pulsating output. The incremental encoder consists of a rotating disk divided into segments, which are alternately opaque and transparent. A photocell and a lamp are placed on both sides of the disk. When the disk rotates, each change in light intensity falling on the photocell provides an output pulse. The rate of pulses per minute provided by the encoder is proportional to the revolutions per minute of the leadscrew.

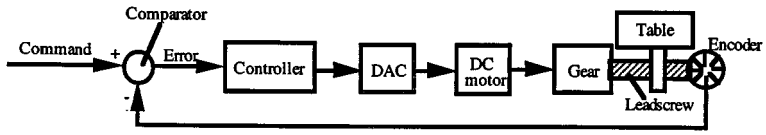

FIGURE 13.3.5 Closed loop of CNC.

Normally, the motor is mechanically coupled to the load via a drive mechanism. For example, robot links and positioning tables are loads. It is usually a good assumption to ignore the dynamics in the current feedback loop and regard the command current as the actual current, which sets the torque input to the mechanical portion of the system. Notice that the inertia and bearing friction of the motor must be considered as a part of the mechanical portion of the motion control system, which strongly influences the design of the velocity and position loop feedback controllers. These controllers can be implemented

in either analog or digital form. In recent years, digital implementation on microprocessors and/or DSPs has become popular, and digital velocity and position controls are often referred to as *digital servo*. The current feedback is usually built into the "drive" (power amplification system). While feedback signals for the velocity and position controllers are usually obtained from the motor, the velocity and position of the load, e.g., a positioning table, at the opposite end of the drive mechanism are the quantities of our ultimate concern. Closed-loop control schemes based on the motor velocity and position are sometimes called semi-closed-loop control schemes. The velocity and position of the load must be fed back for full closed-loop control. Typical drive mechanisms are ballscrews and various types of gears. Several manufacturers provide so-called direct drive (DD) motors, which are capable of delivering large torques but with a significantly reduced maximum speed. DD motors may eliminate drive mechanisms. However, they are heavy and may not always be the best solution depending on applications. Common sensors for positions are potentiometers and shaft encoders, and those for velocities are tachogenerators and frequency-to-voltage convertors (FVC), the input to which is encoder pulses. In digital servos, encoders are popular for measuring positions, and velocities are either estimated from encoder pulses or are obtained from FVCs.

Traditional velocity and position loop feedback controllers are of PID (proportional plus integral plus derivative) type. The output of a PID controller is

$$u(t) = k_p e(t) + k_i \int_0^t e(\tau)\, d\tau + k_d \frac{de(t)}{dt}$$

where e(t) is the error, $u(t)$ is the controlling input, and k_p, k_i, and k_d are, respectively, proportional, integral, and derivative control gains. The above equation represents the PID control law in the continuous-time (analog) form. In digital control, the PID control law is implemented in a discretized form. A typical discrete-time (digital) PID control law is

$$u(k) = k_p e(k) + k_i T \sum_{j=0}^{k} e(j) + \left(\frac{k_d}{T}\right)\left[e(k) - e(k-1)\right]$$

where k denotes the kth sampling instance and T is the sampling period. In position loop feedback control, e and u correspond to the positioning error and the velocity command, respectively. For the velocity loop controller, they are the velocity error and the current command. Another popular linear controller is the lead/lag compensator. Input-output (I/O) interfaces include analog-to-digital convertors (A/D), decoders for processing encoder pulses, and digital-to-analog convertors (D/A). Motion control systems can be built from components and programmed with custom software, they can be purchased as plug-in boards for various buses, or they can be purchased as packaged systems.

PID and lead/lag compensators are simple and utilized in many applications. However, they alone might not be adequate for problems where the performance requirements are stringent. Extreme care must be taken during the design of a closed-loop control system. By increasing the magnitude of the feedback signal (e.g., more pulses per one revolution of the leadscrew), the loop is made more sensitive. That is known as increasing the open-loop gain. Increasing the open-loop gain excessively may cause the closed-loop system to become unstable, which obviously should be avoided.

The basic nature of "feedback" control is that the control action is based on the error. When the reference input for the position loop is fixed, the integral action may assure zero error at the steady state. In tracking control, however, the position command is continuously varying, which combined with the dynamics of the closed-loop system makes tracking errors always remain. For example, in contouring of a circular arc in machining, the command position signal for each motion control axis is sinusoidal. Such an operation is essentially a test of the frequency response of the motion control axis. The controller is normally tuned so that the frequency response gain is close to but is not exactly 1 in the operating range. In high-speed contouring operations, corresponding frequencies are high, and the gain is normally

below unity. Then, the actual diameter is slightly smaller than the desired diameter. This consequence is often called the radial reduction error. Such errors may be reduced by applying the disturbance observer scheme to the position loop. However, the disturbance observer is still a feedback controller, and one sampling time delay in digital implementation further diminishes its effectiveness.

The following discussion describes some principles of motion control systems for PTP machines and contouring machines.

Control Loops for Point-to-Point Systems. The control loops of PTP systems are designed to control the position of the machine tool axes. Each axis is *separately* driven and should follow the command signal. The system design starts by selecting the type of control: open loop or closed loop, a decision which depends on the required specifications of the NC system and economy. Open-loop controls use stepping motors as the drive devices of the machine table. The drive units of the stepping motors are directly fed by the controller output pulses. The selection of the appropriate motor depends on the maximum torque, required velocity, and step size in the system. Stepping motors can be implemented on small-sized PTP systems in which the load torque is small and constant. Larger PTP machines and contouring systems utilize closed-loop control systems.

In PTP systems each axis is driven separately at the maximum allowable velocity. This velocity depends on the drive type and on the mechanical structure of the particular machined or manufacturing system. In order to avoid large overshoots the velocity is decelerated before the target point in which the tool starts to operate (e.g., to drill). Since the path between the points is insignificant, *the deceleration is accomplished in each axis separately.*

In practical systems the deceleration is accomplished by three stages. A typical three-stage deceleration diagram of one axis of the table is given in Figure 13.3.6. The table moves at rapid velocity V until reaching a distance L_1 from the target point, where the table is instructed to move at smaller velocity V_1. After a time delay, which depends on the system inertia, the table moves at a new velocity V_1 until reaching a distance of L_2 units from the target point, where again the velocity is reduced to V_2. When the table is at a distance of L_3 units before the target point, the velocity is reduced once more and the table "creeps" toward the final point at very low velocity V_3, and subsequently stops.

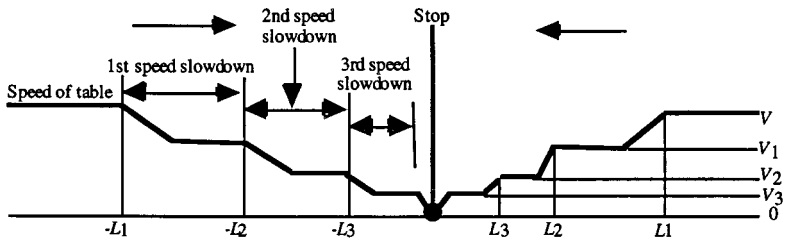

FIGURE 13.3.6 Deceleration procedure in a PTP system.

Control Loops for Contouring Systems. The control in CNC contouring systems operates in closed loops, which compare the command pulses from the interpolator with the feedback signal from the encoder or the resolver. The most sophisticated design applies to the closed-loop control of contouring systems. In the design of these loops, the transfer function of each element must first be determined; the system is then set up in block diagram form, and finally the loop gain is established based on performance analysis. The transfer function of each element is based upon its mathematical model. In establishing the mathematical model the engineer is faced with a compromise between *accuracy* and *complexity,* on one hand, and *approximation* and *simplicity,* on the other. In this section we shall discuss simple models, in which the principles of design can be readily illustrated.

The control loops of contouring systems are usually of the closed-loop type as shown in Figure 13.3.7. They use two feedback devices: a tachometer that measures the motor speed and is included in the drive unit and a position feedback transducer which is capable of also measuring the axis velocity (such as

an encoder, resolver, or inductosyn). In encoder-based systems the encoder is mounted on the leadscrew and emits pulses; each pulse indicates a motion of 1 BLU of axis travel. Therefore, the number of pulses represents position and the encoder pulse frequency is proportional to the axis velocity.

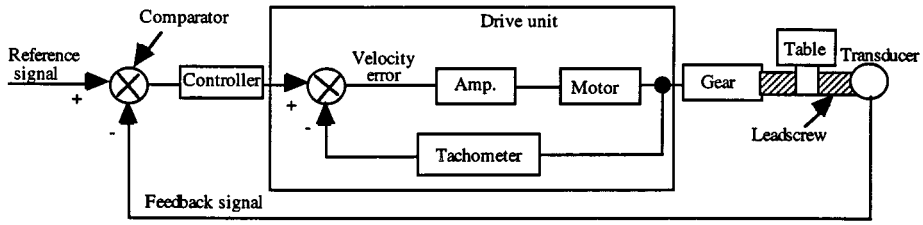

FIGURE 13.3.7 Control loop of contouring system.

Error Sources in CNC Systems

Despite the high precision of the CNC equipment, it still has position and contour errors. Error sources in CNC machines are classified into three categories:

1. Mechanical Hardware Deficiencies
   - Orthogonality of machine axes
   - Straightness of the machine axes
   - Thermal deformation of the machine structure
   - Backlash in the gears and leadscrew nuts
   - Uneven leadscrew pitch
   - Friction in moving components (leadscrews, guideways, etc.)
2. Cutting Process Effects
   - Tool deflection due to cutting forces
   - Large vibrations and chatter
   - Tool wear
   - Workpiece thermal deformations
   - Workpiece deformations due to cutting forces
3. Controller and Drive Dynamics
   - Disturbances due to cutting forces
   - Disturbance due to friction forces in the machine guideways
   - Contour errors caused by tracking errors of nonlinear contours (e.g., circles)
   - Contour errors caused by mismatch of equivalent parameters in the axial controllers
   - Corner errors in contouring operations

In general, errors of the first type, such as machine geometry errors and thermal deformation of the machine structure, can be compensated for by the machine controller. To further understand the measurement of errors, the next section will examine the metrology for precision engineering.

Metrology and Precision Engineering

Kam Lau

Introduction

Precision engineering in manufacturing generally refers to the engineering processes of achieving tighter tolerances or dimensional accuracy of a design. The process of precision engineering begins from the part *design*, part *fabrication*, and, finally, part *inspection*. This section addresses some of today's precision engineering considerations in fabrication and inspection.

Factors in Precision Engineering

The fabrication process is a material transformation process that determines the final part dimensions through material forming, removal, or insertion. Precision in the fabrication generally refers to the dimensional "repeatability and accuracy" of a part transformed under such a process. The factors to be considered to ensure good "precision" are (1) errors of the *machine* system(s), (2) the *environment* in which the machining is being performed, (3) the *manufacturing process*, and (4) the *instrumentation* to verify the performances of the factors.

Machine Errors. Machine errors can be classified into geometric, thermal-induced, dynamic, and structural errors. Geometric errors are errors related to the undesirable machine geometry caused by nonorthogonality (squareness error) of axes, linear positioning (or scale) error, reversal (or backlash) error, straightness error, pitch, yaw, and roll errors of a machine axis during a linear move. If the machine is equipped with a rotary table, geometric error would include axis wobble, rotational positioning error, eccentricity, and parallelism errors.

Geometric Errors: Geometric errors are much better understood in the machine industry than the thermal, dynamic, and structural errors. The techniques and instruments to check for the geometric error are very well established and are commonly applied in the machine tool industry. However, for small- to medium-size machines, geometric errors constitute only about 25% or less of the total manufacturing error. For larger machines, the percentage can go as high as 50%. As such, just knowing the geometric errors of a machine system may not be adequate in the realization of the total manufacturing error.

Traditional devices for measuring different types of geometric errors are the mechanical square, straightedge, autocollimator, electronic level, step gauge, optical polygon, and dial indicator. In some instances, the combined use of these devices is needed. Newer instruments that can offer faster and more precise measurements are the laser interferometer system, the 5-D laser interferometer system, and the telescopic ballbar.

Thermal Errors: Thermally induced machine error is considered one of the key factors affecting the accuracy of a machine tool. Thermally induced errors arise as a result of nonuniform heat generation within the machine such as in motors, bearings, and guideways; heat generated during the cutting process; and the coolant effect as well as the environmental effect resulting in the uneven growth of the machine structure. Thermal error can contribute as much as 50% of the total manufacturing error in small- to medium-size machines. However, this effect has been largely unrecognized or often ignored by the machine tool industry until recently.

There are basically two alternatives to monitor the thermally induced errors — intermittent and continuous monitorings. Intermittent monitoring generally involves the use of a touch probe or dial indicator(s) to periodically measure against one or multiple fixed positions as the machine is going through a thermal exercise. In the case of the dynamic spindle thermal study, an artifact such as a sphere or a rod can be mounted on the spindle while it is running at a certain speed. At some elapsed time (e.g., 1-min interval), the spindle will stop momentarily and the machine will reposition the artifact to the dial indicator(s) to check for the repeatability. Any deviations from the initial position (i.e., cold-start position) are considered as thermal growth due to the spindle warm-up. A typical spindle thermal test takes about 4 to 8 hr to complete. A similar procedure can be applied for the environmental and servomotion-related thermal growth measurements.

The continuous thermal growth monitoring generally involves the use of some noncontact sensors such as capacitance gauges, optical sensors, or inductance sensors arranged in the similar fashion as above. The benefits of continuous monitoring are that there is no interruption of the spindle dynamic and that the machine positioning repeatability does not necessarily interfere with the results. Furthermore, the noncontact nature generally allows the spindle to operate at any speeds, thus giving a much broader range of thermal assessment.

Laser interferometer systems are also used occasionally to monitor thermal growth effects. Because of its ability to identify the growth along the entire axis, the laser measurement is better suited for monitoring the growth of a linear-scale system caused by internal or external heat sources. Linear-scale error caused by axis movement is about one fifth that of the spindle thermal in medium to small machines. It is even less in larger machine since the heat dissipation effect in larger machine is much more effective.

Dynamic Errors: Dynamic errors here refer to those caused by the motions of a CNC machining center. These includes the servo-gain mismatch, servo-stick-slip, servo-oscillation, controller error, etc. Errors pertaining to tool chattering, structural deformation (caused by machine carriage acceleration and deceleration), machine/part deadweight, etc. are considered structural errors and are discussed in the later section.

Servo-gain mismatch is often caused by the electrical (or computer) gain setting of one axis not matching the other. The problem is not severe when the machine is primarily used for static positioning purposes, such as drill, boring, etc.; however, it can be a problem in precision contour milling when two or more axes are to be used in synchronization with each other. The magnified elliptical error is caused by one axis responding faster than the other in reaching the commanded positions. Servo-gain mismatch can easily be corrected in a routine machine maintenance.

Structural Errors: Structural errors include tool-chattering error and structural deformation error (due to acceleration and deceleration of the machine carriage, the deadweight distribution, the cutting force, etc.).

Tool chattering generally affects the machinability and surface finish of the workpiece, not the dimensional accuracy. Structural deformation caused by the acceleration and deceleration of the machine carriage and workpiece is rather insignificant for quasi-static positioning and slow-speed contouring. However, the error can be significant if the contouring speed is high. Another major contributor to the structural error is the cutting force. An excessive amount of cutting force can cause the spindle axis, the tool, the fixture, and the part to deform.

A good device to gauge the potential structural error is a compliance system. A basic compliance system consists of a load cell and a dial indicator, which are set up between the machine table and the spindle. The table is programmed to move in small increments (e.g., 5 mm) in either directions of the load cell. The readings from the load cell (force) and the indicator (actual displacement of the table) are then recorded at every increment. A compliance chart can then be obtained by plotting the forces (F) against the differences between the actual and commanded displacements (DD) of the table (i.e., F vs. DD).

Another type of structural error for large machines is from the machine foundation error. Most large machine bases are built in sections. These sections are then aligned, assembled, and anchored together to a common reinforced concrete foundation. As such, the foundation becomes part of the machine structure and the accuracy and repeatability of the machine are therefore heavily dependent on the stability of the foundation. It is not unusual to find the performance of the machine degraded as a result of floods and earthquakes, and loosening of anchor supports due to prolong use or lack of maintenance.

Errors Introduced by Environmental Effects. For the manufacturing plants that have little or no control of the plant environment, environmental effects can be very significant sources of errors. Two of the most dominant environmental effects are thermal and vibration effects.

Thermal Errors: For many nontemperature-controlled manufacturing plants, it is not unusual to observe a total temperature swing of 20°F throughout a day of operation. This wide fluctuation of environmental temperature can cause significant accuracy and repeatability problems to the machining

systems, as well as the workpieces. Even in a somewhat controlled environment, thermal errors can still be a major problem. For instance, if the machine is located in the vicinity of a frequently operated bay door, where there is a substantial temperature difference between the plant temperature and the outdoor temperature, or if it is placed next to a heat source such as a welder, an electric blower or exhaust, a hydraulic pump, or under direct sunlight, the heat source can still cause tremendous localized thermal distortion of the machining system.

In most cases, one can reduce the localized environmental thermal effect by isolating the heat sources with simple panel shielding or by relocating the machines. If an overall plant temperature control is unachievable or impractical for economic reasons, one may consider (1) applying localized thermal control of certain key machining systems or (2) implementing computer thermal compensation techniques.

Vibration Errors: Environmental vibration error is a result of one or more external vibration sources affecting the structural stability of the machine system. This type of error can be significant if the machining system is located next to a heavy punch press operation or where frequent forklifting operation is present. Using a spindle analyzer or a laser interferometer system to access the amount of the environmental vibration error is common.

Other Errors: Other types of environmental errors are the interference or instability of the electric power source, the factory-supplied pneumatic and hydraulic pressures, air pressure, and humidity, etc. These types of errors may be of lesser magnitude than the above; however, it is always good practice not to underestimate their potential effects in any precision manufacturing considerations.

Errors Introduced by the Manufacturing Process .

The magnitudes of these types of errors are very much dependent on the process control and manufacturing practices implemented by each individual plant. In general, the concerns in this area are the effects of the coolant on the workpiece and the machine structure, the pallet and the fixture, the repeatability of the pallet and tool changer, and the tool deflection in manufacturing.

Coolant Effects: Eighty percent of machining uses coolant, sometimes referred to as *wet machining.* In most cases, the coolant temperature is not controlled. For smaller machining systems, a small coolant tank can be found next to the machine. For larger machines, a large coolant tank can be found underneath the ground. The main purposes of the coolant in machining are (1) for lowering the cutting temperature and (2) for chip removal. As the coolant is being recycled during the machining process, its temperature gradually warms up. This significant increase in temperature affects the workpiece dimensions since the workpiece temperature before machining is generally at room temperature. Similarly, the pallet dimensions are also affected.

Tool and Fixture: The conditions of the pallets, tools, and fixtures often govern the repeatability of a manufacturing system. These components should be checked routinely for wear and chipping. Fixtures and clamping devices should be routinely checked to ensure that proper clamping forces can be applied and that contact surfaces are in good condition. Many of these checks can be accomplished visually or by performing dial indicator repeatability checks.

When excessive cutting force is expected, it is necessary to consider the maximum possible amount of the tool, workpiece, and fixture deflections resulting from the force. The amount, if it exceeds the manufacturing tolerance, should be reduced by either reducing the depth of cut or the feed rate or by strengthening the tool and fixture. A compliance system is a good qualifier to measure the tool deflection under load.

Instrumentation and Inspection in Precision Engineering

This section introduces the instrumentation often used in precision engineering.

CNC Machining Performance Evaluation

The American National Standards Institute developed *ANSI B5.54 Standards for CNC Machining Center Performance Evaluation* for the purpose of providing detailed guidelines for machine tool users and developers to evaluate and compare the performances of CNC machining systems. The *Standards* delineates procedures for the measurements of the machine and environmental errors as stated in the above, as well as choices of conventional and state-of-the-art instruments used in doing the measurements. Experience indicates that these measurements are useful not only for performance evaluation, but also for better understanding of the sources of errors. This information is crucial for preventive maintenance and for accuracy enhancement of CNC machine systems.

Some of the key techniques introduced by the *B5.54 Standards* are the telescopic ballbar measurement, spindle dynamic and thermal drift measurement, laser diagonal measurement, and the 1-day test.

Instrumentation and Metrology

Telescopic Ballbar. The telescopic ballbar test is gradually becoming one of the most powerful and convenient tests for CNC machining center evaluations. As is shown in Figure 13.3.8, a telescopic ballbar consists of a spring-suspended reed having two spheres attached to both ends. The spheres are allowed to move relative to each other with a limited travel, e.g., 3 to 4 mm. Inside the reed is a displacement sensor, known as an LVDT (linearly variable displacement transducer), that measures the relative move of the spheres. The output of the LVDT is connected to a computer.

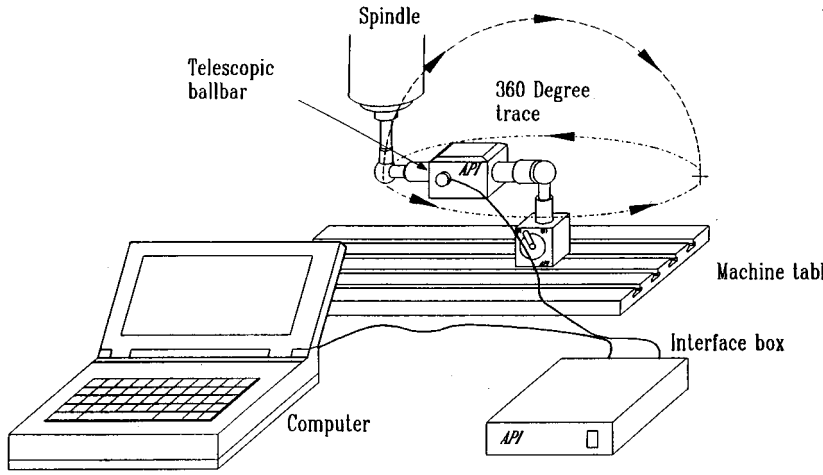

FIGURE 13.3.8 The telescopic ballbar.

To use the telescopic ballbar, one of spheres is magnetically attached to the magnetic socket which is installed on the machine spindle; the other is magnetically attached to a second magnetic socket mounted on the table. The machine is then programmed to contour in a circle in the *X-Y, X-Z,* or *Y-Z* plane, as shown in Figure 13.3.8. As the contouring proceeds, any errors of the machine in contouring will be translated into relative moves picked up by the LVDT and instantaneously recorded by the computer. After the machine has stopped, the computer then plots the errors on a chart for analysis. Errors such as backlash, axes nonsquareness, scale mismatch, servo-gain mismatch, cyclic motion, stick-slip, and certain straightness errors can be readily detected by using a telescopic ballbar.

Laser Interferometer. A laser interferometer system can produce measurements pertaining to the linear, angular, straightness, and squareness errors of a machine system. To many in the manufacturing industry, laser interferometer measurements are considered as the primary calibration standards. However, it is important that when using a laser interferometer, the proper procedures are followed. Precautions should

be taken when using a laser interferometer system: avoid setting up the laser in areas where large air turbulence is present; set up the laser to minimize the cosine error and Abbe error; beware of the environmental effects (i.e., temperature, pressure, and humidity) to the laser accuracy; and understand the material parameters (i.e., material temperature, coefficient of expansion, etc.) to the measuring accuracy. In the event that these effects are significant, it is necessary to compensate for them in the final results.

Setting up a laser interferometer system for machine measurement can be very tedious and sometimes frustrating. It is not unusual to take 2 to 3 days to measure all linear, straightness, angular, and squareness of a mid-size three-axis CNC machine (referred to as 21 parameters measurement). A new laser system known as the 5-D laser interferometer system, developed by Automated Precision, Inc. (Gaithersburg, MD), has the capability of measuring five degrees of freedom (i.e., *X*-, *dY, dZ*, pitch, and yaw) simultaneously in one single setup. In contrast, the 5-D system is able to cut down the measuring time to 3 to 4 hr.

A laser interferometer system should not be confused with an alignment laser system. A laser interferometer system works on the polarized light interference principle and can produce precision to within a tenth (or better) of a wavelength of light (i.e., 630 nm for an HeNe laser). By using the same measuring principle, a laser interferometer system can also generate angle measurements to within 0.1 arc-sec. An alignment laser works on beam-pointing effects and combines the measurements with a photodetector for straightness and angle measurements (not linear measurement). In this case, the laser beam is used as a straightedge. Unless the electro-optics elements are used carefully, the accuracy is much lower than that of a laser interferometer system. Although alignment lasers are commonly used in machine alignment, it should not be construed as a precision calibration standard.

Spindle Analyzer. A spindle analyzer can be used to measure several important parameters of a machining system. These include thermal growth of a machine resulting from environmental variations (i.e., temperature, vibration, etc.) and internal heat sources (i.e., motors, spindle bearings, hydraulic systems, etc.), spindle dynamic errors resulting from a worn or contaminated bearing, and machine axis repeatability.

For advanced applications, it is recommended that the sensors be of noncontact nature since contact sensors can create problem when measuring a high-speed spindle in motion. The noncontact sensors can be optical, capacitive, or inductive. They all have their advantages and disadvantages dependent on their applications. Users should consult with the manufacturers before making their selections.

Other Metrology Instruments. The above-mentioned metrology instruments represent some of the latest and most commonly used instruments in the manufacturing industry. Other instruments that are also used frequently are electronic autocollimators, electronic levels, force gauges, temperature sensors, vibration sensors, dial indicators, proximity sensors, mechanical straightedges, step gauges, precision-indexing tables, etc. One should not, however, overlook the benefits offered by some of the latest data acquisition and data analysis software packages such as the SPC (statistical process control). Of course, the proper selection and use of any instrument are keys to a better understanding of the factors in precision manufacturing.

Inspection System and Metrology

The direct-computer-controlled coordinate measuring machine (DCC-CMM) has been the dominating means for final workpiece dimensional inspection in the manufacturing industry since the early 1980s. Since then, several advanced dimensional measuring devices have also been developed and are gaining wide acceptance in industry. These are the high-speed laser tracking systems and the manually operated measuring robots. There is also a growing interest in the manufacturing industry to reduce the off-line inspection process (i.e., CMM-type applications) by performing some of the inspections on the CNC machining system. This is referred to as on-machine gauging. This section will discuss some of the key considerations related to the use of these advanced inspection systems.

Laser Tracking Interferometer System. The laser tracking interferometer system (LTS) was developed at the National Institute of Standards and Technology (NIST) in the mid-1980s for medium- to large-dimensional inspections. It was then commercialized and introduced to the industry in late 1989. Since then, the LTS has been gaining popularity and is becoming one of the dimensional measuring standards.

Through the combination of a precision dual-axis gimbal, a laser interferometer system and an optical target (i.e., a retroreflector), the laser beam is precisely directed to the target through the manipulation of the gimballed mirror via the control computer. As the beam is sent back to the laser by the target, it is partially deflected to a dual-axis photodetector. The beam position is then interpreted by the computer. As the target moves, the photodetector immediately generates an error signal to the computer which drives the mirror to ensure the beam stays locked onto the target. While it is tracking, the computer acquires the laser measurement and the two angle measurements (*a* and *b* angles) of the mirror and computes for the three-dimensional position of the target.

The advantages of the LTS are that (1) it is considered one of the most accurate large-dimensional coordinate measuring devices with an accuracy of better than 10 ppm (i.e., 100 mm at 10 m); (2) it has a very measurable envelope — 25 m × 360°; (3) it can track a target moving at a speed of 4 m/sec; (4) it can sample up to 1000 samples/sec; and (5) it is compact, portable, and fully automatic. It is well suited for rapid surface scanning, jigs and fixture alignment, replacing conventional CMMs for large structural measurements, and for large CMMs, robotic devices, or CNC machining center calibrations.

The disadvantages are that (1) when used in areas where significant air turbulence is present, the system becomes less reliable; (2) the accuracy may be reduced when used in areas where heavy forklifting activities are present (since the floor foundation is part of the measuring frame); and (3) the system needs zero referencing if the interferometer beam is interrupted during measurement.

On-Machine Gauging. On-machine gauging (or in-process gauging) refers to the dimensional inspection process implemented during or after a machining cycle right on the machining system. In other words, the machining system, retrofitted with a sensor (i.e., a touch probe), is used to serve as a coordinate measuring machine while the workpiece is still on the machine. This concept certainly has merit since most CNC machining systems have control, scale, and structural integrity equal to or better than many DCC-CMMs.

The advantages of performing dimensional inspections on the same machining system are obvious: (1) it eliminates the need of moving the workpiece to a CMM; (2) it reduces the inspection cycle time; and (3) it eliminates realignment error should reworking the workpiece become necessary. The disadvantages, however, are (1) since the same machine frame is used for machining and inspection, if the machining system has any inherent errors (such as geometric errors) which affect the workpiece accuracy, it is incapable of detecting those errors in the inspection and (2) the machine will experience a large degree of thermal distortion caused by the internal heats.

In order to implement on-machine inspection, it is therefore necessary to first perform geometric accuracy evaluation of the machining system according to B5.54 Standards. All efforts should be made to ensure that the accuracy is maintained. Second, a machine thermal growth analysis should be performed to ascertain the limitation of the thermal distortion in inspection. In either case, a minimum rule of thumb of four times the accuracy tolerance should be applied. New techniques of thermal and geometric modeling and compensation of the machining system can be considered in order to achieve the inspection goals.

Other Inspection Systems. Other emerging inspection machines, such as the manually operated robotic measuring device, stereotriangulation measuring systems, and photogrammetry systems, are also gaining popularity in manufacturing. Although they may not offer the same types of accuracy and versatility as the previously mentioned system, they feature a new trend of inspection requirements — portability, agility, shop-floor hardiness, high-speed data acquisition, low cost, and powerful software capability.

Mechatronics in Manufacturing

Tai-Ran Hsu

Introduction

Mechatronics can be defined as: "A technology that involves the design, manufacture and production of *intelligent* products or engineering systems involving *mechanical* and *electronic* functions." Mechatronics is a melding of two English words, *mechanical* and *electronics*. This terminology was first used by Yaskawa Electronic Corp. in Japan during the 1970s. The original notion of mechatronics involved the development and automated production of consumer products such as the Canon SLR autofocus camera (Gilbert, 1992). The application of this technology was soon extended to many other consumer electronic products that included video cassette recorders and the well-known Sony Walkman radios. The rapid advances of microprocessor and microcomputer technologies in the 1980s have broadened the applications of mechatronics to all smart products and systems, ranging from common consumer products to highly sophisticated space engineering equipment. In general, mechatronics systems engineering comprises a number of engineering disciplines. Figure 13.3.9 illustrates interactions of the mechatronics systems engineering with other engineering fields.

Elements of Mechatronic Systems Engineering

Most mechatronic products or systems consist of the following three modules:

1. *The sensing and control module:* This module involves hardware that includes electronic elements, electronic circuits, and the software that provides the commands and operation logics to all components in an automatic control systems. Basic hardware components include *sensors* (position, velocity, acceleration) including tactile, optical, and voice; *actuators* (linear, rotary, voice) driven by electrical, pneumatic, or hydraulic means; *drives* (DC/AC stepper or servomotors); *encoders* (optical or magnetic) and time counters. Other major components include signal processors, amplifiers, power suppliers, and A/D or D/A converters. Control software such as PLC, PID, and other application software are written in C, C^{++}, LISP, FORTH, and RPL programming languages.
2. *Mechanical systems and kinematic linkages module:* The mechanical components in a mechatronic system provide the means to achieve the desired objectives of the product or the system. Principal mechanical components include gears, cams, chains, levers, shafts, pulleys, couplers, bearings, joints, and fasteners. These components are synthesized to construct mechanisms that perform the desired motion of end effects with accurate paths, positions, velocity, and accelerations.
3. *The microprocessors and computer interface module:* Microprocessors act as the brain of the mechatronic product or system. Principal functions of a microprocessor are to manage various instructions to all components such as transducers and actuators in the system, as well as I/O

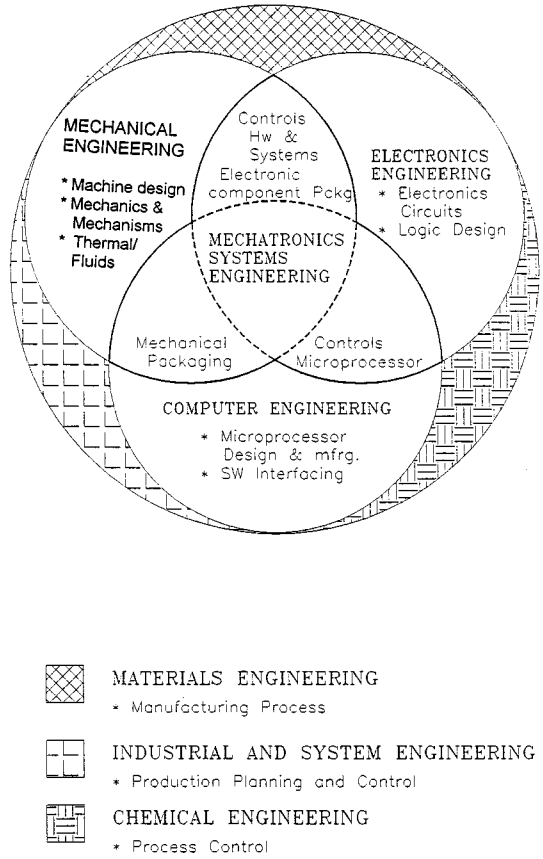

FIGURE 13.3.9 The relationship of various modules in a typical mechatronic device.

interfacing. These processors can also accept function commands from a microcomputer with specific control and applications software.

A block diagram that illustrates the relationship of various modules in a typical mechatronic system is presented in Figure 13.3.10. One may imagine that the microprocessor and microcontroller module functions as the brain, and the sensing/control module and the mechanical systems module each function like the respective sensor-nerve system and the body and limbs in the human anatomy.

13.4 Design and Analysis Tools in Manufacturing

Computer-Aided Design Tools for Manufacturing

David C. Anderson

Introduction

Computer-aided design (CAD) tools for manufacturing are computer programs that evaluate producibility of a product under development using computer models of the product and simulation models for manufacturing processes. Examples of such processes are assembly, casting, molding, stamping, forming, and inspection. The early stages of design are critical to the success of the final product since most of the final cost of a product is committed through decisions about the product's geometry and the materials that lead to the selection and planning of manufacturing processes and production facilities.

Concurrent engineering (CE) is a methodology for product development processes where the tasks are performed simultaneously based on "what if" decision-making processes. CE is a driving force behind the development of CAD tools for manufacturing.

CAD System and Manufacturing

One of the first and most prominent manufacturing applications of CAD system was the automated programming of numerically controlled (NC) machine tools. NC machines were developed in the 1950s, but their widespread use was hindered by the difficulty in writing the requisite NC programs, lists of coded cutting tool motions that directed the machine to cut the desired part. Computer programs that facilitated the generation of NC programs were among the first CAD tools for manufacturing. Early systems focused on profile cutting, generating cutter location data that described the 2D coordinates of the paths of cutting tools that would remove the material to create the final part. Three-dimensional NC programming capabilities are available in most CAD systems today. The user guides the generation of NC data by interactively selecting each surface to be machined and answering questions about tools, approach directions, and machining preferences.

Solid Models and Manufacturing

A key element of virtually all CAD tools for manufacturing is the need to interpret the CAD data according to manufacturing capabilities, requirements, and constraints. Generally, this interpretation involves determining the characteristic shapes in the CAD data related to the manufacturing process of interest and applying knowledge about the process to determine the manufacturing operations and parameters. Solid models are rigorous computer data structures that contain a complete, unambiguous representation of the nominal geometry of an object. Solid models and solid modeling operations, like the Boolean union, difference, and intersection of solids, enabled geometric computations about the design that were not possible with earlier CAD data. With solid modeling, the emphasis in CAD shifted from data for visual communication to product data models that could be used for more sophisticated computer analyses with more automation.

In solid models, geometric features can be described in a form more suitable for engineering and manufacturing applications. As a result, feature-recognition algorithms have become an important element of many CAD tools for manufacturing for translating CAD models into usable geometric data for design evaluations.

However, feature recognition has limitations because it is not possible to translate every solid model into a given set of features. Also, some applications of feature recognition require additional, nongeometric information. This information must be added to the CAD data before, during, or after the feature-recognition process. For example, part tolerance data are required for machining process planning but are not available in current CAD data. Feature-based design (FBD) was developed to overcome some of the limitations of feature recognition. Instead of deriving a features model from a solid model, FBD systems create the product model with features during the design process. Many FBD applications have

been demonstrated in the area of machining, and some commercial CAD vendors have incorporated these features into their systems.

FBD also has limitations. The features that are useful for one manufacturing process may not be useful for another. For example, a model made with cavity features, such as holes, slots, and pockets, provides ready-to-use data for machining planning. However, this model is inappropriate for sheet metal bending or welding processes that require an understanding of the bends and protrusions on a part, not its cavities.

Product Data Standards and Manufacturing

The International Standards Organization (ISO) has developed the Standard for the Exchange of Product model data, STEP. In the U.S., the Integrated Graphics Exchange Specification (IGES)/PDES Organization (IPO) developed the Product Data Exchange Specification, PDES. These efforts merged and PDES was renamed Product Data Exchange using STEP, which is now the American National Standard for STEP. STEP became the international standard (ISO 10303) in March 1994.

STEP is organized as a series of "parts" that are developed and published separately. The parts are organized into numerical series: description methods (parts 11 to 20), integrated resources (parts 41 to 200), application protocols (parts 201 to 1200), abstract test suites (parts 1201 to 2200), implementation methods (parts 21 to 30), and conformance testing (parts 31 to 40). The product information is specified in a formal specification language, EXPRESS, which is documented in Part 11. Part 1 is an overview of the entire standard.

The STEP application protocols (APs) are important to CAD tools for manufacturing. These are the implementable portion of the STEP standard. Each AP draws upon integrated resources and adds specific constraints, relationships, and attributes to meet the information requirements of a particular application. It is expected that several hundred APs may be developed for many different industrial applications.

Design for "X" Tools

Many CAD tools for manufacturing belong to a class of programs described as "design for x," where "x" signifies an application area, such as design for assembly or design for castability. The phrase "design for manufacturability" (DFM) can be considered as a specialization of design for x in which all the applications are manufacturing. Generally, DFM applications are computer programs that perform computations to analyze the producibility of a product with respect to a specific manufacturing process or set of processes. The format of the design data representing the product required by the program varies greatly. The program then provides an evaluation of the suitability of the design according to this domain. The form of this evaluation also varies with each program.

DFM programs act as "manufacturing experts" that provide qualitative, and perhaps quantitative, information about potential problems in a design based on predefined knowledge about a manufacturing process. The programs emulate the process done by human experts, examining the design data and reporting any problems based on experience. Many efforts are based on expert systems technology from the field of artificial intelligence (AI). The searching is performed through the facilities of an AI language, such as PROLOG or LISP, or using an expert system "shell," a preprogrammed generic expert system. Design data are first translated into a knowledge base, the AI version of a database, containing facts and rules. In a sense, the detailed design data are made into logical data that can be processed using AI methods. The program computationally searches the design data for data patterns that match problem conditions represented in the knowledge base of the program. The problem conditions are computer representations of design data that are known to cause manufacturing difficulties for a given process. For example, a "design for injection molding" program may report that an internal corner radius in a geometric model of a part is too small and may cause problems in the mold. In some cases, the program provides a quantitative evaluation of the design, or producibility index. This provides a convenient numerical comparison between two competing designs.

Tools for Manufacturing Process Planning

Tien-Chien Chang

Introduction

Process planning prepares a production documentation which specifies the operations and operation sequence necessary to manufacture a product. Process planning is defined as an act that determines the manufacturing operations, operation sequence, and resources required to make a product. In the process domain, there are machining process planning, welding process planning, EDM process planning, forming process planning, etc. In the product domain, there are mechanical part process planning, mechanical assembly process planning, and electronics assembly process planning. The input to a process planning system (or a human process planner) can be an engineering drawing, a CAD model, or a three-dimensional solid model. While most human planners prefer an engineering drawing on paper or in electronic form, process planning systems usually use CAD models.

The result of the process-planning activity is a "process plan" (see Figure 13.4.1), also called route sheet, operation sheet, or operation planning summary. It can be as aggregate as a list of work center identification numbers or as elaborate as a 50-page document with setup drawings, tool specifications, operation time estimates, etc.

FIGURE 13.4.1 A process plan.

Since the information on the process plan is used in scheduling the production and controlling the machine, the production efficiency and the product quality are affected.

Manual Process Planning

Process planning involves several or all of the following activities:

- Selection of machining operations
- Sequencing of machining operations
- Selection of cutting tools
- Selection of machine tools
- Determination of setup requirements
- Calculations of cutting parameters
- Planning tool path and generation of NC part programs
- Design of jigs and fixtures

The details incorporated in a typical process plan usually vary from industry to industry. It depends on the type of parts, production methods, and documentation needs. A process plan for a tool room–type manufacturing environment typically relies on the experience of the machinist and does not have to be written in any great detail. In fact, the instruction "make as per part print" may suffice. In typical mass-production-type industries, the process-planning activity is embodied in the transfer and flow lines used for manufacturing component parts and assembly. For metal-forming-type manufacturing activities, such as forging, stamping, die casting, sand casting, injection molding, etc., the process-planning requirements are embedded directly into the design of the die/mold used, where most process-planning activity is fairly simple. A process planner must

- Be able to understand and analyze part requirements
- Have extensive knowledge of machine tools, cutting tools, and their capabilities
- Understand the interactions between the part, manufacturing, quality, and cost
- Possess analytical capabilities

Tolerance Charting

During process planning it is important to ensure that the setup and operation sequence will yield a satisfactory part. Tolerancing charting (Figure 13.4.2) has been used to help in allocating process tolerances and verifying the operation sequence. A tolerance chart analyzes one dimension at a time. In a tolerance chart, the top is the part drawing. Dimensions and tolerances are presented with the geometry. Dashed lines show the stock boundary. From the features of the part and the stock, extension lines are drawn to the body of the chart. The section below the drawing shows the critical dimensions and tolerances. These dimensions and tolerances must be satisfied after the processes are complete. Following the process sequence, each operation is listed in the third section of the chart. A line is drawn from the reference surface of a setup to the cut surface. For example, in operation 10, the raw stock boundary at the left is the reference surface. The second surface from the right-hand side is created by this operation. From the chart, one can calculate the resultant tolerances. The results are compared with the blueprint tolerance.

Although traditionally a tolerance chart is implemented on paper and through a fixed procedure, it can also be implemented in a computer. The process tolerance stack-up may be used to verify the design specification and select the appropriate processes and sequences.

Computer-Aided Process Planning

There are two basic approaches to computer-aided process planning — variant and generative. The variant approach is signified by the terminology used by the computer to retrieve plans for similar

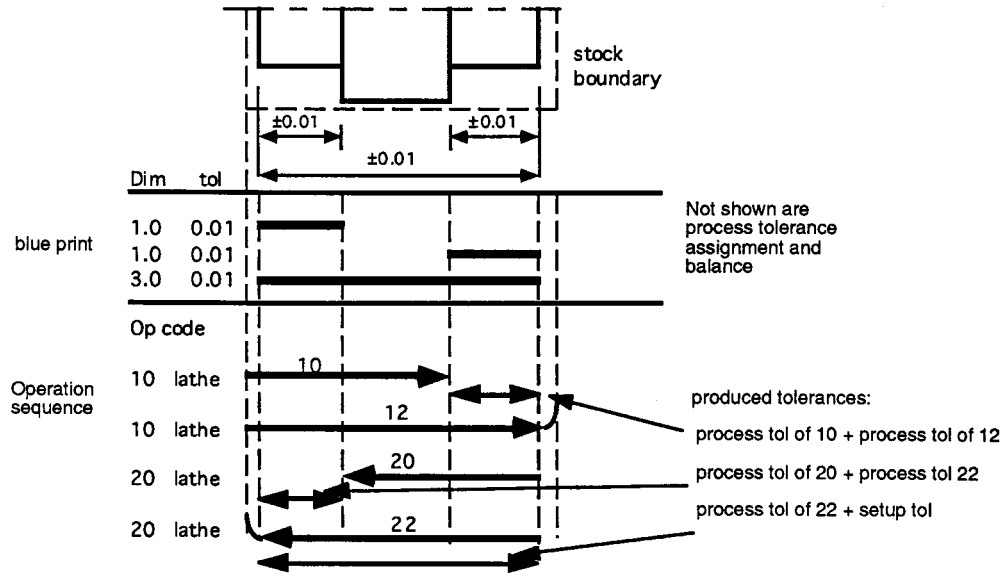

FIGURE 13.4.2 Tolerance chart.

components using table lookup procedures. The human process planner then edits the plan to create a "variant" to suit the specific requirements of the component being planned. Creation and modification of standard plans are the process planner's responsibility. The generative approach generates a plan for each component without referring to existing plans. Generative-type systems can perform many functions in a generative manner, while the remaining functions are performed with the use of humans in the planning loop.

Variant Process Planning

The variant approach to process planning was the first approach used to computerize the planning techniques. It is based on the concept that similar parts will have similar process plans. The computer can be used as a tool to assist in the identification of similar plans, retrieving them and editing the plans to suit the requirements for specific parts.

In order to implement such a concept, part coding and classification based on group technology is used as a foundation. Individual parts are coded based upon several characteristics and attributes. Part families are created of "like" parts having sufficiently common attributes to group them into a family. This family formation is determined by analyzing the codes of the part spectrum. A "standard" plan consisting of a process plan to manufacture the entire family is created and stored for each part family. The development of a variant-process-planning system has two stages: the preparatory stage and the production stage (Figure 13.4.3).

During the preparatory stage, existing components are coded, classified, and later grouped into families. The part family formation can be performed in several ways. Families can be formed based on geometric shapes or process similarities. Several methods can be used to form these groupings. A simple approach would be to compare the similarity of the part code with other part codes. Since similar parts will have similar code characteristics, a logic which compares part of the code or the entire code can be used to determine similarity between parts.

Families can often be described by a set of family matrices. Each family has a binary matrix with a column for each digit in the code and a row for each value a code digit can have. A nonzero entry in the matrix indicates that the particular digit can have the value of that row, e.g., entry (3,2) equals one

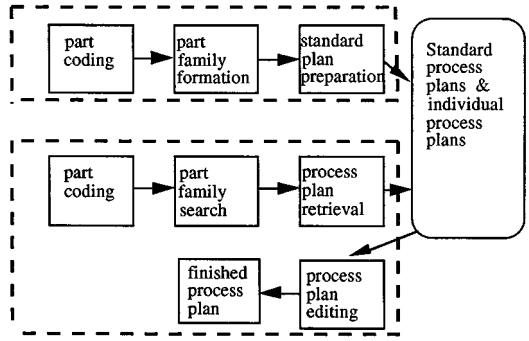

FIGURE 13.4.3 Variant-process-planning approach.

implies that a code x3xxx can be a member of the family. Since the processes of all family members are similar, a standard plan can be assigned to the family. The standard plan is structured and stored in a coded manner using operation codes (OP-codes). An OP-code represents a series of operations on one machine/workstation. For example, an OP-code DRL10 may represent the sequence center drill, change drill, drill hole, change to reamer, and ream hole. A series of OP-codes constitute the representation of the standard process plan.

Before the system can be of any use, coding, classification, family formation, and standard plan preparation must be completed. The effectiveness and performance of the variant-process-planning system depend to a very large extent on the effort put forth at this stage. The preparatory stage is a very time-consuming process.

The production stage occurs when the system is ready for production. New components can be planned in this stage. An incoming component is first coded. The code is then sent to a part family search routine to find the family to which it belongs. Since the standard plan is indexed by family number, the standard plan can be easily retrieved from the database. The standard plan is designed for the entire family rather than for a specific component; thus, editing the plan is unavoidable.

Variant-process-planning systems are relatively easy to build. However, several problems are associated with them., e.g.,

1. The components to be planned are limited to previously planned similar components.
2. Experienced process planners are still required to modify the standard plan for the specific component.
3. Details of the plan cannot be generated.
4. Variant planning cannot be used in an entirely automated manufacturing system, without additional process planning.

Despite these problems, the variant approach is an effective method, especially when the primary objective is to improve the current practice of process planning. In most batch-manufacturing industries, where similar components are produced repetitively, a variant system can improve the planning efficiency dramatically. Some other advantages of variant process planning are

1. Once a standard plan has been written, a variety of components can be planned.
2. Programming and installation are comparatively simple.
3. The system is understandable, and the planner has control of the final plan.
4. It is easy to learn and easy to use.

Generative Approach

Generative process planning is the second type of computer-aided process planning. It can be concisely defined as a system which automatically synthesizes a process plan for a new component. The generative approach envisions the creation of a process plan from information available in a manufacturing database

without human intervention. Upon receiving the design model, the system is able to generate the required operations and operation sequence for the component.

Knowledge of manufacturing has to be captured and encoded into computer programs. By applying decision logic, a process planner's decision-making process can be imitated. Other planning functions, such as machine selection, tool selection, process optimization, etc., can also be automated using generative planning techniques.

A generative-process-planning system comprises three main components:

1. Part description
2. Manufacturing databases
3. Decision-making logic and algorithms

The definition of generative process planning used in industry today is somewhat relaxed. Thus, systems which contain some decision-making capability on process selection are called generative systems. Some of the so-called generative systems use a decision tree to retrieve a standard plan. Generative process planning is regarded as more advanced than variant process planning. Ideally, a generative-process-planning system is a turnkey system with all the decision logic built in. However, due to the differences among manufacturing shops, decision logics have to be customized for each shop.

The generative-process-planning approach has the following advantages:

1. Consistent process plans can be generated rapidly.
2. New components can be planned as easily as existing components.
3. It has potential for integrating with an automated manufacturing facility to provide detailed control information.

There is no fixed representation or procedure that can be identified with generative process planning. The general trend is to use a solid model CAD-based input and expert system or an object-oriented planner construct. Most of the research systems are of this type. A few commercial products can also be classified as generative.

Conclusions

Process planning is a critical function in design and manufacturing. The quality of the product and the cost of production are affected by the process plan. A process plan incorporates information on the shop capability, resource requirement, best routing, etc. In order to produce a good process plan, a planner must be knowledgeable in both the manufacturing practices and the current shop status and capabilities. At this moment most computerized planners are still based on data retrieval and database lookup. As the information technology is further developed and we have better understanding of process capabilities, integrated planning systems will evolve.

Simulation Tools for Manufacturing

Hank Grant

Introduction

Digital simulation uses a mathematical model to represent a real or hypothetical physical system. A computer simulation model of a physical system provides a laboratory in which alternative designs can be explored and analyzed. The model, executed on the computer, is a software replica of the manufacturing system and is controlled so that the behavior of the system can be studied and analyzed. Decisions can be made concerning production alternatives. For example, adding a new lathe can be considered without disrupting the actual physical system.

Simulation depends on describing a system in terms acceptable to the computer language used. To do this, it is necessary to have a *system-state description*, which is typically characterized by a set of state variables included in the computer program that make up the simulation model.

Types of Simulation Models

Simulation models are typically classified into three types: discrete event, continuous, and combined. Simulation software has been designed to address each of these types of models.

Discrete Event. Discrete event simulation is used to model systems when there are specific events in time when the variables of the system may change in values. The mechanics of those changes must be well known and easily characterized. The behavior of the system is represented by the behavior of individual objects of interest called *entities*. The simulation model characterizes the behavior of these entities as they move through the system in simulated time.

Discrete events are points in time where the characteristics of an entity may change and where the state variables of the system may change. For example, when a customer arrives for service, the state of the system may change (number in the system, status of the server, etc.). The modeling of systems using this approach consists of developing descriptions of the events and how they cause the state variables to change and the entities to be manipulated.

The individual events may not always be predictable, and stochastic elements may be present in the operation of the system. For example, the time between arrivals of customers to the system may be a random variable. Simulation languages have many tools to support random variation in models.

A special kind of discrete event model is a *network model*. Network models use a standard set of symbols to represent the flow of entities in the system. They are graphical in nature, and are very useful communication vehicles as well as very powerful in building simulation models quickly and easily. There are several languages available that include network modeling capabilities and they are described below.

Continuous. Continuous simulation is an approach that is popular among engineers and economists. The main building blocks of this approach are as follows (Pidd, 1994).

Aggregated variables: Instead of a concern with individual entities, the main concern is with the aggregated behavior of populations. For example, the changing sales of a product through time.

Smooth changes in continuous time rather than focusing on individual events, where the stress is on the gradual changes which happen as time progresses. Thus, just as the graph of a variable might be smooth, the aim is to model the smooth changes of the variable by developing the suitable continuous equations.

Differential or difference equations: The model consists mainly of a set of equations which define how behavior varies through time; thus, these tend to be differential equations or, in simpler cases such as system dynamics, difference equations.

Nature does not present itself labeled neatly as discrete or continuous; both elements occur in reality. Modeling, however, as mentioned above, involves approximation, and the modeler must decide which of these approaches is most useful in achieving the desired aim of the simulation.

Combined Discrete Event/Continuous. In some cases, both approaches are needed and the result is a mixed discrete-continuous simulation. An example of this might be a factory in which there is a cooking process controlled by known physics which is modeled by continuous equations. Also in the factory is a packing line from which discrete pallets of products emerge. To model the factory will require a mixed approach.

Modeling Languages

Specifically designed computer simulation languages provide many features for managing the updating of the state variables and advancing time. They also provide features for recording system performance statistics and for generating random numbers to introduce system randomness.

The lowest level of computer language typically used is FORTRAN or BASIC. This requires that the entire simulation model be coded, which is labor-intensive. High-level languages, such as SLAM, SIMSCRIPT, and GPSS, facilitate simulation because they provide subroutines for time advancement, entity maintenance, and statistic collections. Higher-level simulation languages are designed for special purposes; MAP/1, SPEED, and MAST are three designed for the simulation of manufacturing systems.

Some simulation languages can produce animations. This permits the simulation to be illustrated graphically on a computer terminal so that the analyst can see the system in action and observe its interactions and behavior, a visual function beyond the scope of standard reporting technique. For example, TESS (a software program) provides animation, as well as model-building and output analysis capabilities, for the SLAM simulation language.

The following discussion by Banks (1994) provides an overview of the primary languages available.

Applications of simulation exist in many arenas such as manufacturing, material handling, health services, military decision support, natural resources, public services, transportation, and communications, to mention a few.

These simulation applications are usually accomplished with the use of specially developed simulation software. This tutorial describes the software in two categories. The first of these is software for general purposes. This type of software can solve almost any discrete simulation problem. In this section, five products, GPSS/H™, GPSS/World™, SIMAN V′, SIMSCRIPT II.5′, and SLAMSYSTEM′, will be discussed to provide a feel for this type of software.

GPSS/H. GPSS/H is a product of Wolverine Software Corporation, Annandale, VA (Smith and Crain, 1993). It is a flexible, yet powerful tool for simulation. It provides improvements over GPSS V that had been released by IBM many years earlier. These enhancements include built-in file and screen I/O, use of an arithmetic expression as a block operand, interactive debugger, faster execution, expanded control statement availability, and ampervariables that allow the arithmetic combinations of values used in the simulation. The latest release of GPSS/H is version 2.0. It added a floating point clock, built-in math functions, and built-in random variate generators. Options available include Student GPSS/H, Personal GPSS/H within the 640K memory limit, and GPSS/H 386 providing unlimited model size.

GPSS World. GPSS World, from Minuteman Software, is a complete redesign of GPSS/PC™ (Cox, 1992). It is designed as a high-power environment for simulation professionals. It includes both discrete and continuous simulation. Its features include interactivity, visualizability, and configuration flexibility. It utilizes 32-bit computing, virtual memory, preemptive multitasking, symmetric multiprocessing, and distributed simulation. Highlights include drag-and-drop model building, 512 megabytes of virtual

memory for models, point-and-shoot debugging, an embedded programming language, built-in probability distributions, multiple data types, and many other improvements to GPSS/PC.

The GPSS World family is a set of three software products including:

1. GPSS World is the center of the family. This self-contained modeling environment includes local Simulation Server™ capabilities.
2. Simulation Server provides simulation services on a remote networked computer. It does not include a model-building user network.
3. Simulation Studio provides hierarchical modeling and user-drawn simulation capabilities.

There is an enhanced memory version of GPSS/PC that is also available. It allows access of up to 32 megabytes of memory.

SIMSCRIPT II.5. SIMSCRIPT II.5 from CACI Products Company is a language that allows models to be constructed that are either process oriented or event oriented (Russell, 1993). The microcomputer and workstation version include the SIMGRAPHICS animation and graphics package. SIMSCRIPT can be used to produce both dynamic and static presentation-quality graphics such as histograms, pie charts, bar charts, levels of meters and dials, and time plots of variables. Animation of the simulation output is also constructed using SIMGRAPHICS. SIMGRAPHICS can be used also to produce interactive graphical front ends or forms for entering model input data. An input form may include such graphical elements as menu bars with pull-down menus, text or data boxes, and buttons that are clicked on with a mouse to select an alternative. The graphical model front end allows for a certain set of modifications to the model to be made without programming, facilitating model use by those who are not programmers.

SIMAN V. SIMAN V from Systems Modeling Corporation is a general-purpose program for modeling discrete and/or continuous systems (Glavach and Sturrock, 1993; Banks et al., 1995). The program distinguishes between the system model and the experiment frame. The system model defines components of the environment such as machines, queues, and transporters and their interrelationships. The experiment frame describes the conditions under which the simulation is conducted, including machine capacities and speeds and types of statistics to be collected. “What-if” questions can usually be asked through changing the experiment frame rather than by changing the model definition. Some important aspects of SIMAN V are as follows:

1. Special features that are useful in modeling manufacturing systems include the ability to describe environments as work centers (stations) and the ability to define a sequence for moving entities through the system.
2. Constructs that enable the modeling of material-handling systems including accumulating and nonaccumulating conveyors, transporters, and guided vehicles.
3. An interactive run controller that permits break points, watches, and other execution control procedures.
4. The ARENA environment that includes menu-driven point-and-click procedures for constructing the SIMAN V model and experiment, animation of the model using Cinema, the input processor that assists in fitting distributions to data, and the output processor that can be used to obtain confidence intervals, histograms, correlograms, and so on. (More aspects of the ARENA environment are discussed later.)
5. Portability of the model to all types of computers.

SLAMSYSTEM. SLAMSYSTEM, from Pritsker Corporation, is an integrated simulation system for PCs based on Microsoft Windows™ (Pritsker, 1986; O’Reilly, 1993). All features are accessible through pull-down menus and dialog boxes and are selected from the SLAMSYSTEM Executive Window. A SLAMSYSTEM project consists of one or more scenarios, each of which represents an alternative system configuration. A project maintainer examines the components of the current scenario to determine if any of them have been modified, indicates whether or not tasks such as model translation should be performed,

and allows the user to accomplish these tasks before the next function is requested. SLAMSYSTEM allows multiple tasks to be performed in parallel while the simulation is operating in the background.

Some of the features of SLAMSYSTEM are as follows:

1. Models may be built using a graphical network builder and a forms-oriented control builder, or text editor. When using the first method, a network symbol is selected with the mouse, then a form is completed specifying the parameters for that symbol. The clipboard allows many other operations such as grouping one or more symbols and placing them elsewhere on the network.
2. Output analysis includes a "report browser" that allows alternative text outputs to be compared side by side. Output may be viewed in the form of bar charts, histograms, pie charts, and plots. Output from multiple scenarios can be displayed at the same time in bar chart form. By using the Windows environment, multiple output windows can be opened simultaneously.
3. Animations are created under Windows using the facility builder to design the static background and the script builder to specify which animation actions should occur when a particular simulation event occurs. Animations can be performed either concurrently or in a postprocessing mode. Two screens can be updated simultaneously and up to 225 screens can be swapped into memory during an animation.
4. SLAMSYSTEM was designed to be used in an integrated manner. For example, historic data may be read to drive the simulation. CAD drawings may be loaded. Output charts and plots created by SLAMSYSTEM may be exported via the clipboard to other applications.

The newest release of SLAMSYSTEM is version 4.0. Some of its unique features include the following:

1. Multiple networks in a single scenario: Networks can be constructed in sections and combined at run time. The sections can be reused in future models.
2. New output graphics: These graphics support three-dimensional X-Y grids and displaying of point plot data.
3. Direct interface to SimStat (product of MC^2 Analysis Systems): These files may be loaded for advanced statistical analysis.
4. OS/2 metafiles for graphics: The OS/2 metafile format can be read for animation backgrounds or icons.

Conclusion

Simulation is a powerful approach to modeling manufacturing systems in that many complex and diverse systems can be represented. Simulation can predict system performance measures that are difficult to assess without a model. It is a proven, successful tool and has been in use since the 1950s. The current languages take advantage of the capabilities of today's microprocessors and provide the user with the needed on-line support for model development, management, and analysis.

Tools for Intelligent Manufacturing Processes and Systems: Neural Networks, Fuzzy Logic, and Expert Systems

Tien-I. Liu

Introduction

Starting in the 1980s, researchers and practitioners became increasingly interested in intelligent machines and intelligent manufacturing. The goal is to model the skills and expertise of professionals so that machines and manufacturing systems can possess some of the characteristics of human intelligence. Three techniques, neural networks, fuzzy logic, and expert systems, have been widely used in manufacturing. This section describes the principles and functions of these tools. Examples in applying these tools to manufacturing applications are highlighted as well.

Neural Networks

Neural networks consist of a set of nodes which are nonlinear computational elements. The pattern of connectivity between nodes, known as weights, can be modified according to some preset learning rule. The knowledge of the networks is stored in their interconnections (Kohonen, 1986).

Since neural networks are parallel distributed processing, they have the following advantages:

1. They are adaptive and can learn from experience.
2. The network can be refined at any time with the addition of new training data.
3. Various model architectures can be used.
4. They can compute very quickly and thus they are very suitable for real-time applications.
5. They can be used for analyzing large amounts of data to determine patterns that may predict certain types of behavior.
6. They can capture the complexities of the process, including nonlinearities, even if the dynamics of the process is unknown.
7. They can make decisions based upon incomplete and noisy information.
8. They degrade gracefully even when parts of the structure have been destroyed.

Neural networks are best at performing the types of tasks which need human perception. These tasks do not have exact answers, e.g., classification and trend analysis. A typical example of such problems is machine diagnosis. An experienced mechanic can point out what is wrong with an automobile by standing beside the car and listening to the sound of the running engine. Another example is character recognition. Any person who is familiar with alphabets can easily identify the letter "A" in any of various typefaces or handwritten scripts. In both cases it is practically impossible to develop a set of if–then rules to let a computer to do the job. These tasks are also difficult to program using standard computer techniques.

Applications of Neural Networks. Many electronics and computer companies have put considerable effort into neural network development. IBM has announced a neural network development package for its computer; Intel Corporation has developed a microchip that supports this technology. Japanese companies such as Fujitsu, Hitachi, Mitsubishi, and Sumitomo Heavy Industries are also working in this field.

A bomb-detection machine which uses neural network technology to detect plastic explosives hidden in baggage has been developed. This machine has been installed in several airports. Neural networks have also been applied to ensure the operation of an industrial power distribution substation. It has replaced a conventional mechanical system and improved the performance by greater than an order of magnitude.

Integrating sensors with neural networks for monitoring and diagnostic purposes can enhance production reliability, prevent potential problems caused by abnormal conditions, and maintain high product quality in the factory (Liu and Iyer, 1993). The applications of neural networks for monitoring and diagnostic purposes have been used with ball-and-roller bearings, turning processes, milling processes, drilling processes, tapping processes, glass furnaces, etc. The results are very successful (Liu and Anatharaman, 1994).

Neural networks have also been used in the image processing for computer vision and speech-recognition systems (Badal, 1993). They also are used for the control of machines and processes. The neural network controller is capable of on-line learning of the system dynamics and then taking adequate action to achieve the predetermined goal. They also can be used to tune the gain of control systems.

Fuzzy Logic

The theory of fuzzy sets has been developed as a methodology for the formulation and solution of problems which are too complex or too ill defined to be solved by traditional techniques. In fuzzy logic, the membership in a set is not either 0 or 1; instead it is a value between 0 and 1. Membership functions span some problem domain, such as length or weight, and show the membership for each value of the problem domain. Membership functions are subjective evaluations and can be represented by many kinds of curve. However, the membership function cannot be assigned arbitrarily. The formulation of the membership function should be based upon the professional feeling and physical understanding of the problem. Let $S = \{s\}$ represent a space of objects. Then a fuzzy set X in S is a set of ordered pairs

$$X = \left\{s, f_x(s)\right\}, \quad s \_ S(1)$$

where $f_x(s)$ is the grade of membership of s in X and $f_x(s)$ is a number in the interval (0,1).

Fuzzy mathematics, which consists of precise rules to combine vague expressions, such as “very high” and “somewhat heavy,” has been developed (Kandel, 1986). Generally speaking, fuzzy logic systems have the following advantages:

1. They are inherently flexible.
2. They are robust to noisy or missing data, unexpected disturbances, and errors in problem modeling.
3. They are suitable to deal with problems for which knowledge is approximate or problems which are so complex that it is difficult to develop an adequate mathematical model.
4. They usually are energy efficient.

Applications of Fuzzy Logic. Fuzzy mathematical techniques are very suitable for the control of machine tools, robots, and electronic systems (Mamdani, 1993). They are also applicable to image understanding for computer vision and pattern classification for the monitoring and diagnosis of manufacturing processes (Du et al., 1992).

The very first application of fuzzy logic was the control of the fuel-intake rate and gas flow of a rotating kiln used to produce cement. Since then, it has been used to control many automated manufacturing processes. Fuzzy logic has resulted in significant improvements to many commercial products,

such as cameras and air conditioners. Although fuzzy logic was developed in the U.S., most of the action is in Japan. The most impressive application is a subway system operated by a fuzzy computer. It was installed in the 1980s by Hitachi at Sendai, about 200 mi north of Tokyo, Japan. This system is more than 10% energy efficient and is so smooth that passengers do not need to hang onto straps.

At AT&T Bell Laboratories, Dr. M. Togai and Dr. H. Watanabe developed the very first fuzzy logic processing chip in 1985. NASA is developing fuzzy controllers to help astronauts pilot the space shuttle in earth orbit. In the U.S. the interest in applying fuzzy logic is growing continuously.

Expert Systems

An expert system is a computer system which possesses the capability of a human expert. An expert system has the following five essential parts (Figure 13.4.4):

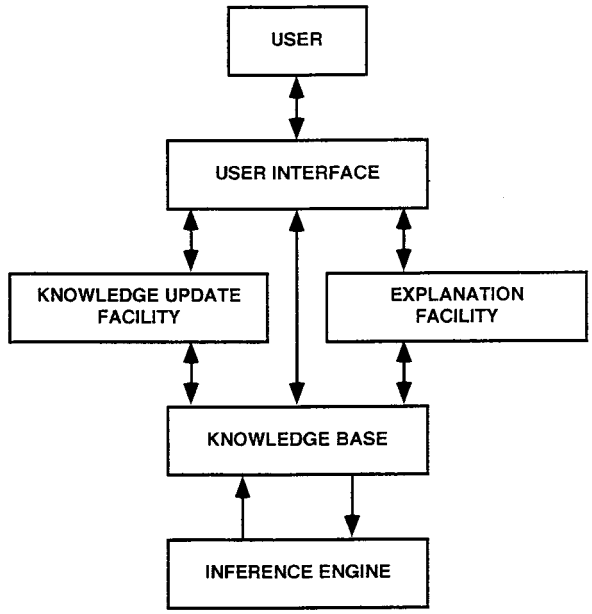

FIGURE 13.4.4 Typical expert system architecture.

1. *User Interface.* This module is the interface between the user and other parts of the expert system.
2. *Knowledge Base.* The knowledge about solving specific problems is stored in the knowledge base of an expert system. The process of building the knowledge base is called knowledge engineering and is done by a knowledge engineer (Figure 13.4.5). Knowledge engineering refers to the acquisition of knowledge from a human expert or other source and the coding of it into the expert system. The knowledge base usually consists of rules and facts. Rules are made up of English-like sentences or clauses. Rules are often defined using an if–then syntax that logically connects one or more antecedent clauses with one or more consequent clauses as follows:

   IF antecedent THEN consequent

   A rule says that if the antecedent is true, then the consequent is also true. The antecedent and consequent of rules refer to a specific fact that describes the state of the world. On the other hand, each fact is a single sentence that describes some aspect of the state of the world.
3. *Inference Engine.* The inference engine can infer new knowledge from existing knowledge stored in the knowledge base. Two general inference approaches are commonly used: forward chaining and backward chaining. Forward chaining is the reasoning from facts to conclusions resulting

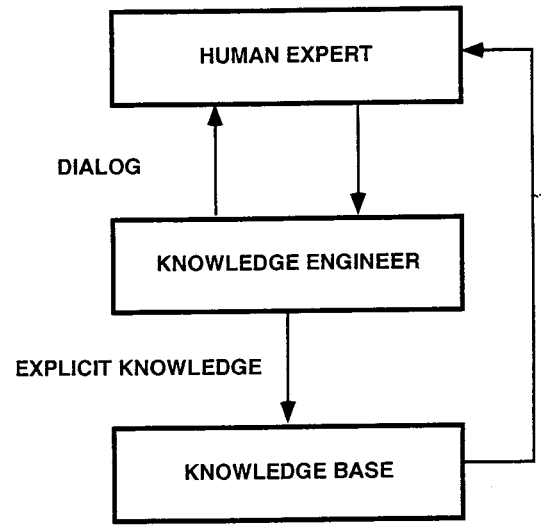

FIGURE 13.4.5 Knowledge engineering.

from those facts. Backward chaining involves reasoning in reverse from a hypothesis to the facts which support the hypothesis.

4. *Knowledge Update Facility.* The knowledge in many fields, including engineering and manufacturing, changes with time. The expert system can be updated through this facility.
5. *Explanation Facility.* Just like a human expert can explain how a specific conclusion has been drawn, the explanation facility can explain its reasoning to enhance the credibility of an expert system.

Expert systems are quite different from conventional programs because the problems usually have no algorithmic solution and rely on inferences to achieve a reasonable solution. In other words, the expert system is very suitable to solve problems which require heuristic rules. These heuristic rules can be stored in the knowledge base.

Expert systems have the following advantages as compared with the human expert:

1. They are steady and unemotional and have high reliability. Therefore, errors are reduced.
2. They have high availability. Users can get answers any time.
3. The expert system can be installed and used at multiple sites.
4. They can explain how a conclusion has been reached. Thus, the users feel comfortable working with expert systems.

Expert systems can help people solve problems. They can free the human expert from the routine job to do other work. Hence, they can increase efficiency and reduce cost.

Applications of Expert Systems. Expert systems have been used in many fields. There are many commercialized expert systems running on different computer platforms which help professionals in various fields, enhancing efficiency and productivity greatly.

Manufacturing, assembly, quality, reliability, and cost need to be taken into consideration in the early stage of product design. Expert systems have been developed for DFM, design for assembly (DFA), design for quality and reliability, product cost estimation, etc. These expert systems can be integrated with the existing CAD/CAM systems (Liu et al., 1995). Many expert systems have also been built and used in the areas of facility design, production planning and control, computer-aided process planning, material handling, quality control, equipment maintenance and repair, and real-time control (Alto et al., 1994). In simple words, design and manufacturing work can be upgraded from an experience-based to a science-based function by using expert systems.

Conclusion

Neural networks, fuzzy logic, and expert systems are the way of the future. They can make machines and manufacturing processes much smarter. Applying these techniques can lead to the realization of a fully automated factory in the future.

Tools for Manufacturing Facilities Planning

J. M. A. Tanchoco, Andrew C. Lee, and Su-Hsia Yang

Introduction

The main function of facility planning is the design of efficient flow of products from raw material to finished goods. It is one of the most important determinants of operating efficiency and production cost. Traditionally, the facility-planning problem is divided into three areas, namely, group technology (GT), material handling, and facility layout (see Figure 13.4.6). GT, which is closely related to cellular manufacturing, is usually defined as the grouping of dissimilar machines in close vicinity. Each group or cell is dedicated to the production of one or more parts families. The parts in the family are similar in their processing requirements (Wemmerlov and Hyer, 1989). Two of the most fundamental elements in facility planning are the facility layout and the material-handling system.

Facility layout positions the workstations around the fixed product based on the processing sequence. In a product layout, machines are arranged according to the processing sequence of the product, e.g., the assembly of automobiles, certain electronic products, etc. The machines are located so as to provide smooth and logical flow of material. In a group layout, also referred to as a cellular layout, products are grouped into logical product families. All machines which perform similar operations are grouped together in the process layout. A process layout is characterized by a high degree of flexibility and machine utilization. Regardless of the type of facility, a detailed layout should not be designed without giving serious consideration to material-handling requirements. The choice of material-handling methods and equipment is an integral part of the layout design. The facility layout design component performs two basic functions. The first function is to decide how to locate cells with respect to each other. The objective is to minimize either the total material flow distance or transportation time. The second function is to resolve the machine location and orientation relative to each other within the cell. The constraints in layout design or facility structure could prohibit the placement of the cells or machines in some

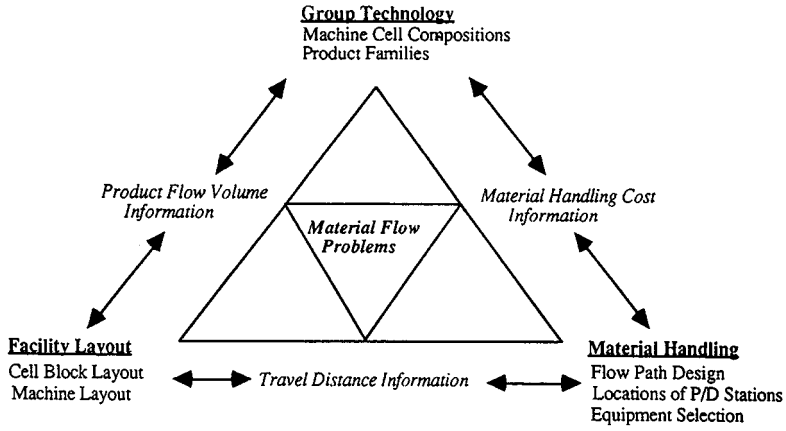

FIGURE 13.4.6 Facilities-planning framework components.

locations, thus changing the machine compositions of the cells. The resolution from this design problem has a significant impact on the distance that material has to be moved.

Material handling performs a critical function in modern dynamic manufacturing systems. The transportation of materials within a production system is often accomplished with limited resources, e.g., conveyors, forklift trucks, or automated guided vehicles (AGVs). Such transfer mechanisms not only deliver material in a timely fashion, but also provide temporary storage capacity. These limited resources require a capital investment, which increases the overall production costs. Excess transportation capability represents expenditures that are not accompanied by increased value. Insufficient capacity, on the other hand, can adversely affect production by delaying the delivery of material, thus reducing the total production volume. Material handling is generally considered as a non-value-adding activitiy. However, one can argue that material handling adds time and space value by making the material available and ready for processing. The material handling has three functions. First, the flow path design selects the route that material transfers from cell to cell or from machine to machine. Limited by the cost of remodeling, the existing plant configuration (such as the aisle width) might not be able to accommodate the traffic flow. Therefore, considerations must be given to the overall facility layout and building structure. The second function is to locate the pickup and delivery stations along the flow path. Along with the facility layout and flow path design, it is one of the most important determinants of the operating cost of material handling. Finally, the best combination of material-handling equipment is determined. Because of the complex, ill-structured, and experience-based nature of the problem, the decisions for choosing material-handling equipment tend not to be based on rigorous criteria. However, the designers must recognize that there is an appropriate level of technology for every application that will meet the combined need for maximum handling efficiency and acceptable cost.

Decision Factors for Facilities Planning

The effectiveness of a facility-planning system depends on the careful integration of GT, facility layout, and the material-handling system.

Group Technology. Mitrofanov (1959) is recognized as the first person to introduce the concept of GT and machine grouping. Since then, a number of researchers have developed techniques for machine grouping and part family formation. In general, these techniques can be categorized as follows:

1. *Machine-Component Matrix* (McAuley, 1972; King, 1980; McCormick et al., 1972): The main idea behind this approach is to delineate cells by grouping binary entries of a machine–component incidence matrix into fuzzy blocks along the matrix diagonal.

2. *Mathematical Programming Formulation* (Kusiak et al. 1986; Askin and Standridge, 1993): In this approach, a large, combinatorial mixed integer programming formulation is usually required to model the problem.
3. *Graph-Based Formulation/Partitioning* (Rajagopalan and Batra, 1975; Faber and Carter 1986): In this approach, the machine–part matrix is represented by a bipartite, transition, or boundary graph. Then, it is solved using graph theoretic clustering methodology.

Facility Layout. The facility layout problem has been formulated as a quadratic assignment problem (QAP). The objective function for this type of formulation is to minimize the total material-handling cost. Given the complexity of the QAP formulation, the size of problems which could be solved by optimal methods is very limited. Thus, heuristic algorithms are more suitable. These heuristics can be classified into two major groups. The first group is called construction algorithms (Seehof and Evans, 1967; Lee and Moore, 1967; Foulds and Giffin, 1985; Hassan and Hogg, 1991). The main idea behind these methods is to build the layout by adding one more block (a cell or a department) to a partial block layout until all blocks have been located. The methodology requires two steps: a selection step and a placement step. The selection step determines the order by which the blocks enter the layout, while the placement step selects the location of the new block to enter the layout relative to the blocks that are already in the layout. The objective is to maximize some kinds of performance criteria, e.g., total closeness rating. Graph theoretic methods have been applied as a solution methodology for this approach.

The second group of the layout heuristics is called improvement algorithms. This approach starts from an initial layout, and improvements are made by successive pairwise interchanges of blocks. The general form of an improvement algorithm consists of the following steps: (1) select a pair of activities, (2) estimate the cost of interchange, (3) exchange if the total cost is reduced, and (4) repeat until no more improvement can be made. This category of heuristics includes the computerized relative allocation of facilities technique (CRAFT) of Armour and Buffa (1963) and Buffa et al. (1964) and the methods of Hillier (1963), Fortenberry and Cox (1985), and Co et al. (1989).

Recognizing the weaknesses of both construction and improvement algorithms when applied separately, Golany and Rosenblatt (1989) proposed a hybrid method that takes advantages of both construction and improvement algorithms. They use the layout resulting from the construction algorithm as the initial layout and improve upon it using an improvement algorithm. Since most of the heuristics for facility layout are based on the "greedy approach," the solution is very sensitive to the initial layout. The final layout given by the algorithm may not be the best.

Material Handling. Material handling involves moving, storing, and controlling the flow of materials. There are several components, such as the flow path design, the locations of pickup and delivery stations, and the material-handling equipment selected, that have significant effects on the overall effectiveness of the material-handling system. The objective of flow path design is to determine the best "street network" that transporters pass through when parts are moved from one machine to the next. It is one of the major determinants in the calculations of travel times, operating expenses, and installation costs of the material-handling system. There are numerous types of flow path network configurations. The most widely adopted flow path design is the conventional flow network. It is usually a unidirectional flow network where any cell boundary is used as part of the flow path. In a unidirectional network, one has to determine the flow direction for each aisle. Its flexibility, reliability, and efficiency have made this type of network a popular choice especially when AGVs are used. In comparison, the potential of using a bidirectional flow network could make the system more efficient (Egbelu and Tanchoco, 1986). The same authors also developed guidelines for the use of a single-lane bidirectional flow network. However, the advanced hardware requirements and complicated system controllers are viewed negatively.

A single-loop flow path network can be found in many flexible manufacturing systems. The entire flow path design is made up of a single loop. This type of network can potentially minimize some of the problems associated with a conventional flow network. Congestion is inherently low and the operating rules are simple. It also has relatively low initial investment and maintenance costs.

Recently, a new flow path network configuration, a segmented flow topology (SFT), was developed by Sinriech and Tanchoco (1994). It is comprised of one or more zones, each of which is separated into nonoverlapping segments. Each segment is serviced by a single bidirectional material-handling device. Transfer buffers are located at both ends of each segment. The flow structure in each zone is determined by the logical flow requirements and by the existing aisle network. The SFT provides a simple flow structure and control system. The research also suggested that it can achieve a higher throughput capability compared to other material flow path network configurations.

The locations of pickup and delivery stations have generally been considered as a secondary issue in the design phase of facility layout and a material-handling system. Yet it can have detrimental effects on the costs of material handling and the a machine layout configuration. In a study by Warnecke et al. (1985), they confirmed that the actual pickup and delivery station flow distance is much more representative than taking the rectilinear distance between the centers of machine blocks. Since then, several design procedures have been proposed to find the optimal location of material-transfer stations. Montreuil and Ratliff (1988) suggested a systematic methodology for locating pickup and delivery stations within a facility layout using multifacility location theory. The objective function is to minimize the sum of the rectilinear distance traveled by all intercellular flows, given the boundary regions on station location. Luxhoj (1991) developed a two-phase design procedure that is suitable for the spine layout where the active flow lines are well defined.

In terms of material-handling equipment selection, there is a large variety of equipment types available with their own special functions and characteristics. Each equipment type has its own capability and limitations. Some of these characteristics are difficult to quantify. The integrated nature of the manufacturing systems complicates the material-handling selection problem. The problem was first addressed by Webster and Reed (1971). The procedure they suggested initially assigns material-handling equipment to departmental moves based on cost alone. Then, move assignments are interchanged to seek improvement in equipment utilization and total cost. Hassan et al. (1985) reformulated Webster and Reed's model as an integer programming model with the objective of minimizing the total operating and capital costs of the selected equipment. Due to the combinatorial nature of the problem, it is solved using a construction heuristic that exploits some similarities to both knapsack and the loading problems. Material Handling Equipment Selection System (MATHES) was developed by Fisher et al. (1988). MATHES is a rule-based system for the selection from 24 different types of material-handling equipment.

Conclusion

The framework discussed in this section provides an alternative perspective from the material flow viewpoint. It integrates all of the important design factors associated with facilities planning. It incorporates most of the desired properties with respect to the overall plant operations. At the same time, the framework also summarizes the difficulties and complexities which confront the facility designer. The description of the framework is intended as a general exposition of the fundamental concepts and a direction for future research in facilities planning.

13.5 Rapid Prototyping

Takeo Nakagawa

Manufacturing Processes in Parts Production

The rapid progress of CAD technology for the design of machine parts has now made it easy to store three-dimensional shape data on computers. The application of this three-dimensional data has realized NC programming by CAD/CAM, resulting in the remarkable advance of automated production. The increase in highly functional machine parts and advanced designs has led to the design of more and more complicated surfaces using CAD. To reduce the lead time and costs for the development of new industrial products, "rapid prototyping" has been recognized as a unique, layered manufacturing technique for making prototypes.

With this rapid prototyping, shapes of machine parts are created by building up layers and layers of materials, unlike the material-removal technique which shapes by gradual machining using a cutting tool. In this sense, rapid prototyping resembles the joining technique of small particles or thin layers. Various different types of rapid prototyping methods have been born over the last couple of years. A common feature of these methods is that parts are directly shaped fully automatically according to CAD data. Specifically, in all of these methods, the three-dimensional CAD data is taken as composed of thin layers of two-dimensional data. The thin layers are formed using the two-dimensional data and built up to form an actual three-dimensional solid product. With the nature of the processing steps, this rapid prototyping technique is called *layered manufacturing.* As the method can also be used in other applications than prototyping, it is also referred to as *free-form fabrication.* Because three-dimensional objects can be made from three-dimensional CAD data, this new rapid-prototyping method is also called three-dimensional plotting. At the present time, laser stereolithography is the most widespread rapid-prototyping method.

Rapid Prototyping by Laser Stereolithography

Laser stereolithography involves the use of a liquid photocurable resin which cures instantaneously when scanned with a laser as a result of polymerization. As shown in Figure 13.5.1, the laser is scanned over this resin repeatedly to form thin layers of cured resin, which eventually build up to form a three-dimensional solid product. Specifically, the process involves first slicing a model based on three-dimensional CAD data stored on computer horizontally into equal thickness. Based on this slice data, the laser scans the thin liquid resin layer to form the first solid layer. Liquid resin is then poured over this cured layer of resin and again scanned by laser to form the next layer according to the next slice data. To ensure that the liquid resin on the cured resin is even, its surface is often swept by a blade. So, by repeating this process and forming layer over layer of cured resin, a solid object is formed.

Although the surface accuracy problems are resolved by making each layer extremely thin, a small amount of roughness of the surface eventually remains and subsequent polishing is often performed to achieve a smooth finish. For shapes which cannot be formed by building the layers upward, the resin is cured on a support. This support is also made of the same photocurable resin and is removed after the product has been formed. For some types of resins which do not cure completely with a laser alone, the whole product is cured by exposure to an ultraviolet lamp after it has been formed.

The photocurable resin is composed of photopolymerizing oligomer, reactive diluent, and photoinitiator. When a laser is irradiated onto this resin, the monomer undergoes a series of reactions to form a solid polymer which has a three-dimensional network structure. The resins used for laser stereolithography are the radical polymerization type, the cation polymerization type, or the hybrid type, which is a combination of the first two types. The curing properties and mechanical properties of the cured resin are important, because these affect the applications of the cured product formed by laser stereolithography. These resins are prepared minutely by adjusting the mixture rate of the resin components and the additives to suit laser stereolithography.

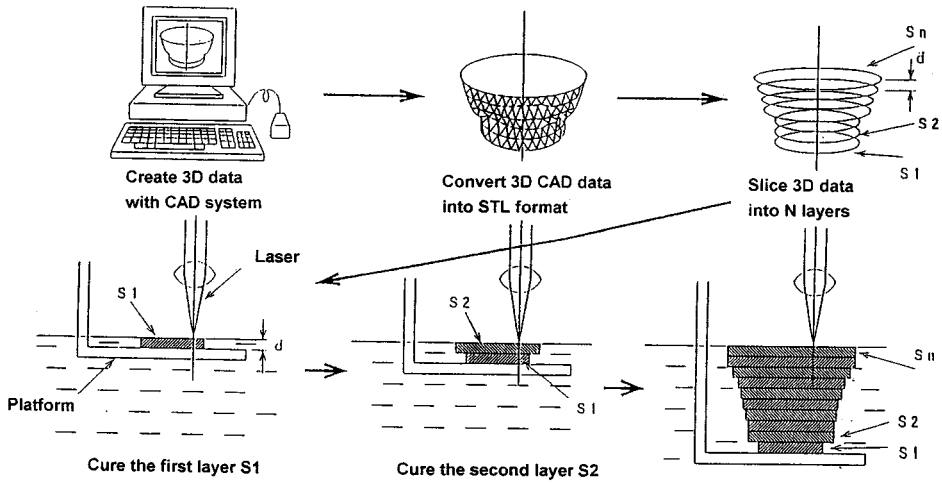

FIGURE 13.5.1 Principle of photocurable resin process.

In most cases, the He-Cd laser with 325-mm wavelength or Ar laser with 364-mm wavelength is used as the light source. Higher-power lasers like Ar perform higher-speed beam scanning, resulting in the increase of modeling speed. As shown in Figure 13.5.2, these lasers scan at very high speed in the same way as the laser printer by rotating galvanomirrors. In some special machines, the laser beam is exposed from the bottom as shown in Figure 13.5.3 by an *XY* plotter.

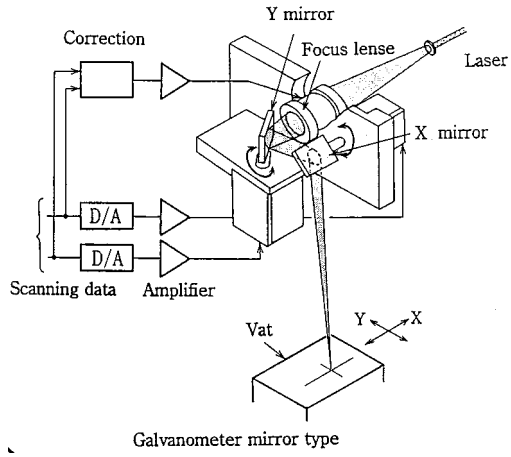

FIGURE 13.5.2 Scanning system of UV laser beam.

Laser stereolithography requires three-dimensional CAD data composed of surface or solid data in order to create solid models. Many types of CAD systems are now available on the market, and most of the CAD data they provide can be transmitted to laser stereolithography systems. At the same time, the laser stereolithography system is equipped with a scanning program, support and reinforcing rib design software, magnification/contraction functions, functions to determine the scanning and operating conditions, and simulation functions. Figure 13.5.4 shows a software flowchart in laser stereolithography.

The following shows the advantages of rapid-prototyping over material-removing processes such as machining.

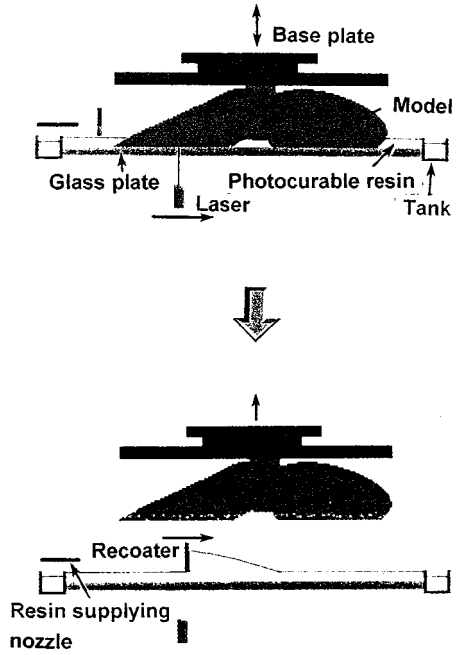

FIGURE 13.5.3 Laser beam radiation from below (Denken).

1. Deep holes and structures with complicated internal shapes which cannot be machined simply by cutting tools can be formed in a single process. Moreover, one rapid-prototyping machine is usually capable of fabricating any type of shape.
2. Rapid prototyping requires no complicated control programs such as tool path and repositioning of the workpiece. With the three-dimensional CAD data, there is no need for special knowledge of the cutting process, and operations from data input to actual fabrication are simple and short.
3. The rapid-prototyping systems produce no machining wastes. Because they do not vibrate and are silent, they can be used in offices like OA business machines. They can also be operated fully automatically even at night since there is no need for the management of tooling.

The major shortcomings of laser stereolithography are that only photocurable resins can be used and the material strength of these materials is slightly worse than the common polymer. In addition, metal products cannot be manufactured directly by laser stereolithography.

Other Rapid-Prototyping Methods

The laser stereolithography method was developed in an early stage and is currently applied extensively. Besides laser stereolithography, many different types of new rapid-prototyping methods have also emerged. As shown in Figure 13.5.5, rapid prototyping can broadly be classified into photopolymer, powder sintering, ink jetting, fused deposition, and sheet cutting. Figure 13.5.6 shows the history of these rapid prototyping systems. Most of the methods were developed in the U.S., but the photopolymer process and sheet lamination were first proposed in Japan.

Another photopolymer process is the mask pattern-curing method shown in Figure 13.5.7. Similar to the photocopying process, a master pattern based on slice data is created, this pattern on the glass sheet is placed over a photocurable resin layer, and this layer is exposed to ultraviolet light. Although the machine is large, the exposing speed is faster than the above-mentioned laser beam method, and the thickness of the product is very precise because each surface formed is cut by milling to obtain precise thin layers.

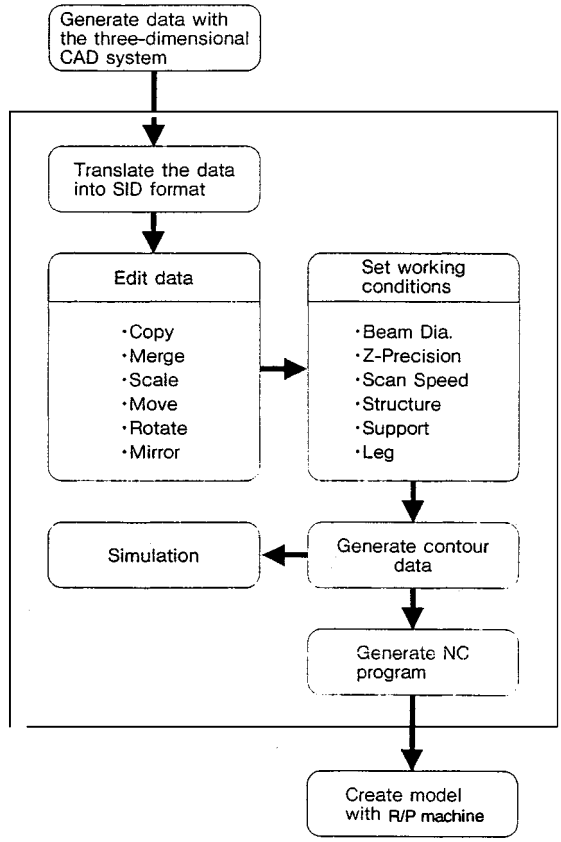

FIGURE 13.5.4 Software for R/P system (CMET).

Three-dimensional objects can also be formed by powder sintering. In the process shown in Figure 13.5.8, powder is used instead of liquid photocurable resin. The powder is evened out using a roller, a CO_2 laser is beamed, and the powder is bonded by heat fusion. In this case, powder is heated up beforehand to the temperature just below the melting point in the antioxidation environment using N_2 gas. It is possible to create high-density polymer solid models as well as porous models.

Porous polycarbonate models are quite suitable for the investment casting model. With this method, metal and ceramic powders can also be used. Metal and ceramic powders used are coated by resin and each metal or ceramic powder is bonded by the coated resin. Sintered porous ceramic molds can be used for casting molds. Powder binding can be performed by spraying binding material on the loose powder layer through the ink jet nozzle as shown in Figure 13.5.9. This is also used for making the sand mold for casting. When wax or resin is sprayed from the jet nozzle, wax or resin models can be fabricated as shown in Figure 13.5.10. In this case, the surface of the sprayed thin layer should be machined smoothly and flatly in order to obtain vertical accuracy.

Figure 13.5.11 shows the fused deposition method. In this method, a fine nozzle deposits a layer of resin or wax. Wax is normally used to form lost wax models. Fused deposition systems, in which material is supplied by the pellet or wire, enable materials to be formed very similarly to general injection mold materials like ABS and nylon. One of the two nozzles is used for making the support, where the support material is usually wax with lower melting points.

Figure 13.5.12 shows two methods which cut thin sheets according to slice data and laminate them to form three-dimentional objects. One method uses a laser to cut sheets applied with adhesive which are then laminated by hot toll pressing, while the other uses a knife to cut the sheets. In the latter case,

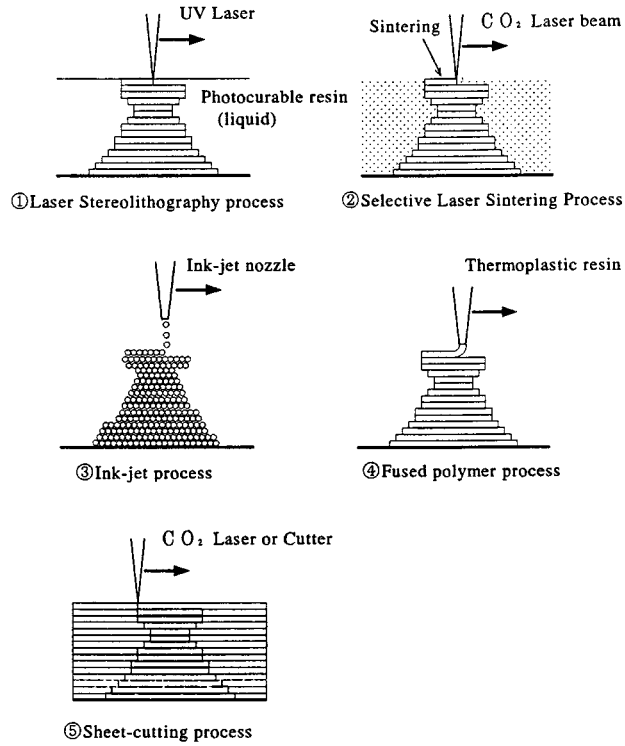

FIGURE 13.5.5 Schematic of various layer-additive fabrication processes.

adhesive is applied to sheets of paper according to the desired shape by spraying the toner using a dry Xerox-type copy machine. Due to the use of paper in these sheet lamination methods, the model formed should be immediately coated to prevent the absorption of moisture. Although there is a limit to the shapes that can be made, the method is nevertheless used for making wood models for casting, because it is inexpensive and enables large-sized models to be made and the model material is similar to wood.

The common feature of all of these methods is that slice data is obtained from three-dimentional CAD data and this slice data is used to laminate thin layers of material, which means that the same software can be used for all of these methods. Another feature is that all rapid-prototyping machines use the modified printing technology.

While many of these rapid-prototyping machines tend to be costly, inexpensive models are also now available. Machine cost reduction has been achieved by proper utilization of key parts which are used for the printer. New and improved methods should continue to be developed with the introduction of printing technology.

Application of Rapid Prototyping

Figure 13.5.13 shows the applications of three-dimentional models made by rapid prototyping. They are mainly intended for verifying CAD data, checking the designs, functional checks of prototypes, wax models for investment casting, master models for die and model making, mold making for prototype manufacturing, casting models, and medical use CT and MRI data. Although dimensional accuracy was given little importance in the verification stage of CAD data and design, high dimensional accuracy is now demanded of the functional check of prototypes. Because photocurable resins contract in the solidification process, slight distortions are generated in the fabricated product. Among the various rapid-prototyping machines, the photocurable resin process is most suitable for making very complicated shapes and obtaining the highest accuracy.

Even in laser stereolithography, accuracy has improved to a considerable extent with the improvement of the resin and scanning method and the accumulation of know-how for positioning the reinforcing rib. It should also be possible to attain the same accuracy as injection molds by measuring formed products, correcting the data, or predicting errors.

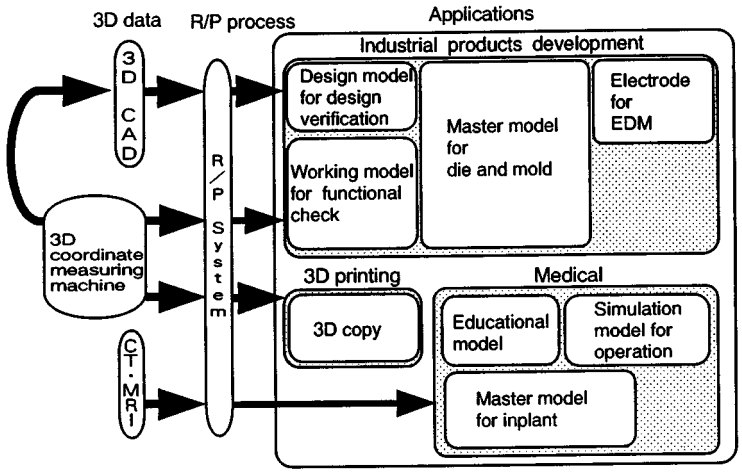

FIGURE 13.5.13 Application of rapid prototyping (source: CMET).

In general, photocurable resins are generally weak and brittle as compared with conventional polymer parts produced by injection molds. Urethane resin which is usually used for vacuum casting with a silicon rubber mold reversely copied from a rapid-prototyping model also lacks the required strength. In order to carry out the functional check of the prototypes created, other processes which can use normal thermoplastic should be used.

Figure 13.5.14 shows an intake manifold for car engines made by laser stereolithography. This serves as a test model for checking fluid performance of air. For such purposes, current photocurable resins available prove relatively satisfactory.

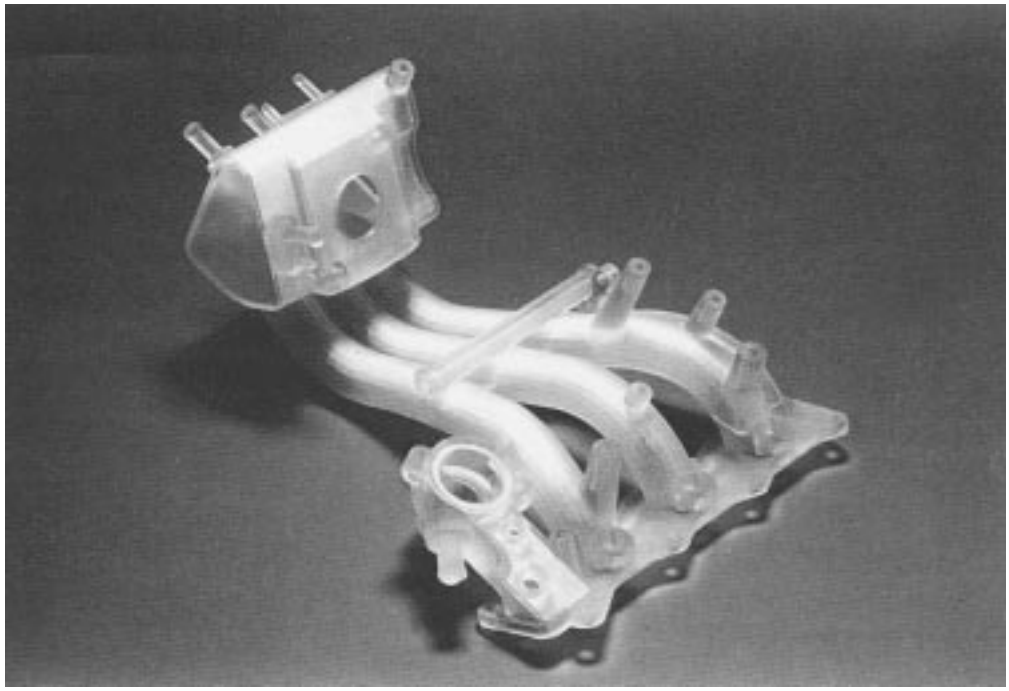

FIGURE 13.5.14 Sample for fluid dynamic analysis.

Although the powder sintering process can apply some metals, there is no suitable rapid-prototyping technique which can directly form products from metal materials at the moment. Research activities are underway to study the feasibility of producing molds from metal materials directly using a three-dimentional printing technique. In a general application, the lost wax models are first made by rapid prototyping and then used for creating metal prototypes by investment casting.

Rapid prototyping is still a relatively new technology, and therefore there are considerable opportunities for technical improvements.

General Rapid Prototyping in Production

For rapid prototyping to be carried out, three-dimentional CAD data must be available. Creating the CAD data takes far more time than creating the three-dimentional models based on the CAD data. By realizing efficient concurrent engineering, rapid prototyping will no doubt become a very important tool. In general, many other types of production systems can be included in the list of systems currently termed *general rapid prototyping* (casting and machining, etc.).

Use of Three-Dimentional CAD Data

Casting methods which are able to produce green sand molds satisfy the conditions of rapid prototyping. Expendable pattern casting is also suitable for rapid manufacturing. In this case, a three-dimentional polystyrene foam model is made by machining or binding. Most of the industrial products around us are produced with dies and molds. Because they are expensive to manufacture, dies and molds are unsuitable for making prototypes and for small-lot production. This may be a reason why rapid prototyping was developed; however, some prototype production methods do involve the use of dies and molds. Flexible prototype production has been carried out in sheet metal forming with the use of the turret punch press, laser beam cutting machine, and NC press brake. Producing dies and molds rapidly and manufacturing using such dies and molds also fit into the category of general rapid prototyping in the broad sense. Examples include what is known as the low-cost blanking dies using steel rule, deep drawing die made of zinc alloy and bismuth alloy.

Among the many general rapid-prototyping systems that exist, those newly developed rapid-prototyping methods discussed are gradually becoming methods for creating complicated products accurately with the use of three-dimentional CAD data. In terms of the total cost, applications of these new methods are still limited, but the spread of three-dimentional CAD data and technological progress of rapid prototyping should make them one of the common manufacturing techniques in the near future.

13.6 Underlying Paradigms in Manufacturing Systems and Enterprise Management for the 21st Century

Quality Systems

H. E. Cook

Introduction

Quality engineering has been described as the process of minimizing the sum of the total costs and the functional losses of manufactured products. Total costs include variable costs, investment, maintenance/repair costs, environmental losses, and costs of disposal or recycling. Functional losses arise from deviations from ideal performance. A subset of total quality management, quality engineering, focuses on parameter and tolerance design after the target specifications for the product have been developed as part of system design.

In contrast to quality engineering, total quality management embraces the entire product realization process. Its objective should be to maximize the net value of the product to society which includes buyer, seller, and the rest of society. Product value is determined solely by the customer and can be set equal to the maximum amount the customer would be willing to pay for the product. For a product to be purchased, its price must be less than its perceived value to the customer at the time of purchase. Consumer surplus is the difference between value and price.

The true value of a product is formed by the customer after assessing the product's performance over the complete time period that he or she used it. Functional quality loss is also known as the cost of inferior quality which is equal to the loss of value incurred by a product as a result of its attributes being off their ideal specification points (Figure 13.6.1). When manufacturing costs are added to value, the resulting sum (equal to total quality less environmental losses) is maximized when the attribute is off its ideal specification because of the impossibly high costs required to make a product perfect.

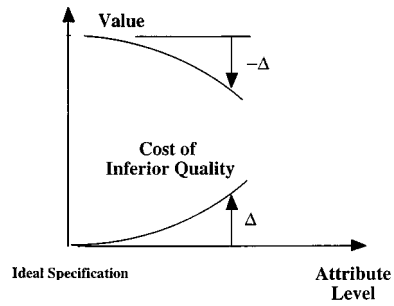

FIGURE 13.6.1 The relation of product value to the cost of inferior quality.

Requirements Flow

The systems viewpoint, as expressed by the flow of requirements shown in Figure 13.6.2, is helpful in considering the full ramifications of total quality management. Every system can be divided into subsystems and every system is but a subsystem of a larger system. Each task receives input requirements from its customer (either internal or external) and sends output requirements to its suppliers.

Task Objectives

A major objective of the system task is to assess customer needs, to translate those needs into a complete set of system-level specifications for the product, and to send a key (but partial) set of subsystem requirements to those responsible for the subsystem tasks. The system specifications and subsystem requirements developed by the system task should be such that (1) customers will want to purchase the product in a competitive marketplace and, with use, find that the product meets or exceeds their

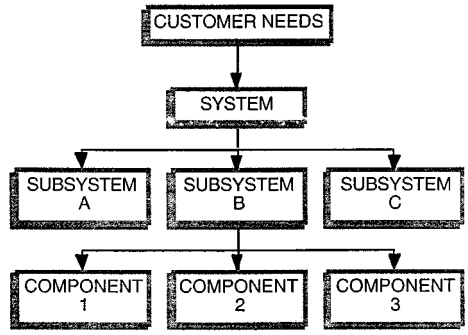

FIGURE 13.6.2 Flow of requirements from customer through enterprise.

expectations, (2) the product will meet the profitability objectives of the enterprise, and (3) all environmental rules and regulations are met. The system task also has the responsibility of resolving conflicts which arise between subsystem tasks.

The subsystem task receives the key requirements from its internal customer and translates these into a complete set of subsystem requirements and sends a key (but partial) set of component requirements to those responsible for the component tasks. In turn, those responsible for each component task translate the requirements received into a complete set of component requirements and a partial (but key) set of raw material requirements. Requirements set at each level include controls on variable costs, investment, performance, reliability, durability, service, disposal, environmental quality, package, assembly, and timing for both production and prototype parts. Synchronization is very important to total quality management as parts should be received exactly when needed with minimal inventory.

Parts Flow

The response to the requirements flow is a parts flow in the opposite direction that begins with the conversion of raw materials into components. This is followed by the assembly of components into subsystems which are shipped to the system task for final assembly. The process is completed by shipping the finished product to the customer. Thus, each task shown in Figure 13.6.1 has both a planning or design function as well as other functions including manufacturing, assembly, purchasing, marketing, service, accounting, and finance. The actions taken to meet customer needs should be traceable as the requirements flow through the enterprise. With the systems viewpoint, all parameters are measured or computed at the full system level including value, costs, and investment.

Task Management

Within each task shown in Figure 13.6.2 are subtasks. The combined flow of requirements and parts between several subtasks is shown in Figure 13.6.3 using a modified IDEF representation. Requirements are shown as controls which flow from left to right, and parts, in response, are shown as flowing from right to left.

Each task is accomplished by exercising its authority, responsibility, and capability. Authority to set requirements on parts should rest fully and undiluted with the task receiving the parts. The task which ships the parts should possess the full authority, responsibility, and capability to manufacture the parts for its customer. Before sourcing of parts, demonstration of capability by the manufacturer is a vital element of sound quality engineering. Capability is ultimately determined by the set of tools which the task has at its disposal and includes the skills and experience of the people as well as the hardware and software used by them.

Because a broad range of skills is needed, the required expertise is generated by forming a team to carry out the task. Quality tools used by the teams include structured methodologies such as Taguchi methods (design of experiments), quality function deployment, failure mode effects and criticality

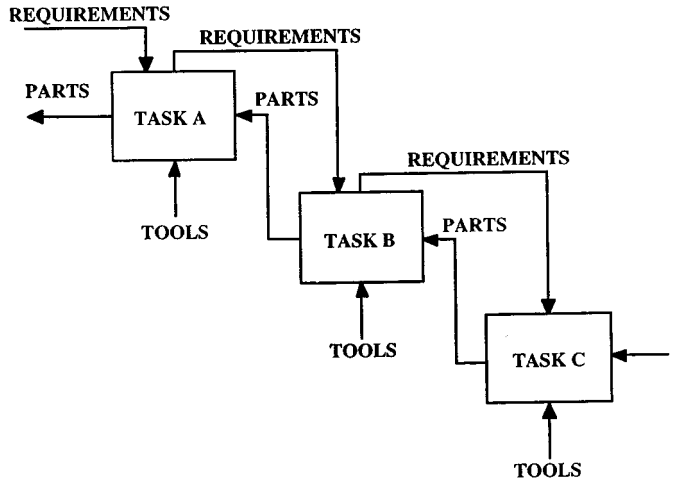

FIGURE 13.6.3 The flow of requirements and parts in a modified IDEF0 (function model) representation.

analysis, statistical process control, cost analysis, and value analysis. It is highly recommended that final authority and responsibility for each task rest with one person.

Fundamental and Bottom-Line Metrics

A variety of parameters can be used to measure the progress of quality improvements. These include things such as the degree of customer satisfaction expressed for the product, the frequency of repair, and the variance found in product dimensions and performance levels that directly impact value to the customer. Repair and operating costs borne by the customer subtract from value if they are greater than what was anticipated by the customer. Likewise, resale price subtracts form value if it is below what the customer expected. Performance degradation of the product over its lifetime of use subtracts from its value. Noise and atmospheric pollution caused by the manufacture and use of the product subtract from the net value of the product to society. The costs to manufacture and develop the product subtract from the net value received by the manufacturer. Moreover, products which are not improved in value and reduced in costs at the pace of competing products will likely be eliminated from the market in time.

These metrics can be grouped into one of three categories — value, cost, and the pace of innovation. They represent the fundamental metrics for the product because they determine what the bottom-line metrics of profitability and market share will be. Management of the fundamental metrics is the management of total quality and, likewise, the management of the total enterprise. The level of sustained profitability is the best measure of how well total quality is being managed in competitive markets.

Collaborative Manufacturing

James J. Solberg

Introduction

The world of manufacturing is undergoing rapid change in almost every aspect. It has become something of a cliché to speak of paradigm shifts, but there is no doubt that many assumptions, beliefs, and practices of the past are being seriously questioned. Meanwhile, the daily struggle of manufacturing enterprises to cope with the ordinary problems of producing products and satisfying customers goes on. In ecological terms, manufacturing companies are faced with a competitive struggle for survival (as always), augmented with the additional challenge of a changing climate. It is not surprising that many people are confused about what is happening and what to do about it.

What Is Collaborative Manufacturing (CM)?

CM is a very broad arena which incorporates many other topical themes of the day, including team design, computer-supported collaborative work, agile manufacturing, enterprise integration, virtual enterprises, high-performance distributed computing, concurrent engineering, computer-integrated manufacturing, virtual reality, global sourcing, and business process reengineering. In general, CM is defined by the following attributes:

- Integrated product and process development, including customers and suppliers;
- Flexible manufacturing distributed over networks of cooperating facilities;
- Teamwork among geographically and organizationally distributed units;
- High-technology support for the collaboration, including high-speed information networks and integration methodology;
- Multidisciplines and multiple objectives.

What is the payoff for CM? Companies that can engage effectively in CM will have the potential for

- Better market opportunities;
- A wider range of design and processing options over which to optimize;
- Fewer and looser constraints restricting their capabilities;
- Lower investment costs;
- Better utilization of resources;
- Faster response to changes.

Obviously, we are still a long way from being able to do what was described in our scenario. However, many of the pieces are already available, and many of the enabling technologies are rapidly coming into commercial use. The high-speed networks (well beyond current Internet speeds) are being developed and are certain to become both cost-effective and ubiquitous within a few years. The needed software developments, such as agent programming languages and interoperability standards, are progressing nicely. Nevertheless, an enormous agenda for needed research can be derived from unmet needs, particularly in areas that directly relate traditional manufacturing to information technology. Bridging these two research communities will not be easy, but the effort will offer great rewards to those who succeed.

Who Is Doing CM?

A great deal of the current work in CM and related themes is best accessed through the Internet. Understandably, the most active researchers in these fields are “Internet aware” and use it for both gathering and distributing their knowledge. Consequently, the best way to survey recent work is to browse the net, following links to associated sites. Unfortunately, the medium is so dynamic that material can appear or disappear at any time. A few of the better home pages are given here as starting points. Search engines can pick up more current connections.

Electronic Data Interchange

Chris Wang

Introduction

Electronic data interchange (EDI) is a method to exchange business information between computer systems. In a traditional purchasing environment, buyers, when placing computer-generated orders, will mail them to suppliers, and it could take days before the suppliers receive them and then rekey the orders into their computer system. Using EDI, the buyer's computer system can generate an EDI standard order transaction and transmit it directly to the supplier's inventory system for material pickup. It happens instantly. The benefit of EDI is quite obvious in this case as it reduces material lead time dramatically. Consequently, the objectives of EDI implementation should not be limited to just reducing paperwork and clerical work; instead, it should be used as a methodology to streamline company processes and become competitive in the marketplace.

EDI Elements

EDI consists of the following elements:

- Trading partners — The parties, such as a manufacturer and a supplier, who agree to exchange information.
- Standards — The industry-supplied national, or international formats to which information is converted, allowing disparate computer systems and applications to interchange it. This will be discussed in more detail later.
- Applications — The programs that process business information. For example, an orders application can communicate with an orders entry application of the trading partner.
- Translation — The process of converting business information, usually from a format used by an application, to a standard format, and vice versa.

- Electronic transmission — The means by which the information is delivered, such as a public network. Some companies may choose to build their own transmission facilities. For others, VAN (value-added network) seems to be a good choice as companies do not have to invest heavily in communication equipment and personnel to support it. The VAN provider can handle disparate communication hardware and software and provide wide-area network access at a reasonable cost.

EDI in Manufacturing

In the present-day business environment, many companies are turning to just-in-time (JIT) and other techniques to compete as effectively as possible. EDI can make an important contribution to the success of JIT by ensuring that information exchanged between business partners is also just in time.

In traditional manufacturing, material is stored in quantities much larger than required because of faulty components and possible waste in the production process. To solve problems of carrying safety stock and still producing high-quality product, JIT seems to be an effective technology.

JIT systems are designed to pull raw materials and subassemblies through the manufacturing process only when they are needed and exactly when they are needed. Also, with rapidly changing production needs, orders are getting smaller and are issued more frequently. The traditional paperwork environment simply cannot effectively cope with this change. This is why EDI comes in to play a key role to provide fast, accurate information to achieve these JIT goals. In other words, EDI can provide JIT information in manufacturing processes.

- EDI cuts order delivery and lead time — The more control points you have in a process, the greater the number of potential problems. EDI eliminates "control points" for the order process. It eliminates the need to mail orders and rekey order information at the receiving end. It reduces the material lead time for production use.
- Connect applications and processes — With EDI capability, information, such as scheduling, orders, advance delivery notice, statistical process control data, and material safety data sheets can pass quickly and accurately from the supplier's computer application to the customer's computer application, so that arriving material can be put to production use with confidence. This meets one of the important goals of JIT, that is, to turn the supplier's entire production line into a vast stockroom so a company does not have to maintain a huge warehouse and the working capital tied to excess inventory.
- Improve relationship with customers and suppliers — In the supply chain environment, the quicker the chain moves, the better the customers' needs can be met. With quicker orders, acknowledgments, order changes, and invoices, EDI can satisfy customers' needs more quickly. Also, the time spent on order tracking and error recovery can now be used in a more productive way and can improve customer/supplier relationships. Companies deeply involved in EDI may see the number of suppliers reduced. This is because through the EDI process, a company can weed out many suppliers who are not efficient and reliable.

EDI Standards

When two organizations exchange business forms electronically, information is encoded and decoded by the computer software of both parties. Therefore, the information must be unambiguous, in order to avoid different interpretations. This relates to the meaning of the terms used, the representation of data used, the codes to be used for data, and the sequence in which data are to be transmitted. All these parameters must be arranged between the two parties on a detailed level.

There are many standard types — it can be based on bilateral agreement, imposed by a dominating party in a certain marketplace, or jointly developed by an industrial group. Some standards have been ratified by international organizations.

The pioneer of EDI standard development was the transportation industry. TDCC (Transportation Data Coordinating Committee) developed sets of standards for transportation mode — air, ocean, motor,

and rail. Later, the U.S. grocery industry developed a set of standards, UCS (Uniform Communication Standard), based on TDCC structure.

The TDCC and UCS are more geared toward the business forms exchanged by shipper/carrier, for example, bill of lading. Not until the American National Standards Institute got involved did a general use standard for all industries start to develop, leading to the birth of ANSI X12 standards.

The ANSI X12 is popular in the U.S. Although ANSI X12 is intended for all industries, different user groups still come up with their own conventions to address their specific needs but remain under the X12 umbrella. To name a few, there are AIAG (Automotive Industry Action Group) for the auto industry, CIDX for the chemical industry, and EIDC for the electronic industry.

In Europe, at approximately the same time period, under the leadership of the United Kingdom, the TDI (Trade Data Interchange) was developed. The TDI syntax and structure are quite different from the ANSI X12. To resolve the incompatibility, the U.N. organization UNJEDI was formed to develop an EDI international standard containing features from both TDI and ANSI X12. The result was EDIFACT (EDI for Administrative, Commerce, and Transport). This is the standard to which the world is trying to convert.

EDI Implementation

Before implementation of EDI, planning is critical to success. First, get all the right people involved in planning and implementation of EDI. Ensure that every employee gets EDI education on how to use EDI as a business tool to manage his or her job. Prepare a strategic plan to get approval and support from top management. Top management should be aware of the significant benefits of EDI and has to appreciate the potential of EDI as a business methodology to improve the bottom line.

As part of a strategic plan, it is crucial to perform an operational evaluation. This evaluation details how the internal departments of the company function. For each paper document under evaluation, information flow is tracked, processing procedures are scrutinized, time is measured, and costs are calculated. This will provide top management with valuable information as important as industry trends and competition information. The operational evaluation provides the company with detailed documentation about how it does business in a paper-based environment. This information then serves as a benchmark against which to measure projected costs and benefits of the EDI model.

Once the strategic plan is in place, available resources must be allocated to the departments that will generate the most benefits for the company. Once EDI is implemented in the company, the next step is to sell it to trading partners to maximize the EDI investment.

Summary

EDI is on a fast growing path. EDI software and communication services are available and not expensive. It will not be too long before EDI becomes mandatory as a business practice. If a company is determined to implement EDI, it should look beyond just connecting two computer systems. To achieve the best return on the EDI investment, one should try to use EDI to improve the existing processes within the organization and the relationship with customers and suppliers.

14.1 Introduction

The word "robot" was introduced by the Czech playright Karel Čapek in his 1920 play *Rossum's Universal Robots.* The word "robota" in Czech means simply "work." In spite of such practical beginnings, science fiction writers and early Hollywood movies have given us a romantic notion of robots. Thus, in the 1960s robots held out great promises for miraculously revolutionizing industry overnight. In fact, many of the more far-fetched expectations from robots have failed to materialize. For instance, in underwater assembly and oil mining, teleoperated robots are very difficult to manipulate and have largely been replaced or augmented by "smart" quick-fit couplings that simplify the assembly task. However, through good design practices and painstaking attention to detail, engineers have succeeded in applying robotic systems to a wide variety of industrial and manufacturing situations where the environment is structured or predictable. Today, through developments in computers and artificial intelligence techniques and often motivated by the space program, we are on the verge of another breakthrough in robotics that will afford some levels of autonomy in unstructured environments.

On a practical level, robots are distinguished from other electromechanical motion equipment by their dexterous manipulation capability in that robots can work, position, and move tools and other objects with far greater dexterity than other machines found in the factory. Process robot systems are functional components with grippers, end effectors, sensors, and process equipment organized to perform a controlled sequence of tasks to execute a process — they require sophisticated control systems.

The first successful commercial implementation of process robotics was in the U.S. automobile industry. The word "automation" was coined in the 1940s at Ford Motor Company, as a contraction of "automatic motivation." By 1985 thousands of spot welding, machine loading, and material handling applications were working reliably. It is no longer possible to mass produce automobiles while meeting currently accepted quality and cost levels without using robots. By the beginning of 1995 there were over 25,000 robots in use in the U.S. automobile industry. More are applied to spot welding than any other process. For all applications and industries, the world's stock of robots is expected to exceed 1,000,000 units by 1999.

The single most important factor in robot technology development to date has been the use of microprocessor-based control. By 1975 microprocessor controllers for robots made programming and executing coordinated motion of complex multiple degrees-of-freedom (DOF) robots practical and reliable. The robot industry experienced rapid growth and humans were replaced in several manufacturing processes requiring tool and/or workpiece manipulation. As a result the immediate and cumulative dangers of exposure of workers to manipulation-related hazards once accepted as necessary costs have been removed.

A distinguishing feature of robotics is its multidisciplinary nature — to successfully design robotic systems one must have a grasp of electrical, mechanical, industrial, and computer engineering, as well as economics and business practices. The purpose of this chapter is to provide a background in all these areas so that design for robotic applications may be confronted from a position of insight and confidence. The material covered here falls into two broad areas: function and analysis of the single robot, and design and analysis of robot-based systems and workcells.

Section 14.2 presents the available configurations of commercial robot manipulators, with Section 14.3 providing a follow-on in mathematical terms of basic robot geometric issues. The next four sections provide particulars in end-effectors and tooling, sensors and actuators, robot programming languages, and dynamics and real-time control. Section 14.8 deals with planning and intelligent control. The next three sections cover the design of robotic systems for manufacturing and material handling. Specifically, Section 14.9 covers workcell layout and part feeding, Section 14.10 covers product design and economic analysis, and Section 14.11 deals with manufacturing and industrial processes. The final section deals with some special classes of robots including mobile robots, lightweight flexible arms, and the versatile parallel-link arms including the Stewart platform.

14.2 Commercial Robot Manipulators

John M. Fitzgerald

In the most active segments of the robot market, some end-users now buy robots in such large quantities (occasionally a single customer will order hundreds of robots at a time) that market prices are determined primarily by configuration and size category, not by brand. The robot has in this way become like an economic commodity. In just 30 years, the core industrial robotics industry has reached an important level of maturity, which is evidenced by consolidation and recent growth of robot companies. Robots are highly reliable, dependable, and technologically advanced factory equipment. There is a sound body of practical knowledge derived from a large and successful installed base. A strong foundation of theoretical robotics engineering knowledge promises to support continued technical growth.

The majority of the world's robots are supplied by established stable companies using well-established off-the-shelf component technologies. All commercial industrial robots have two physically separate basic elements: the manipulator arm and the controller. The basic architecture of all commercial robots is fundamentally the same. Among the major suppliers the vast majority of industrial robots uses digital servo-controlled electrical motor drives. All are serial link kinematic machines with no more than six axes (degrees of freedom). All are supplied with a proprietary controller. Virtually all robot applications require significant effort of trained skilled engineers and technicians to design and implement them. What makes each robot unique is how the components are put together to achieve performance that yields a competitive product. Clever design refinements compete for applications by pushing existing performance envelopes, or sometimes creating new ones. The most important considerations in the application of an industrial robot center on two issues: Manipulation and Integration.

Commercial Robot Manipulators

Manipulator Performance Characteristics

The combined effects of kinematic structure, axis drive mechanism design, and real-time motion control determine the major manipulation performance characteristics: reach and dexterity, payload, quickness, and precision. Caution must be used when making decisions and comparisons based on manufacturers' published performance specifications because the methods for measuring and reporting them are not standardized across the industry. Published performance specifications provide a reasonable comparison of robots of similar kinematic configuration and size, but more detailed analysis and testing will insure that a particular robot model can reach all of the poses and make all of the moves with the required payload and precision for a specific application.

Reach is characterized by measuring the extents of the space described by the robot motion and *dexterity* by the angular displacement of the individual joints. Horizontal reach, measured radially out from the center of rotation of the base axis to the furthest point of reach in the horizontal plane, is usually specified in robot technical descriptions. For Cartesian robots the range of motion of the first three axes describes the reachable workspace. Some robots will have unusable spaces such as dead zones, singular poses, and wrist-wrap poses inside of the boundaries of their reach. Usually motion test, simulations, or other analysis are used to verify reach and dexterity for each application.

Payload weight is specified by the manufacturer for all industrial robots. Some manufacturers also specify inertial loading for rotational wrist axes. It is common for the payload to be given for extreme velocity and reach conditions. Load limits should be verified for each application, since many robots can lift and move larger-than-specified loads if reach and speed are reduced. Weight and inertia of all tooling, workpieces, cables, and hoses must be included as part of the payload.

Quickness is critical in determining throughput but difficult to determine from published robot specifications. Most manufacturers will specify a maximum speed of either individual joints or for a specific kinematic tool point. Maximum speed ratings can give some indication of the robot's quickness but may be more confusing and misleading than useful. Average speed in a working cycle is the quickness

characteristic of interest. Some manufacturers give cycle times for well-described motion cycles. These motion profiles give a much better representation of quickness. Most robot manufacturers address the issue by conducting application-specific feasibility tests for customer applications.

Precision is usually characterized by measuring repeatability. Virtually all robot manufacturers specify static position repeatability. Usually, tool point repeatability is given, but occasionally repeatability will be quoted for each individual axis. *Accuracy* is rarely specified, but it is likely to be at least four times larger than repeatability. Dynamic precision, or the repeatability and accuracy in tracking position, velocity, and acceleration on a continuous path, is not usually specified.

Common Kinematic Configurations

All common commercial industrial robots are serial link manipulators with no more than six kinematically coupled axes of motion. By convention, the axes of motion are numbered in sequence as they are encountered from the base on out to the wrist. The first three axes account for the spatial positioning motion of the robot; their configuration determines the shape of the space through which the robot can be positioned. Any subsequent axes in the kinematic chain provide rotational motions to orient the end of the robot arm and are referred to as wrist axes. There are, in principle, two primary types of motion that a *robot axis* can produce in its driven link: either *revolute* or *prismatic*. It is often useful to classify robots according to the orientation and type of their first three axes. There are four very common commercial robot configurations: Articulated, Type 1 *SCARA,* Type 2 SCARA, and Cartesian. Two other configurations, Cylindrical and Spherical, are now much less common.

Articulated Arms. The variety of commercial articulated arms, most of which have six axes, is very large. All of these robots' axes are revolute. The second and third axes are parallel and work together to produce motion in a vertical plane. The first axis in the base is vertical and revolves the arm sweeping out a large work volume. The need for improved reach, quickness, and payload have continually motivated refinements and improvements of articulated arm designs for decades. Many different types of drive mechanisms have been devised to allow wrist and forearm drive motors and gearboxes to be mounted close in to the first and second axis rotation to minimize the extended mass of the arm. Arm structural designs have been refined to maximize stiffness and strength while reducing weight and inertia. Special designs have been developed to match the performance requirements of nearly all industrial applications and processes. The workspace efficiency of well-designed articulated arms, which is the degree of quick dexterous reach with respect to arm size, is unsurpassed by other arm configurations when five or more degrees of freedom are needed. Some have wide ranges of angular displacement for both the second and third axis, expanding the amount of overhead workspace and allowing the arm to reach behind itself without making a 180° base rotation. Some can be inverted and mounted overhead on moving gantries for transportation over large work areas. A major limiting factor in articulated arm performance is that the second axis has to work to lift both the subsequent arm structure and payload. Springs, pneumatic struts, and counterweights are often used to extend useful reach. Historically, articulated arms have not been capable of achieving accuracy as well as other arm configurations. All axes have joint angle position errors which are multiplied by link radius and accumulated for the entire arm. However, new articulated arm designs continue to demonstrate improved repeatability, and with practical calibration methods they can yield accuracy within two to three times the repeatability. An example of extreme precision in articulated arms is the Staubli Unimation RX arm (see Figure 14.2.1).

Type I SCARA. The Type I SCARA (selectively compliant assembly robot arm) arm uses two parallel revolute joints to produce motion in the horizontal plane. The arm structure is weight-bearing but the first and second axes do no lifting. The third axis of the Type 1 SCARA provides work volume by adding a vertical or Z axis. A fourth revolute axis will add rotation about the Z axis to control orientation in the horizontal plane. This type of robot is rarely found with more than four axes. The Type 1 SCARA is used extensively in the assembly of electronic components and devices, and it is used broadly for the assembly of small- to medium-sized mechanical assemblies. Competition for robot sales in high speed electronics assembly has driven designers to optimize for quickness and precision of motion. A

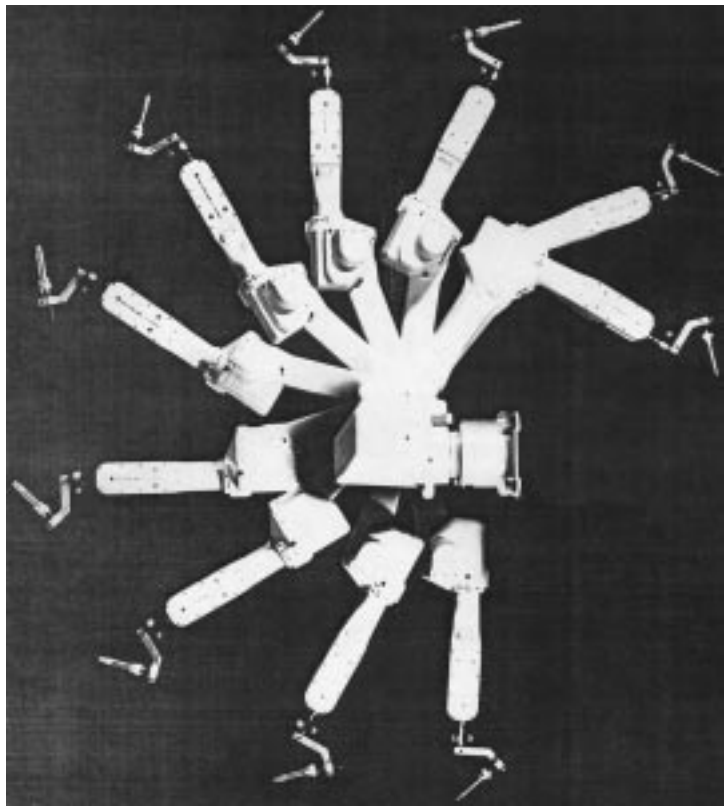
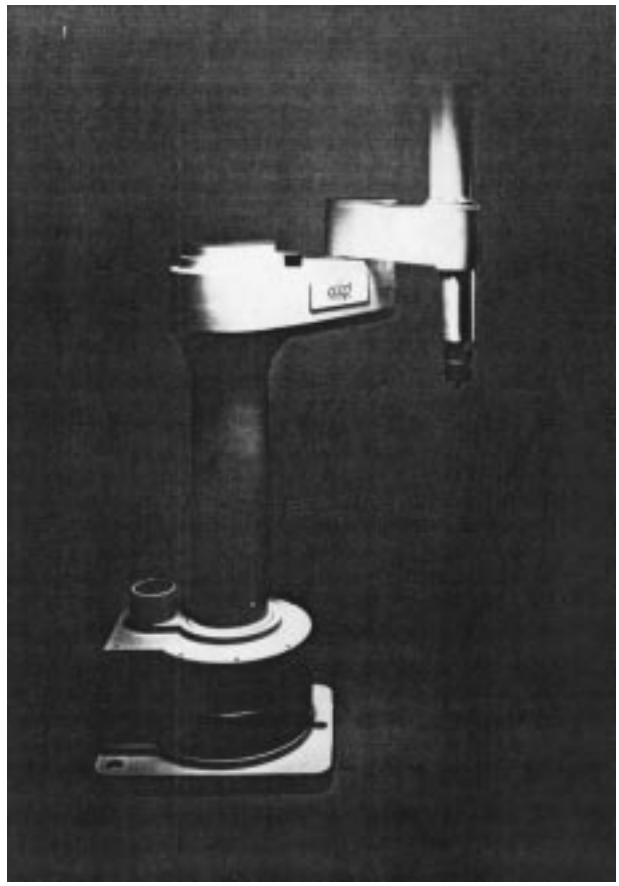
(c)



(d)

FIGURE 14.2.1 continued

well-known optimal SCARA design is the AdeptOne robot shown in Figure 14.2.2a. It can move a 20-lb payload from point "A" up 1 in. over 12 in. and down 1 in. to point "B" and return through the same path back to point "A" in less than 0.8 sec (see Figure 14.2.2).

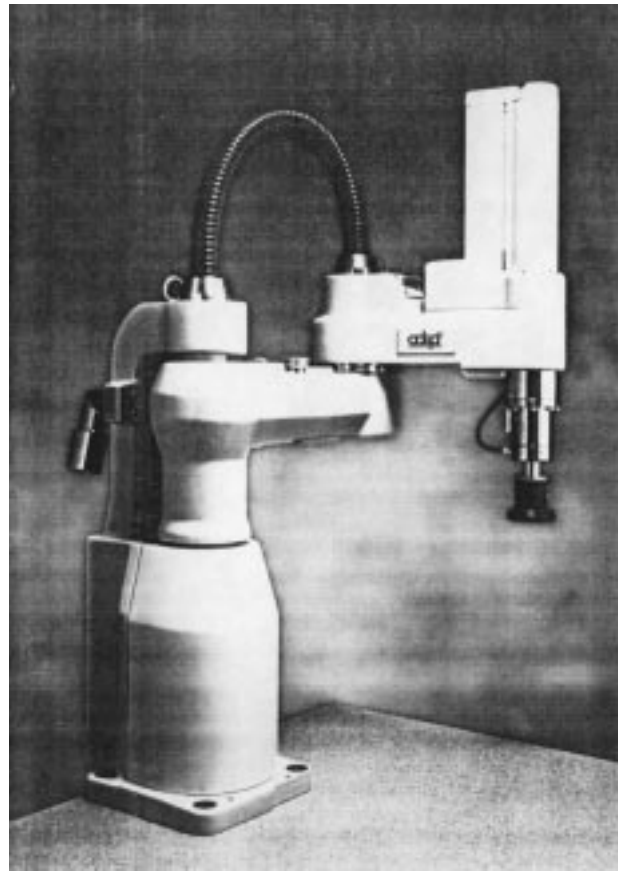


(a)

FIGURE 14.2.2 Type 1 SCARA arms (courtesy of Adept Technologies, Inc.). (a) High precision, high speed midsized SCARA; (b) table top SCARA used for small assemblies.

Type II SCARA. The Type 2 SCARA, also a four-axis configuration, differs from Type 1 in that the first axis is a long, vertical, prismatic Z stroke which lifts the two parallel revolute axes and their links. For quickly moving heavier loads (over approximately 75 lb) over longer distances (over about 3 ft), the Type 2 SCARA configuration is more efficient than the Type 1. The trade-off of weight vs. inertia vs. quickness favors placement of the massive vertical lift mechanism at the base. This configuration is well suited to large mechanical assembly and is most frequently applied to palletizing, packaging, and other heavy material handling applications (see Figure 14.2.3).

Cartesian Coordinate Robots. Cartesian coordinate robots use orthogonal prismatic axes, usually referred to as X, Y, and Z, to translate their end-effector or payload through their rectangular workspace. One, two, or three revolute wrist axes may be added for orientation. Commercial robot companies supply several types of Cartesian coordinate robots with workspace sizes ranging from a few cubic inches to tens of thousands of cubic feet, and payloads ranging to several hundred pounds. Gantry robots are the most common Cartesian style. They have an elevated bridge structure which translates in one horizontal direction on a pair of runway bearings (usually referred to as the X direction), and a carriage which



(b)

FIGURE 14.2.2 continued

moves along the bridge in the horizontal "Y" direction also usually on linear bearings. The third orthogonal axis, which moves in the Z direction, is suspended from the carriage. More than one robot can be operated on a gantry structure by using multiple bridges and carriages. Gantry robots are usually supplied as semicustom designs in size ranges rather than set sizes. Gantry robots have the unique capacity for huge accurate work spaces through the use of rigid structures, precision drives, and work-space calibration. They are well suited to material handling applications where large areas and/or large loads must be serviced. As process robots they are particularly useful in applications such as arc welding, waterjet cutting, and inspection of large, complex, precision parts.

Modular Cartesian robots are also commonly available from several commercial sources. Each module is a self-contained completely functional single axis actuator. Standard liner axis modules which contain all the drive and feedback mechanisms in one complete structural/functional element are coupled to perform coordinated three-axis motion. These modular Cartesian robots have work volumes usually on the order of 10 to 30 in. in X and Y with shorter Z strokes, and payloads under 40 lb. They are typically used in many electronic and small mechanical assembly applications where lower performance than Type 1 SCARA robots is suitable (see Figure 14.2.4).

Spherical and Cylindrical Coordinate Robots. The first two axes of the spherical coordinate robot are revolute and orthogonal to one another, and the third axis provides prismatic radial extension. The result is a natural spherical coordinate system and a work volume that is spherical. The first axis of cylindrical coordinate robots is a revolute base rotation. The second and third are prismatic, resulting in a natural cylindrical motion.

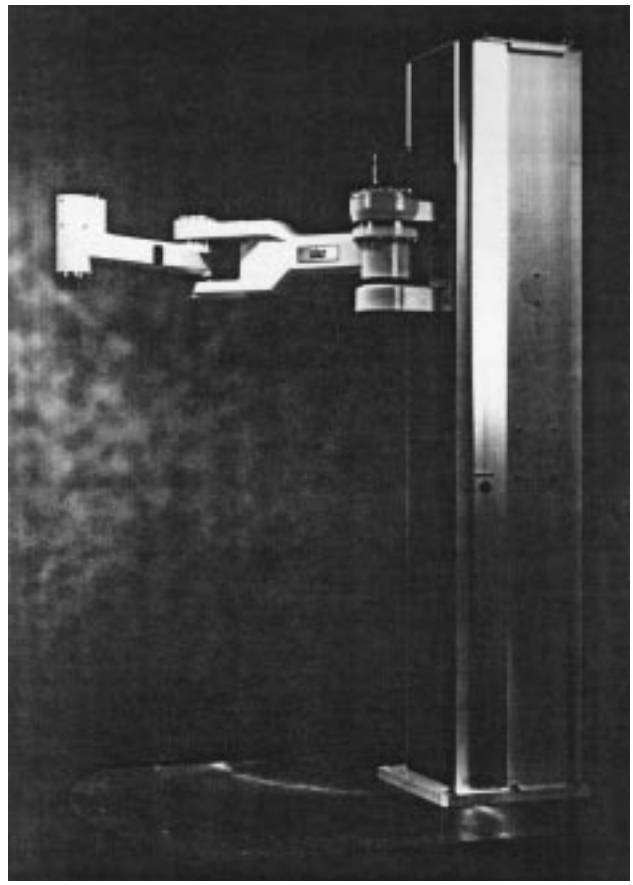


FIGURE 14.2.3 Type 2 SCARA (courtesy of Adept Technologies, Inc.).

Commerical models of spherical and cylindrical robots were originally very common and popular in machine tending and material handling applications. Hundreds are still in use but now there are only a few commercially available models. The Unimate model 2000, a hydraulic-powered spherical coordinate robot, was at one time the most popular robot model in the world. Several models of cylindrical coordinate robots were also available, including a standard model with the largest payload of any robot, the Prab model FC, with a payload of over 600 kg. The decline in use of these two configuations is attributed to problems arising from use of the prismatic link for radial extension/retraction motion. A solid boom requires clearance to fully retract. Hydraulic cylinders used for the same function can retract to less than half of their fully extended length. Type 2 SCARA arms and other revolute jointed arms have displaced most of the cylindrical and spherical coordinate robots (see Figure 14.2.5).

Basic Performance Specifications. Figure 14.2.6 sumarizes the kinematic configurations just described. Table 14.2.1 is a table of basic performance specifications of selected robot models that illustrates the broad spectrum of manipulator performance available from commercial sources. The information contained in the table has been supplied by the respective robot manufacturers. This is not an endorsement by the author or publisher of the robot brands selected, nor is it a verification or validation of the performance values. For more detailed and specific information on the availability of robots, the reader is advised to contact the Robotic Industries Association, 900 Victors Way, P.O. Box 3724, Ann Arbor, MI 48106, or a robot industry trade association in your country for a listing of commercial robot suppliers and system integrators.

Drive Types of Commerical Robots

The vast majority of commerical industrial robots uses electric servo motor drives with speed-reducting transmissions. Both AC and DC motors are popular. Some servo hydraulic articulated arm robots are available now for painting applications. It is rare to find robots with servo pneumatic drive axes. All types of mechanical transmissions are used, but the tendency is toward low and zero backlash-type drives. Some robots use direct drive methods to eliminate the amplification of inertia and mechanical backlash associated with other drives. The first axis of the AdeptOne and AdeptThree Type I SCARA

robots is a direct drive motor with the motor stator integrated into the robot base and its armature rotor integral with the first link. Other more common speed-reducing low backlash drive transmissions include toothed belts, roller chains, roller drives, and harmonic drives.

Joint angle position and velocity feedback devices are generally considered an important part of the drive axis. Real-time control performance for tracking position and velocity commands and precision is often affected by the fidelity of feedback. Resolution, signal-to-noise, and innate sampling frequency are important motion control factors ultimately limited by the type of feedback device used.

Given a good robot design, the quality of fabrication and assembly of the drive components must be high to yield good performance. Because of their precision requirements, the drive components are sensitive to manufacturing errors which can readily translate to less than specified manipulator performance.

Commercial Robot Controllers

Commercial robot controllers are specialized multiprocessor computing systems that provide four basic processes allowing integration of the robot into an automation system. These functions which must be factored and weighed for each specific application are Motion Generation, Motion/Process Integration, Human Integration, and Information Integration.

Motion Generation

There are two important controller-related aspects of industrial robot motion generation. One is the extent of manipulation that can be programmed; the other is the ability to execute controlled programmed motion. The unique aspect of each robot system is its real-time kinematic motion control. The details of real-time control are typically not revealed to the user due to safety and proprietary information secrecy reasons. Each robot controller, through its operating system programs, converts digital data into coordinated motion through precise coordination and high speed distribution and communication of the individual axis motion commands which are executed by individual joint controllers. The higher level programming accessed by the end user is a reflection of the sophistication of the real-time controller.

Of greatest importance to the robot user is the motion programming. Each robot manufacturer has its own proprietary programming language. The variety of motion and position command types in a programming language is usually a good indication of the robot's motion generation capability. Program commands which produce complex motion should be available to support the manipulation needs of the application. If palletizing is the application, then simple methods of creating position commands for arrays of positions are essential. If continuous path motion is needed, an associated set of continuous motion commands should be available. The range of motion generation capabilities of commercial industrial robots is wide. Suitability for a particular application can be determined by writing test code.

Motion/Process Integration

Motion/process integration involves methods available to coordinate manipulator motion with process sensor or process controller devices. The most primitive process integration is through discrete digital I/O. For example, an external (to the robot controller) machine controller might send a one-bit signal indicating whether it is ready to be loaded by the robot. The robot control must have the ability to read the signal and to perform logical operations (if then, wait until, do until, etc.) using the signal. At the extreme of process integration, the robot controller can access and operate on large amounts of data in real time during the execution of motion-related processes. For example, in arc welding, sensor data are used to correct tool point positions as the robot is executing a weld path. This requires continuous communication between the welding process sensor and the robot motion generation functions so that there are both a data interface with the controller and motion generation code structure to act on it. Vision-guided high precision pick and place and assembly are major applications in the electronics and semiconductor industries. Experience has shown that the best integrated vision/robot performance has come from running both the robot and the vision system internal to the same computing platform. The

reasons are that data communication is much more efficient due to data bus access, and computing operations are coordinated by one operating system.

Human Integration

Operator integration is critical to the expeditious setup, programming, and maintenance of the robot system. Three controller elements most important for effective human integration are the human *I/O devices*, the information available to the operator in graphic form, and the modes of operation available for human interaction. Position and path teaching effort is dramatically influenced by the type of manual I/O devices available. A teach pendant is needed if the teacher must have access to several vantage points for posing the robot. Some robots have teleoperator-style input devices which allow coordinated manual motion command inputs. These are extremely useful for teaching multiple complex poses. Graphical interfaces, available on some industrial robots, are very effective for conveying information to the operator quickly and efficiently. A graphical interface is most important for applications which require frequent reprogramming and setup changes. Several very useful off-line programming software systems are available from third-party suppliers. These systems use computer models of commercially available robots to simulate path motion and provide rapid programming functions.

Information Integration

Information integration is becoming more important as the trend toward increasing flexibility and agility impacts robotics. Automatic and computer-aided robot task planning and process control functions will require both access to data and the ability to resolve relevant information from CAD systems, process plans and schedules, upstream inspections, and other sources of complex data and information. Many robot controllers now support information integration functions by employing integrated PC interfaces through the communications ports, or in some through direct connections to the robot controller data bus.

14.3 Robot Configurations

Ian D. Walker

Fundamentals and Design Issues

A robot manipulator is fundamentally a collection of *links* connected to each other by *joints*, typically with an *end effector* (designed to contact the environment in some useful fashion) connected to the mechanism. A typical arrangement is to have the links connected serially by the joints in an open-chain fashion. Each joint provides one or more degree of freedom to the mechanism.

Manipulator designs are typically characterized by the number of independent degrees of freedom in the mechanism, the types of joints providing the degrees of freedom, and the geometry of the links connecting the joints. The degrees of freedom can be revolute (relative rotational motion θ between joints) or prismatic (relative linear motion d between joints). A joint may have more than one degree of freedom. Most industrial robots have a total of six independent degrees of freedom. In addition, most current robots have essentially rigid links (we will focus on rigid-link robots throughout this section).

Robots are also characterized by the type of actuators employed. Typically manipulators have hydraulic or electric actuation. In some cases where high precision is not important, pneumatic actuators are used.

A number of successful manipulator designs have emerged, each with a different arrangement of joints and links. Some "elbow" designs, such as the PUMA robots and the SPAR Remote Manipulator System, have a fairly anthropomorphic structure, with revolute joints arranged into "shoulder," "elbow," and "wrist" sections. A mix of revolute and prismatic joints has been adopted in the Stanford Manipulator and the SCARA types of arms. Other arms, such as those produced by IBM, feature prismatic joints for the "shoulder," with a spherical wrist attached. In this case, the prismatic joints are essentially used as positioning devices, with the wrist used for fine motions.

The above designs have six or fewer degrees of freedom. More recent manipulators, such as those of the Robotics Research Corporation series of arms, feature seven or more degrees of freedom. These arms are termed kinematically redundant, which is a useful feature as we will see later.

Key factors that influence the design of a manipulator are the tractability of its geometric (kinematic) analysis and the size and location of its workspace. The workspace of a manipulator can be defined as the set of points that are reachable by the manipulator (with fixed base). Both shape and total volume are important. Manipulator designs such as the SCARA are useful for manufacturing since they have a simple semicylindrical connected volume for their workspace (Spong and Vidyasagar, 1989), which facilitates workcell design. Elbow manipulators tend to have a wider volume of workspace, however the workspace is often more difficult to characterize. The kinematic design of a manipulator can tailor the workspace to some extent to the operational requirements of the robot.

In addition, if a manipulator can be designed so that it has a simplified kinematic analysis, many planning and control functions will in turn be greatly simplified. For example, robots with spherical wrists tend to have much simpler inverse kinematics than those without this feature. Simplification of the kinematic analysis required for a robot can significantly enhance the real-time motion planning and control performance of the robot system. For the rest of this section, we will concentrate on the kinematics of manipulators.

For the purposes of analysis, a set of *joint variables* (which may contain both revolute and prismatic variables), are augmented into a vector q, which uniquely defines the geometric state, or configuration of the robot. However, task description for manipulators is most naturally expressed in terms of a different set of *task coordinates*. These can be the position and orientation of the robot end effector, or of a special task frame, and are denoted here by Y. Thus Y most naturally represents the performance of a task, and q most naturally represents the mechanism used to perform the task. Each of the coordinate systems q and Y contains information critical to the understanding of the overall status of the manipulator. Much of the kinematic analysis of robots therefore centers on transformations between the various sets of coordinates of interest.

Manipulator Kinematics

The study of manipulator kinematics at the position (geometric) level separates naturally into two subproblems: (1) finding the position/orientation of the end effector, or task, frame, given the angles and/or displacements of the joints *(Forward Kinematics);* and (2) finding possible angles/displacements of the joints given the position/orientation of the end effector, or task, frame *(Inverse Kinematics)*. At the velocity level, the *Manipulator Jacobian* relates joint velocities to end effector velocities and is important in motion planning and for identifying *Singularities*. In the case of *Redundant Manipulators*, the Jacobian is particularly crucial in planning and controlling robot motions. We will explore each of these issues in turn in the following subsections.

Example 14.3.1

Figure 14.3.1 shows a planar three-degrees-of-freedom manipulator. The first two joints are revolute, and the third is prismatic. The end effector position (x, y) is expressed with respect to the (fixed) world coordinate frame (x_0, y_0), and the orientation of the end effector is defined as the angle of the second link ϕ measured from the x_0 axis as shown. The link length l_1 is constant. The joint variables are given by the angles θ_1 and θ_2 and the displacement d_3, and are defined as shown. The example will be used throughout this section to demonstrate the ideas behind the various kinematic problems of interest.

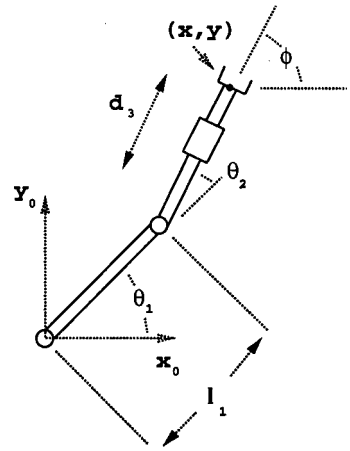

FIGURE 14.3.1 Planar RRP manipulator.

Forward (Direct) Kinematics

Since robots typically have sensors at their joints, making available measurements of the joint configurations, and we are interested in performing tasks at the robot end effector, a natural issue is that of determining the end effector position/orientation Y given a joint configuration q. This problem is the forward kinematics problem and may be expressed symbolically as

$$Y = f(q) \tag{14.3.1}$$

The forward kinematic problem yields a unique solution for Y given q. In some simple cases (such as the example below) the forward kinematics can be derived by inspection. In general, however, the relationship f can be quite complex. A systematic method for determining the function f for any manipulator geometry was proposed by Denavit and Hartenberg (Denavit and Hartenberg, 1955).

The Denavit/Hartenberg (or D-H) technique has become the standard method in robotics for describing the forward kinematics of a manipulator. Essentially, by careful placement of a series of coordinate

frames fixed in each link, the D-H technique reduces the forward kinematics problem to that of combining a series of straightforward consecutive link-to-link transformations from the base to the end effector frame. Using this method, the forward kinematics for any manipulator is summarized in a table of parameters (the D-H parameters). A maximum of three nonzero parameters per link are sufficient to uniquely specify the map *f*. Lack of space prevents us from detailing the method further. The interested reader is referred to Denavit and Hartenberg (1955) and Spong and Vidyasagar (1989).

To summarize, forward kinematics is an extremely important problem in robotics which is also well understood, and for which there is a standard solution technique

Example 14.3.2

In our example, we consider the task space to be the position and orientation of the end effector, i.e., $Y = [x, y, \phi]^T$ as shown. We choose joint coordinates (one for each degree of freedom) by $q = [\theta_1, \theta_2, d_3]^T$. From Figure 14.3.1, with the values as given it may be seen by inspection that

$$x = l_1 \cos(\theta_1) + d_3 \cos(\theta_1 + \theta_2) \tag{14.3.2}$$

$$y = l_1 \sin(\theta_1) + d_3 \sin(\theta_1 + \theta_2) \tag{14.3.3}$$

$$\phi = \theta_1 + \theta_2 \tag{14.3.4}$$

Equations (14.3.2) to (14.3.4) form the forward kinematics for the example robot. Notice that the solution for $Y = [x, y, \phi]^T$ is unique given $q = [\theta_1, \theta_2, d_3]^T$.

Inverse Kinematics

The *inverse kinematics* problem consists of finding possible joint configurations q corresponding to a given end effector position/orientation Y. This transformation is essential for planning joint positions of the manipulator which will result in desired end effector positions (note that task requirements will specify Y, and a corresponding q must be planned to perform the task). Conceptually the problem is stated as

$$q = f^{-1}(Y) \tag{14.3.5}$$

In contrast to the forward kinematics problem, the inverse kinematics cannot be solved for arbitrary manipulators by a systematic technique such as the Denavit-Hartenberg method. The relationship (1) does not, in general, invert to a unique solution for q, and, indeed, for many manipulators, expressions for q cannot even be found in closed form!

For some important types of manipulator design (particularly those mechanisms featuring spherical wrists), closed-form solutions for the inverse kinematics can be found. However, even in these cases, there are at best multiple solutions for q (corresponding to "elbow-up," "elbow-down" possibilities for the arm to achieve the end effector configuration in multiple ways). For some designs, there may be an infinite number of solutions for q given Y, such as in the case of kinematically redundant manipulators discussed shortly.

Extensive investigations of manipulator kinematics have been performed for wide classes of robot designs (Bottema and Roth, 1979; Duffy, 1980). A significant body of work has been built up in the area of inverse kinematics. Solution techniques are often determined by the geometry of a given manipulator design. A number of elegant techniques have been developed for special classes of manipulator designs, and the area continues to be the focus of active research. In cases where closed-form solutions cannot be found, a number of iterative numerical techniques have been developed.

Example 14.3.3

For our planar manipulator, the inverse kinematics requires the solution for $q = [\theta_1, \theta_2, d_3]^T$ given $Y = [x, y, \phi]^T$. Figure 14.3.2 illustrates the situation, with $[x, y, \phi]^T$ given as shown. Notice that for the Y specified in Figure 14.3.2, there are two solutions, corresponding two distinct configurations q.

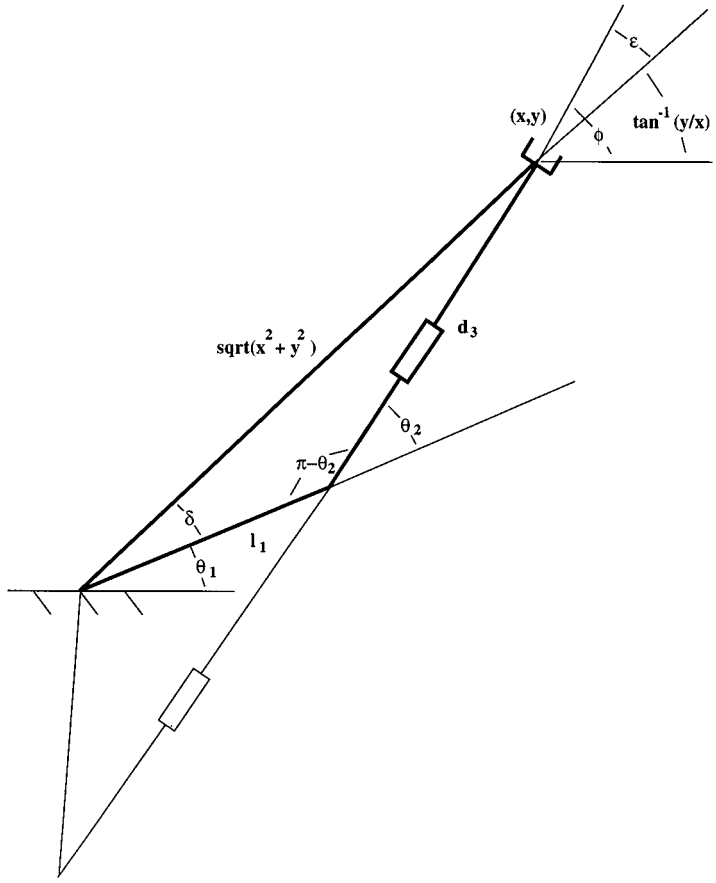

FIGURE 14.3.2 Planar RRP arm inverse kinematics.

The two solutions are sketched in Figure 14.3.2, with the solution for the configuration in bold the focus of the analysis below. The solutions may be found in a number of ways, one of which is outlined here. Consider the triangle formed by the two links of the manipulator and the vector (x, y) in Figure 14.3.2. We see that the angle ε can be found as

$$\varepsilon = \phi - \tan^{-1}(y/x)$$

Now, using the sine rule, we have that

$$l_1/\sin(\varepsilon) = \left(\sqrt{x^2 + y^2}\right)\Big/\sin(\pi - \theta_2) = \left(\sqrt{x^2 + y^2}\right)\Big/\sin(\theta_2)$$

and thus

$$\sin(\theta_2) = \left(\sqrt{x^2 + y^2}\right)\sin(\varepsilon)/l_1$$

The above equation could be used to solve for θ_2. Alternatively, we can find θ_2 as follows. Defining D to be $(\sqrt{x^2 + y^2})\sin(\varepsilon)/l_1$ we have that $\cos(\theta_2) = \pm\sqrt{1 - D^2}$. Then θ_2 can be found as

$$\theta_2 = \tan^{-1}\left[D/\pm\sqrt{1 - D^2}\right] \tag{14.3.6}$$

Notice that this method picks out both possible values of θ_2, corresponding to the two possible inverse kinematic solutions. We now take the solution for θ_2 corresponding to the positive root of $\pm(\sqrt{1 - D^2})$ (i.e., the bold robot configuration in the figure).

Using this solution for θ_2, we can now solve for θ_1 and d_3 as follows. Summing the angles inside the triangle in Figure 14.3.2, we obtain $\pi - [(\pi - \theta_2) + \varepsilon + \delta] = 0$ or

$$\delta = \theta_2 - \varepsilon$$

From Figure 14.3.2 we see that

$$\theta_1 = \tan^{-1}(y/x) - \delta \tag{14.3.7}$$

Finally, use of the cosine rule leads us to a solution for d_3:

$$d_3^2 = l_1^2 + \left(x^2 + y^2\right) - 2l_1\left(\sqrt{x^2 + y^2}\right)\cos(\delta)$$

or

$$d_3 = \sqrt{l_1^2 + \left(x^2 + y^2\right) - 2l_1\left(\sqrt{x^2 + y^2}\right)\cos(\delta)} \tag{14.3.8}$$

Equations (14.3.6) to (14.3.8) comprise an inverse kinematics solution for the manipulator.

Velocity Kinematics: The Manipulator Jacobian

The previous techniques, while extremely important, have been limited to positional analysis. For motion planning purposes, we are also interested in the relationship between joint velocities and task (end effector) velocities. The (linearized) relationship between the joint velocities $\dot{q}$ and the end effector velocities $\dot{Y}$ can be expressed (from Equation (14.3.1)) as

$$\dot{Y} = \left[J(q)\right]\dot{q} \tag{14.3.9}$$

where J is the *manipulator Jacobian* and is given by $\partial f/\partial q$. The manipulator Jacobian is an extremely important quantity in robot analysis, planning, and control. The Jacobian is particularly useful in determining singular configurations, as we shall see shortly.

Given the forward kinematic function f, the Jacobian can be obtained by direct differentiation (as in the example below). Alternatively, the Jacobian can be obtained column by column in a straightforward fashion from quantities in the Denavit-Hartenberg formulation referred to earlier. Since the Denavit-Hartenberg technique is almost always used in the forward kinematics, this is often an efficient and preferred method. For more details of this approach, see Spong and Vidyasagar (1989).

The Jacobian can be used to perform inverse kinematics at the velocity level as follows. If we define $[J^{-1}]$ to be the inverse of the Jacobian (assuming J is square and nonsingular), then

$$\dot{q} = \left[J^{-1}(q)\right]\dot{Y} \tag{14.3.10}$$

and the above expression can be solved iteratively for $\dot{q}$ (and hence q by numerical integration) given a desired end effector trajectory $\dot{Y}$ and the current state q of the manipulator. This method for determining joint trajectories given desired end effector trajectories is known as Resolved Rate Control and has become increasingly popular. The technique is particularly useful when the positional inverse kinematics is difficult or intractable for a given manipulator.

Notice, however, that the above expression requires that *J is* both nonsingular and square. Violation of the nonsingularity assumption means that the robot is in a singular configuration, and if J has more columns than rows, then the robot is kinematically redundant. These two issues will be discussed in the following subsections.

Example 14.3.4

By direct differentiation of the forward kinematics derived earlier for our example,

$$\begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\phi} \end{bmatrix} = \begin{bmatrix} -l_1 \sin(\theta_1) - d_3 \sin(\theta_1 + \theta_2) & -d_3 \sin(\theta_1 + \theta_2) & \cos(\theta_1 + \theta_2) \\ l_1 \cos(\theta_1) + d_3 \cos(\theta_1 + \theta_2) & d_3 \cos(\theta_1 + \theta_2) & \sin(\theta_1 + \theta_2) \\ 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} \dot{\theta}_1 \\ \dot{\theta}_2 \\ \dot{d}_3 \end{bmatrix} \tag{14.3.11}$$

Notice that each column of the Jacobian represents the (instantaneous) effect of the corresponding joint on the end effector motions. Thus, considering the third column of the Jacobian, we confirm that the third joint (with variable d_3) cannot cause any change in the orientation (ϕ) of the end effector.

Singularities

A significant issue in kinematic analysis surrounds so-called singular configurations. These are defined to be configurations q_s at which $J(q_s)$ has less than full rank (Spong and Vidyasagar, 1989). Physically, these configurations correspond to situations where the *robot joints* have been aligned in such a way that there is at least one direction of motion (the singular direction[s]) for the end effector that physically cannot be achieved by the mechanism. This occurs at workspace boundaries, and when the axes of two (or more) joints line up and are redundantly contributing to an end effector motion, at the cost of another end effector degree of freedom being lost. It is straightforward to show that the singular direction is orthogonal to the column space of $J(q_s)$.

It can also be shown that every manipulator must have singular configurations, i.e., the existence of singularities cannot be eliminated, even by careful design. Singularities are a serious cause of difficulties in robotic analysis and control. Motions have to be carefully planned in the region of singularities. This is not only because at the singularities themselves there will be an unobtainable motion at the end effector, but also because many real-time motion planning and control algorithms make use of the (inverse of the) manipulator Jacobian. In the region surrounding a *singularity*, the Jacobian will become ill-conditioned, leading to the generation of joint velocities in Equation (14.3.10) which are extremely high, even for relatively small end effector velocities. This can lead to numerical instability, and unexpected wild motions of the arm for small, desired end effector motions (this type of behavior characterizes motion near a singularity).

For the above reasons, the analysis of singularities is an important issue in robotics and continues to be the subject of active research.

Example 14.3.5

For our example manipulator, we can find the singular configurations by taking the determinant of its Jacobian found in the previous section and evaluating the joint configurations that cause this determinant to become zero. A straightforward calculation yields

$$\det(J) = l_1 \cos(\theta_1) \tag{14.3.12}$$

and we note that this determinant is zero exactly when θ_1 is a multiple of $\pi/2$. One such configuration ($\theta_1 = \pi/2$, $\theta_2 = -\pi/2$) is shown in Figure 14.3.3. For this configuration, with $l_1 = 1 = d_3$, the Jacobian is given by

$$\begin{bmatrix} -1 & 0 & 1 \\ 1 & 1 & 0 \\ 1 & 1 & 0 \end{bmatrix}$$

and by inspection, the columns of J are orthogonal to $[0, -1, 1]^T$, which is therefore a singular direction of the manipulator in this configuration. This implies that from the (singular) configuration shown in Figure 14.3.3, the direction $\dot{Y} = [0, -1, 1]^T$ cannot be physically achieved. This can be confirmed by considering the physical device (motion in the negative y direction cannot be achieved while simultaneously increasing the orientation angle ϕ).

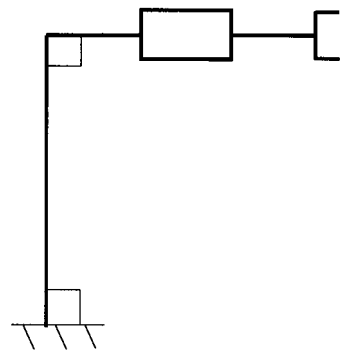

FIGURE 14.3.3 Singular configuration of planar RRP arm.

Redundant Manipulator Kinematics

If the dimension of q is n, the dimension of Y is m, and n is larger than m, then a manipulator is said to be *kinematically redundant* for the task described by Y. This situation occurs for a manipulator with seven or more degrees of freedom when Y is a six-dimensional position/orientation task, or, for example, when a six-degrees-of-freedom manipulator is performing a position task and orientation is not specified.

In this case, the robot mechanism has more degrees of freedom than required by the task. This gives rise to extra complexity in the kinematic analysis due to the extra joints. However, the existence of these extra joints gives rise to the extremely useful *self-motion* property inherent in redundant arms. A self-motion occurs when, with the end effector location held constant, the joints of the manipulator can move (creating an "orbit" of the joints). This allows a much wider variety of configurations (typically an infinite number) for a given end effector location. This added maneuverability is the key feature and advantage of kinematically redundant arms. Note that the human hand/arm has this property. The key question for redundant arms is how to best utilize the self-motion property while still performing specified

end effector motions $\dot{Y}$. A number of motion-planning algorithms have been developed in the last few years for redundant arms (Siciliano, 1990). Most of them center on the Jacobian pseudoinverse as follows.

For kinematically redundant arms, the Jacobian has more columns than rows. If J is of full rank, and we choose $[J^+]$ to be a pseudoinverse of the Jacobian such that $JJ^+ = I$ [for example $J^+ = J^T(JJ^T)^{-1}$], where I is the $m \times m$ identity matrix, then from Equation (14.3.9) a solution for $\dot{q}$ which satisfies end effector velocity of $\dot{Y}$ is given by

$$\dot{q} = \left[J^+(q)\right]\dot{Y} + \left[I - J^+(q)\,J(q)\right]\varepsilon \tag{14.3.13}$$

where ε *is* an $(n \times 1)$ column vector whose values may be arbitrarily selected. Note that conventional nonredundant manipulators have $m = n$, in which case the pseudoinverse becomes J^{-1} and the problem reduces to the resolved rate approach (Equation 14.3.10).

The above solution for $\dot{q}$ has two components. The first component, $[J^+(q)]\,\dot{Y}$, are joint velocities that produce the desired end effector motion $\dot{Y}$ (this can be easily seen by substitution into Equation (14.3.9)). The second term, $[I - J^+(q)J(q)]\varepsilon$, comprises joint velocities which produce no end effector velocities (again, this can be seen by substitution of this term into Equation (14.3.9)). Therefore, the second term produces a self-motion of the arm, which can be tuned by appropriately altering ε. Thus different choices of ε correspond to different choices of the self-motion and various algorithms have been developed to exploit this choice to perform useful subtasks (Siciliano, 1990).

Redundant manipulator analysis has been an active research area in the past few years. A number of arms, such as those recently produced by Robotics Research Corporation, have been designed with seven degrees of freedom to exploit kinematic redundancy. The self-motion in redundant arms can be used to configure the arm to evade obstacles, avoid singularities, minimize effort, and a great many more subtasks in addition to performing the desired main task described by $\dot{Y}$. For a good review of the area, the reader is referred to Siciliano (1990).

Example 14.3.6

If, for our example, we are only concerned with the position of the end effector in the plane, then the arm becomes kinematically redundant. Figure 14.3.4 shows several different (from an infinite number of) configurations for the arm given one end effector position. In this case, J becomes the 2×3 matrix formed by the top two rows of the Jacobian in Equation (14.3.11). The pseudoinverse J^+ will therefore be a 3×2 matrix. Formation of the pseudoinverse is left to the reader as an exercise.

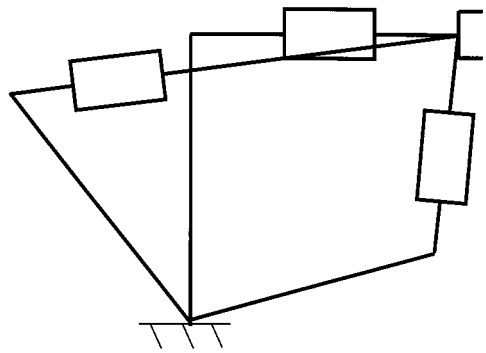

FIGURE 14.3.4 Multiple configurations for RRP arm for specified end effector position only.

Summary

Kinematic analysis is an interesting and important area, a solid understanding of which is required for robot motion planning and control. A number of techniques have been developed and are available to the robotics engineer. For positional analysis, the Denavit-Hartenberg technique provides a systematic approach for forward kinematics. Inverse kinematic solutions typically have been developed on a manipulator (or class of manipulator)-specific basis. However, a number of insightful effective techniques exist for positional inverse kinematic analysis. The manipulator Jacobian is a key tool for analyzing singularities and motion planning at the velocity level. Its use is particularly critical for the emerging generation of kinematically redundant arms

14.4 End Effectors and Tooling

Mark R. Cutkosky and Peter McCormick

End effectors or end-of-arm tools are the devices through which a robot interacts with the world around it, grasping and manipulating parts, inspecting surfaces, and working on them. As such, end effectors are among the most important elements of a robotic application — not "accessories" but an integral component of the overall tooling, fixturing, and sensing strategy. As robots grow more sophisticated and begin to work in more demanding applications, end effector design is becoming increasingly important.

The purpose of this chapter is to introduce some of the main types of end effectors and tooling and to cover issues associated with their design and selection. References are provided for the reader who wishes to go into greater depth on each topic. For those interested in designing their own end effectors, a number of texts including Wright and Cutkosky (1985) provide additional examples.

A Taxonomy of Common End Effectors

Robotic end effectors today include everything from simple two-fingered grippers and vacuum attachments to elaborate multifingered hands. Perhaps the best way to become familiar with end effector design issues is to first review the main end effector types.

Figure 14.4.1 is a taxonomy of common end effectors. It is inspired by an analogous taxonomy of grasps that humans adopt when working with different kinds of objects and in tasks requiring different amounts of precision and strength (Wright and Cutkosky, 1985). The left side includes "passive" grippers that can hold parts, but cannot manipulate them or actively control the grasp force. The right-hand side includes active servo grippers and *dextrous* robot hands found in research laboratories and teleoperated applications.

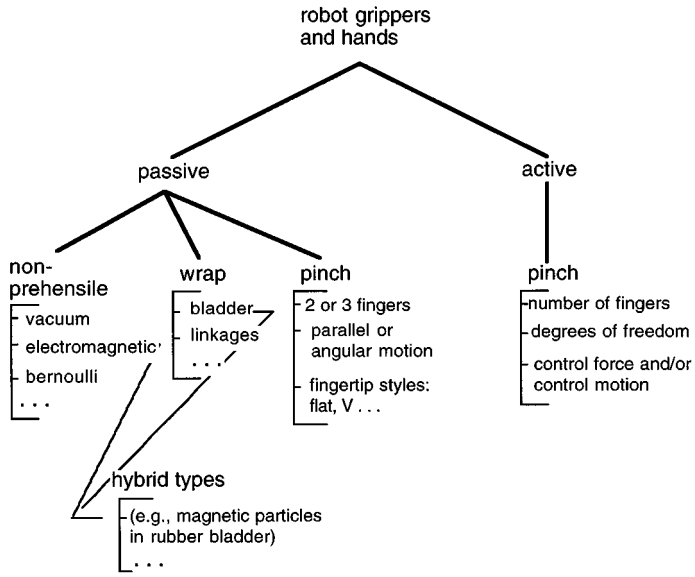

FIGURE 14.4.1 A taxonomy of the basic end effector types.

Passive End Effectors

Most end effectors in use today are passive; they emulate the grasps that people use for holding a heavy object or tool, without manipulating it in the fingers. However, a passive end effector may (and generally should) be equipped with sensors, and the information from these sensors may be used in controlling the robot arm.

The left-most branch of the "passive" side of the taxonomy includes vacuum, electromagnetic, and Bernoulli-effect end effectors. Vacuum grippers, either singly or in combination, are perhaps the most commonly used gripping device in industry today. They are easily adapted to a wide variety of parts — from surface mount microprocessor chips and other small items that require precise placement to large, bulky items such as automobile windshields and aircraft panels. These end effectors are classified as "nonprehensile" because they neither enclose parts nor apply grasp forces across them. Consequently, they are ideal for handling large and delicate items such as glass panels. Unlike grippers with fingers, vacuum grippers to not tend to "center" or relocate parts as they pick them up. As discussed in Table 14.4.1, this feature can be useful when initial part placement is accurate.

TABLE 14.4.1 Task Considerations in End Effector Design

Initial Accuracy. Is the initial accuracy of the part high (as when retrieving a part from a fixture or lathe chuck) or low (as when picking unfixtured components off a conveyor)? In the former case, design the gripper so that it will conform to the part position and orientation (as do the grippers in Figures 14.4.5 and 14.4.6. In the latter case, make the gripper center the part (as will most parallel-jaw grippers).
Final Accuracy. Is the final accuracy of the part high or low? In the former case (as when putting a precisely machined peg into a chamfered hole) the gripper and/or robot arm will need *compliance*. In the latter case, use an end effector that centers the part.
Anticipated Forces. What are the magnitudes of the expected task forces and from what directions will they come? Are these forces resisted directly by the gripper jaws, or indirectly through friction? High forces may lead to the adoption of a "wrap"-type end effector that effectively encircles the part or contacts it at many points.
Other Tasks. Is it useful to add sensing or other tooling at the end effector to reduce cycle time? Is it desirable for the robot to carry multiple parts to minimize cycle time? In such cases consider *compound end effectors*.
Speed and Cycle Time. Are speeds and accelerations large enough that inertial forces and moments should be considered in computing the required grip force?

If difficulties are encountered with a vacuum gripper, it is helpful to remember that problem can be addressed in several ways, including increasing the suction cup area through larger cups or multiple cups, redesigning the parts to be grasped so that they present a smoother surface (perhaps by affixing smooth tape to a surface), and augmenting suction with grasping as discussed below. Figure 14.4.2 shows a large gripper with multiple suction cups for handling thermoplastic auto body panels. This end effector also has pneumatic actuators for providing local left/right and up/down motions.

An interesting noncontact variation on the vacuum end effector is illustrated in Figure 14.4.3. This end effector is designed to lift and transport delicate silicon wafers. It lifts the wafers by blowing gently on them from above so that aerodynamic lift is created via the Bernoulli effect. Thin guides around the periphery of the wafers keep them centered beneath the air source.

The second branch of end effector taxonomy includes "wrap" grippers that hold a part in the same way that a person might hold a heavy hammer or a grapefruit. In such applications, humans use *wrap grasps* in which the fingers envelop a part, and maintain a nearly uniform pressure so that friction is used to maximum advantage. Figures 14.4.4 and 14.4.5 show two kinds of end effectors that achieve a similar effect.

Another approach to handling irregular or soft objects is to augment a vacuum or magnetic gripper with a bladder containing particles or a fluid. When handling ferrous parts, one can employ an electromagnet and iron particles underneath a membrane. Still another approach is to use fingertips filled with an electrorheological fluid that stiffens under the application of an electrostatic field.

The middle branch of the end effector taxonomy includes common two-fingered grippers. These grippers employ a strong "pinch" force between two fingers, in the same way that a person might grasp a key when opening a lock. Most such grippers are sold without fingertips since they are the most product-specific part of the design. The fingertips are designed to match the size of components, the

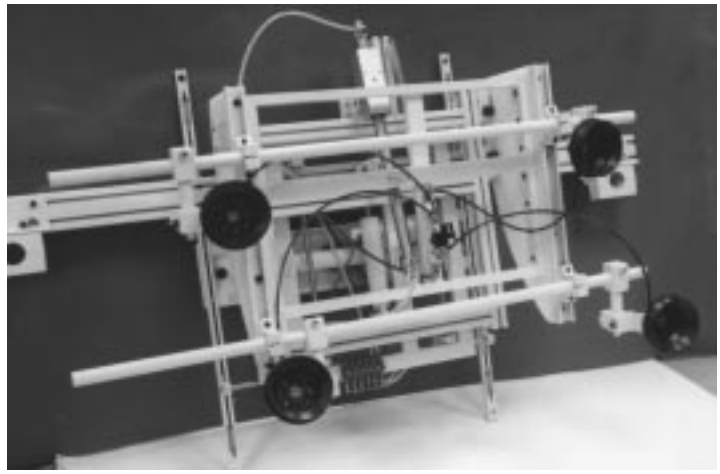

FIGURE 14.4.2 A large end effector for handling autobody panels with actuators for local motions. (Photo courtesy of EOA Systems Inc., Dallas, TX.)

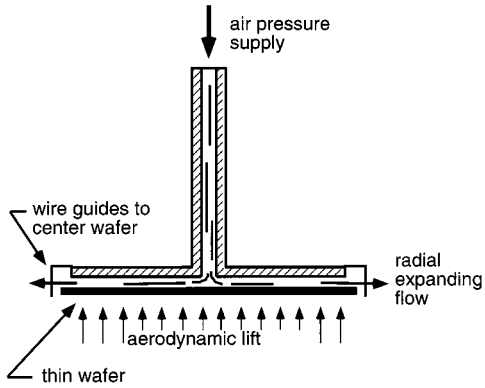

FIGURE 14.4.3 A noncontact end effector for acquiring and transporting delicate wafers.

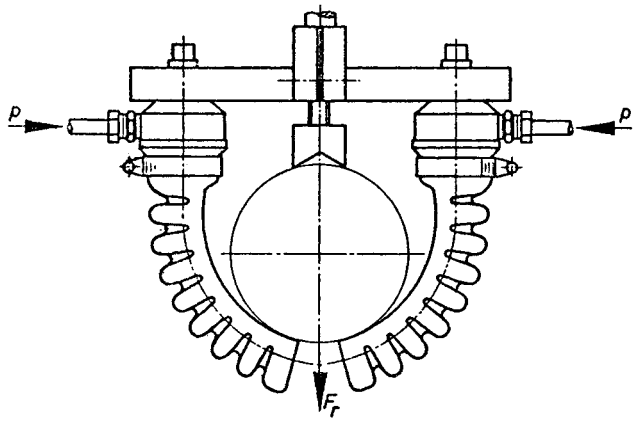

FIGURE 14.4.4 A compliant pneumatic gripper that executes a gentle wrap grasp. (From U.S. Patent No. 3981528, Simrit Corp., Arlington Hts., IL, 1984.)

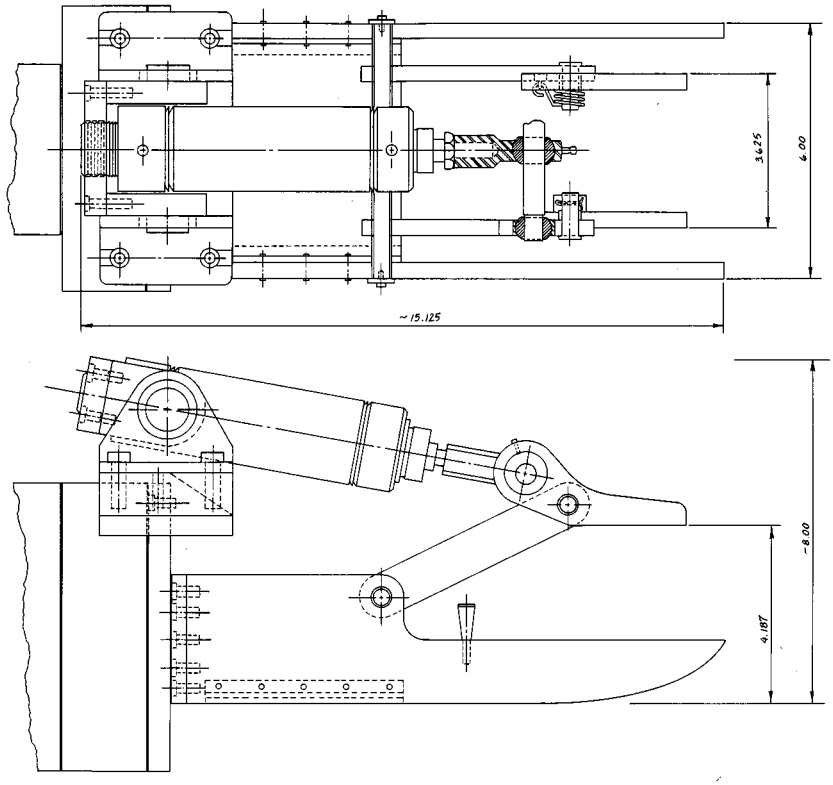

FIGURE 14.4.5 A gripper with pivoted fingers designed to conform to the position and orientation of heavy, irregular parts and to hold them securely. (From U.S. Patent No. 4,545,722, Cutkosky and Kurokawa, 1985.)

shape of components (e.g., flat or V-grooved for cylindrical parts), and the material (e.g., rubber or plastic to avoid damaging fragile objects).

Note that since two-fingered end effectors typically use a single air cylinder or motor that operates both fingers in unison, they will tend to center parts that they grasp. This means that when they grasp constrained parts (e.g., pegs that have been set in holes or parts held in fixtures) some compliance must be added, perhaps with a compliant wrist as discussed in "Wrists and Other End-of-Arm Tooling" below.

Active End Effectors and Hands

The right-hand branch of the taxonomy includes servo grippers and dextrous multifingered hands. Here the distinctions depend largely on the number of fingers and the number of joints or degrees of freedom per finger. For example, the comparatively simple two-fingered servo gripper of Figure 14.4.6 is confined to *"pinch" grasps*, like commercial two-fingered grippers.

Servo-controlled end effectors provide advantages for fine-motion tasks. In comparison to a robot arm, the fingertips are small and light, which means that they can move quickly and precisely. The total range of motion is also small, which permits fine-resolution position and velocity measurements. When equipped with force sensors such as strain gages, the fingers can provide force sensing and control, typically with better accuracy than can be obtained with robot wrist- or joint-mounted sensors. A servo gripper can also be programmed either to control the position of an unconstrained part or to accommodate to the position of a constrained part as discussed in Table 14.4.1.

The sensors of a servo-controlled end effector also provide useful information for robot programming. For example, position sensors can be used to measure the width of a grasped component, thereby providing a check that the correct component has been grasped. Similarly, force sensors are useful for weighing grasped objects and monitoring task-related forces.

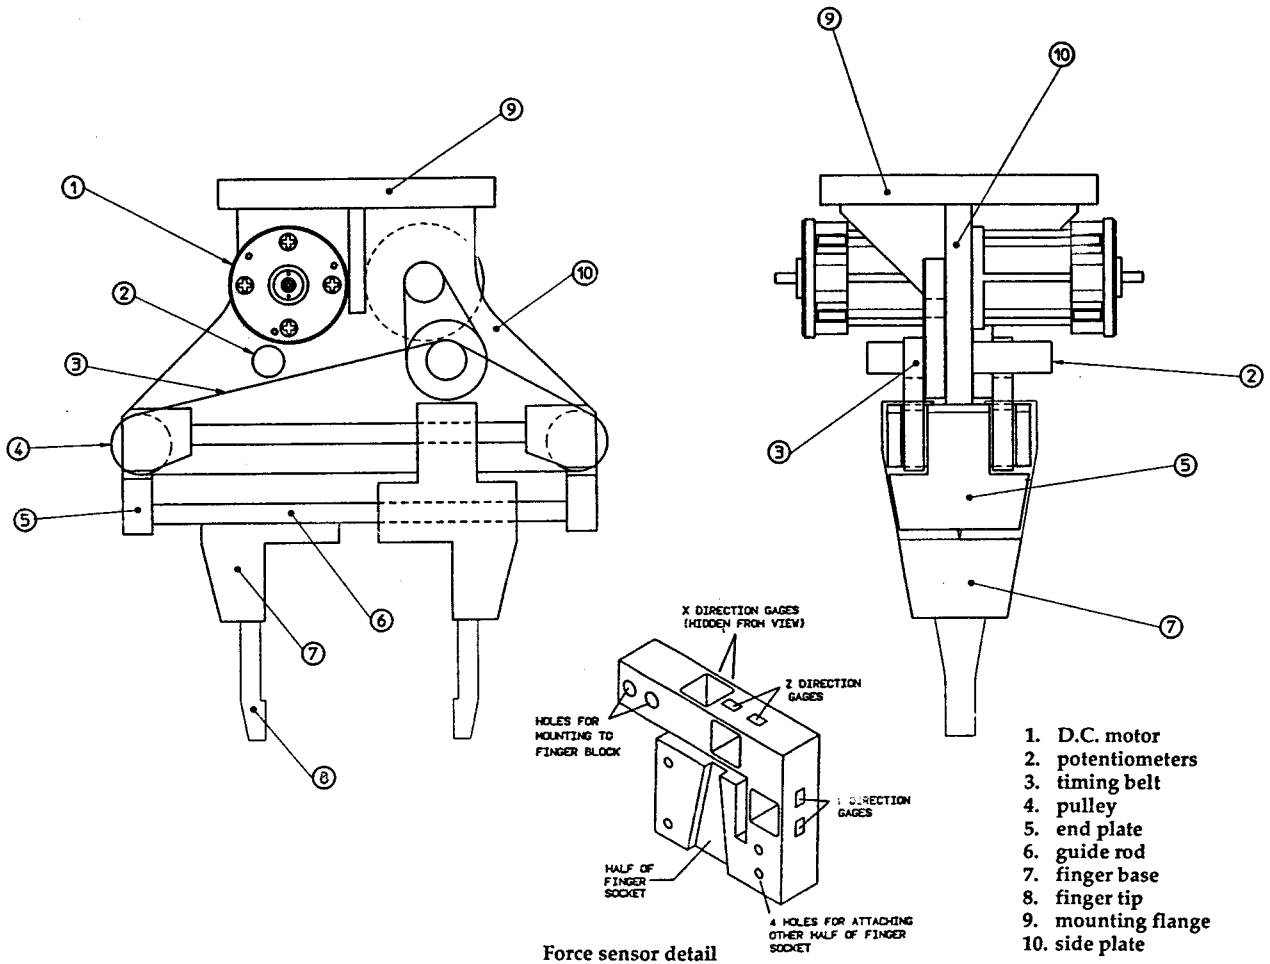

FIGURE 14.4.6 A two-finger servo gripper with force sensing and changeable fingertips. (From E. Pearce et. al, ME210 Report, Stanford University, 1987.)

For applications requiring a combination of dexterity and versatility for grasping a wide range of objects, a dextrous multifingered hand is the ultimate solution. A number of multifingered hands have been described in the literature (see, for example, Jacobsen et al. [1984]) and commercial versions are available. Most of these hands are frankly anthropomorphic, although kinematic criteria such as workspace and *grasp isotropy* (basically a measure of how accurately motions and forces can be controlled in different directions) have also been used.

Despite their practical advantages, dextrous hands have thus far been confined to a few research laboratories. One reason is that the design and control of such hands present numerous difficult tradeoffs among cost, size, power, flexibility and ease of control. For example, the desire to reduce the dimensions of the hand, while providing adequate power, leads to the use of cables that run through the wrist to drive the fingers. These cables bring attendant control problems due to elasticity and friction (Jacobsen et al., 1984).

A second reason for slow progress in applying dextrous hands to manipulation tasks is the formidable challenge of programming and controlling them. The equations associated with several fingertips sliding and rolling on a grasped object are complex — the problem amounts to coordinating several little robots at the end of a robot. In addition, the mechanics of the hand/object system are sensitive to variations in the contact conditions between the fingertips and object (e.g., variations in the object profile and local coefficient of friction). Moreover, during manipulation the fingers are continually making and breaking contact with the object, starting and stopping sliding, etc., with attendant changes in the dynamic and kinematic equations which must be accounted for in controlling the hand. A survey of the dextrous manipulation literature can be found in Pertin-Trocaz (1989).

Wrists and Other End-of-Arm Tooling

In many applications, an active servo gripper is undesirably complicated, fragile, and expensive, and yet it is desirable to obtain some of the compliant force/motion characteristics that an actively controlled gripper can provide. For example, when assembling close-fitting parts, compliance at the end effector can prevent large contact forces from arising due to minor position errors of the robot or manufacturing tolerances in the parts themselves. For such applications a compliant wrist, mounted between the gripper and the robot arm, may be the solution. In particular, *remote center of compliance (RCC)* wrists allow the force/deflection properties of the end effector to be tailored to suit a task. Active wrists have also been developed for use with end effectors for precise, high-bandwidth control of forces and fine motions (Hollis et al., 1988).

Force sensing and quick-change wrists are also commercially available. The former measure the interaction forces between the end effector and the environment and typically come with a dedicated microprocessor for filtering the signals, computing calibration matrices, and communicating with the robot controller. The latter permit end effectors to be automatically engaged or disengaged by the robot and typically include provisions for routing air or hydraulic power as well as electrical signals. They may also contain provisions for overload sensing.

End Effector Design Issues

Good end effector design is in many ways the same as good design of any mechanical device. Foremost, it requires:

- A formal understanding of the functional specifications and relevant constraints. In the authors, experience, most design “failures” occurred not through faulty engineering, but through incompletely articulated requirements and constraints. In other words, the end effector solved the wrong problem.
- A “concurrent engineering” approach in which such issues as ease of maintenance, as well as related problems in fixturing, robot programming, etc., are addressed in parallel with end effector design.

- An attention to details in which issues such as power requirements, impact resistance, and sensor signal routing are not left as an afterthought.

Some of the main considerations are briefly discussed below.

Sensing

Sensors are vital for some manufacturing applications and useful in many others for detecting error conditions. Virtually every end effector design can benefit from the addition of limit switches, proximity sensors, and force overload switches for detecting improperly grasped parts, dropped parts, excessive assembly forces, etc. These binary sensors are inexpensive and easy to connect to most industrial controllers. The next level of sophistication includes analog sensors such as strain gages and thermocouples. For these sensors, a dedicated microprocessor as well as analog instrumentation is typically required to interpret the signals and communicate with the robot controller. The most complex class of sensors includes cameras and tactile arrays. A number of commercial solutions for visual and tactile imaging are available, and may include dedicated microprocessors and software. Although vision systems are usually thought of as separate from end effector design, it is sometimes desirable to build a camera into the end effector; this approach can reduce cycle times because the robot does not have to deposit parts under a separate station for inspecting them.

Actuation

The actuation of industrial end effectors is most commonly pneumatic, due to the availability of compressed air in most applications and the high power-to-weight ratio that can be obtained. The grasp force is controlled by regulating air pressure. The chief drawbacks of pneumatic actuation are the difficulties in achieving precise position control for active hands (due primarily to the compressibility of air) and the need to run air lines down what is otherwise an all-electric robot arm. Electric motors are also common. In these, the grasp force is regulated via the motor current. A variety of drive mechanisms can be employed between the motor or cylinder and the gripper jaws, including worm gears, rack and pinion, toggle linkages, and cams to achieve either uniform grasping forces or a self-locking effect. For a comparison of different actuation technologies, with emphasis on servo-controlled applications, see Hollerbach et al. (1992).

Versatility

Figure 14.4.7 shows a how/why diagram for a hypothetical design problem in which the designer has been asked to redesign an end effector so that it can grasp a wide range of part shapes or types. Designing a versatile end effector or hand might be the most obvious solution, but it is rarely the most economical. A good starting point in such an exercise is to examine the end effector taxonomy in conjunction with the guidelines in Tables 14.4.1 and 14.4.2 to identify promising classes of solutions for the desired range of parts and tasks. The next step is to consider how best to provide the desired range of solutions. Some combination of the following approaches is likely to be effective.

Interchangeable End Effectors. These are perhaps the most common solution for grasping a wider array of part sizes and shapes. The usual approach is to provide a magazine of end effectors and a quick-change wrist so the robot can easily mount and dismount them as required. A similar strategy, and a simpler one if sensory information is to be routed from the end effector down the robot arm, is to provide changeable fingertips for a single end effector.

Compound End Effectors. These are a “Swiss army knife” approach that consists of putting a combination of end effectors on a single arm, or a combination of fingertips on a single end effector. As long as the end effectors or fingertips do not interfere with each other and the ensemble does not weigh too much for the robot arm, this solution combines the advantage of not having to pause to change end effectors with the advantages of custom-designed tooling. Figure 14.4.8 shows a compound end effector with tools for feeding, measuring, cutting, and laying down wires in a cable harness.

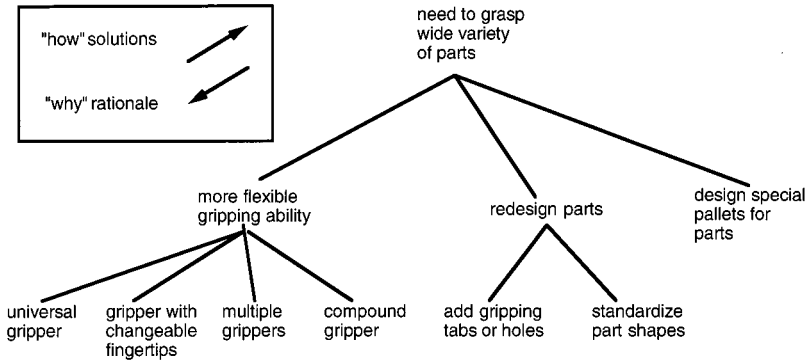

FIGURE 14.4.7 A "how/why" diagram of solutions and rationale for a design problem involving a need to grasp a wide range of parts.

TABLE 14.4.2 Part Characteristics and Associated End Effector Solutions

Size, weight	
Large, heavy	Grippers using wrap grips, taking advantage of friction or *vacuum* or electromagnetic holding
Small, light	Two-fingered gripper; vacuum cup if smooth surface, electromagnet if ferrous alloy
Shape	
Prismatic	Two-fingered parallel-jaw gripper; angular motion if all parts have approximately same dimensions
Cylindrical	Parallel or angular motion two-finger gripper with V-jaw fingertips if light; wrap gripper if heavy; consider gripping on end with three-finger gripper if task or fixtures permit
Flat	Parallel or angular motion gripper or vacuum attachment
Irregular	Wrap grasp using linkages or bladder; consider augmenting grasp with vacuum or electromagnetic holding for heavy parts
Surface	
Smooth	Good for vacuum attachments, simple electromagnets, two-fingered grippers with flat fingertips
Rough	Compliant material (e.g., low durometer rubber) on fingertips or compliant membrane filled with powder or magnetic particles; grippers that use a wrap grasp are less sensitive to variations in surface quality
Slippery	Consider electromagnet or vacuum to help hold onto slippery material; grippers that use a wrap grasp are less sensitive to variations in friction
Material	
Ferrous	Electromagnet (provided that other concerns do not rule out the presence of strong magnetic fields)
Soft	Consider vacuum or soft gripping materials
Very delicate	Soft wrap grippers and vacuum grippers such as those in Figure 14.4.4 can grip very gently; compliant fingertips with foam rubber, or a membrane covering a powder, can also be used to distribute the contact pressure; if the part is very light and fragile consider lifting it using the Bernoulli effect

Redesigned Parts and Fixtures. Stepping back from the end effector, it is useful to recall that the design of the end effector is coupled with the design of fixtures, parts, and the robot. Perhaps we can design special pallets or adapters for the parts that make them simpler to grasp. Another solution is to standardize the design of the parts, using Group Technology principles to reduce the variability in sizes and geometries. When it is difficult to reduce the range of parts to a few standard families (or when the parts are simply hard to grip), consider adding special nonfunctional features such as tabs or handles so that a simple end effector can work with them.

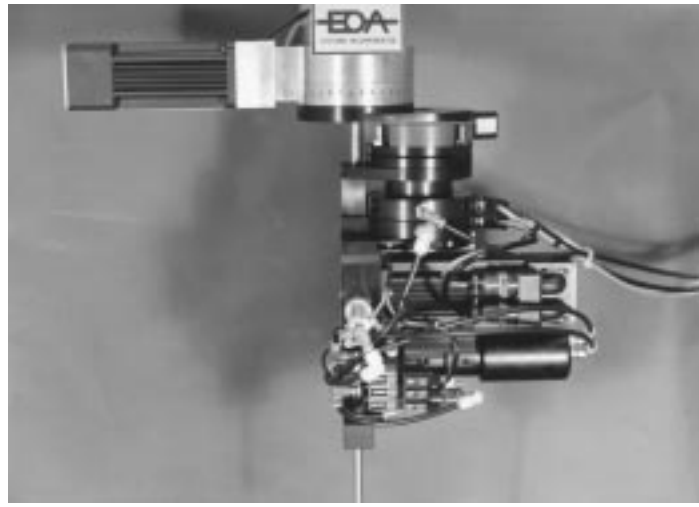

FIGURE 14.4.8 A "compound" end effector with tools for feeding, measuring, cutting, and laying down wires in a cable harness. (Photo courtesy of EOA Systems Inc., Dallas, TX.)

Summary

In summary, we observe that end effector design and selection are inextricably coupled with the design of parts, robots, fixtures, and tooling. While this interdependence complicates end effector design, it also provides opportunities because difficult problems involving geometry, sensing, or task-related forces can be tackled on all of these fronts.

14.5 Sensors and Actuators

Kok-Meng Lee

Sensors and actuators play an important role in robotic manipulation and its applications. They must operate precisely and function reliably as they directly influence the performance of the robot operation. A transducer, a sensor or actuator, like most devices, is described by a number of characteristics and distinctive features. In this section, we describe in detail the different sensing and actuation methods for robotic applications, the operating principle describing the energy conversion, and various significant designs that incorporate these methods. This section is divided into four subsections, namely, tactile and proximity sensors, force sensors, vision, and actuators.

By definition, tactile sensing is the continuously variable sensing of forces and force gradients over an area. This task is usually performed by an $m \times n$ array of industrial sensors called forcels. By considering the outputs from all of the individual forcels, it is possible to construct a tactile image of the targeted object. This ability is a form of sensory feedback which is important in development of robots. These robots will incorporate tactile sensing pads in their end effectors. By using the tactile image of the grasped object, it will be possible to determine such factors as the presence, size, shape, texture, and thermal conductivity of the grasped object. The location and orientation of the object as well as reaction forces and moments could also be detected. Finally, the tactile image could be used to detect the onset of part slipping. Much of the tactile sensor data processing is parallel with that of the vision sensing. Recognition of contacting objects by extracting and classifying features in the tactile image has been a primary goal. Thus, the description of tactile sensor in the following subsection will be focused on transduction methods and their relative advantages and disadvantages.

Proximity sensing, on the other hand, is the detection of approach to a workplace or obstacle prior to touching. Proximity sensing is required for really competent general-purpose robots. Even in a highly structured environment where object location is presumably known, accidental collision may occur, and foreign object could intrude. Avoidance of damaging collision is imperative. However, even if the environment is structured as planned, it is often necessary to slow a working manipulator from a high slew rate to a slow approach just prior to touch. Since workpiece position accuracy always has some tolerance, proximity sensing is still useful.

Many robotic processes require sensors to transduce contact force information for use in loop closure and data gathering functions. Contact sensors, wrist force/torque sensors, and force probes are used in many applications such as grasping, assembly, and part inspection. Unlike tactile sensing which measures pressure over a relatively large area, force sensing measures action applied to a spot. Tactile sensing concerns extracting features of the object being touched, whereas quantitative measurement is of particular interest in force sensing. However, many transduction methods for tactile sensing are appropriate for force sensing.

In the last three decades, computer vision has been extensively studied in many application areas which include character recognition, medical diagnosis, target detection, and remote sensing. The capabilities of commercial vision systems for robotic applications, however, are still limited. One reason for this slow progress is that robotic tasks often require sophisticated vision interpretation, yet demand low cost and high speed, accuracy, reliability, and flexibility. Factors limiting the commercially available computer vision techniques and methods to facilitate vision applications in robotics are highlights of the subsection on vision.

Tactile and Proximity Sensors

A review of past investigations (see Nichols and Lee [1989] for details) has shown that a tactile sensor should have the following characteristics: most important, the sensor surface should be both compliant and durable, and the response of individual forcels should be stable, repeatable, free from hysteresis. The response must be monotonic, though not necessarily linear. The forcels should be capable of detecting

TABLE 14.5.1 Advantages and Disadvantages of Different Tactile Transduction Methods

Type	Advantages	Disadvantages
Resistive and conductive	Wide dynamic range Durability Good overload tolerance Compatibility with integrated circuitry	Hysteresis in some designs Limited spatial resolution Monotonic response, but often not linear
Capacitive	Wide dynamic range Linear response Robust	Susceptible to noise Temperature-sensitive Limiting spatial resolution
Magnetoelastic	Wide dynamic range Low hysteresis Linear response Robust	Susceptibility to stray fields and noise as circuitry requires
Optical	Very high resolution Compatible with vision technology No electrical interference problems	Some hysteresis, depends on elastomer in some designs
Piezoelectric and pyroelectric	Wide dynamic range Durability Good mechanical properties Capable of temperature as well as force sensing	Difficult to separate piezoelectric from pyroelectric effects Inherently dynamic
Thermal	Combined force and temperature	Slow in response

loads ranging from 0 to 1000 g, having a 1-g sensitivity, a dynamic range of 1000:1, and a bandwidth of approximately 100 Hz. Furthermore, forcers should be spaced no more than 2 mm apart and on at least a 10 × 10 grid. A wide range of transduction techniques have been used in the designs of the present generation of tactile sensors. These techniques are compared in Table 14.5.1 and the principles of transduction methods are described as follows.

Resistive and Conductive Transduction

This technique involves measuring the resistance either through or across the thickness of a conductive elastomer. As illustrated in Figure 14.5.1, the measured resistance changes with the amount of force applied to the materials, resulting from the deformation of the elastomer altering the particle density within it. Most commonly used elastomers are made from carbon or silicon-doped rubber, and the construction is such that the sensor is made up of a grid of discrete sites at which the resistance is measured.

A number of the conductive and resistive designs have been quite successful. A design using carbon-loaded rubber originated by Purbrick at MIT formed the basis for several later designs. It was constructed

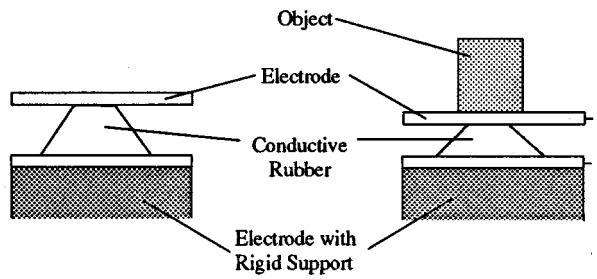

FIGURE 14.5.1 Resistive tactile element.

from a simple grid of silicon rubber conductors. Resistance at the electrodes was measured, which corresponds to loads. A novel variation of this design developed by Raibeit is to place the conductive sheet rubber over a printed circuit board (PCB) which incorporates VLSI circuitry, each forcel not only transduces its data but processes it as well. Each site performs transduction and processing operations at the same time as all the others. The computer is thus a parallel processor.

Capacitive Transduction

Capacitive tactile sensors are concerned with measuring capacitance, which is made to vary under applied load. A common sensor design is to use an elastomeric separator between the plates to provide compliance such that the capacitance will vary according to applied load. The capacitance of a parallel plate capacitor is proportional to its congruous area and the permitivity of dielectric, and inversely proportional to the separation of the plates. Alteration of any of the three parameters causes a change of capacitance. Since the capacitance decreases with decreasing congruous area, the sensor becomes rather cumbersome for design of small forcels.

To allow for a more compact design, an alternative tactile sensor array can be designed based on a moving dielectric element as illustrated in Figure 14.5.2. Each sensing element has two coaxial capacitor cylinders, acting as plates, fixed to a PCB. A dielectric element is spring-mounted in the space between the cylinders. The dielectric is displaced by contact with an external stimulus; hence it moves up and down between the capacitor plates as contact loads vary. A force-displacement relationship is thereby established.

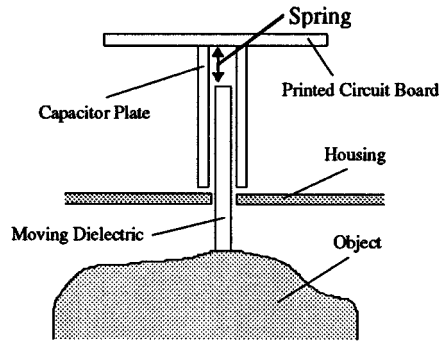

FIGURE 14.5.2 Mechanical/capacitive tactile element.

A novel slip sensor using the change in capacitance caused by relative contact movement between sensor and object is described by Luo (Nichols and Lee, 1989). The contacting sensor surface comprises a set of parallel rollers. Each roller is a half cylinder of conductive material, and a half cylinder of nonconductive material. The rollers are mounted in a nonconductive material.

The casing and rollers act as a variable capacitor. A slipping object will rotate the rollers, causing the capacitance to change, which is then measured, thereby facilitating a slip sensor. The sensor measures the change of phase angle, with the amount of phase shift providing a measure of the scale of slip. A highly linear relationship between detected phase shift angle and sensor output was established.

Magnetoelastic Transduction

Magnetoelastic sensors are a kind of inductive sensor that differs from those described above; they are not based on a change of geometry or on the position of conductive or capacitive materials. Instead, they are based on the Villari effect, consisting of reversible changes in the magnetization curve of a ferromagnetic material when it is subjected to a mechanical stress. It consists of changes of shape and volume during the magnetization process. Magnetoelastic materials undergo changes in their magnetic field when subjected to stress and therefore suggest themselves as possible transducers in tactile sensors.

Figure 14.5.3 illustrates this transduction principle in tactile sensor design. This method of tactile transduction has seen little development in robotics, although there are several papers on the subject (Fraden, 1993).

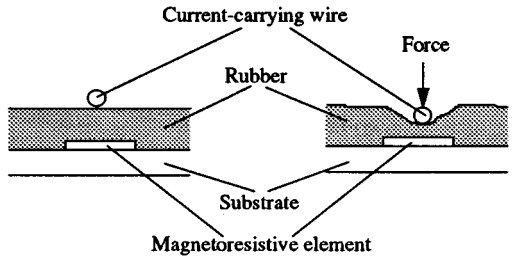

FIGURE 14.5.3 Magnetoresistive tactile element.

Fiber Optics Proximity and Tactile Sensors

The development of optical fiber technology and solid-state cameras has led to some interesting new tactile sensor designs. The capability for high-spatial-resolution images, freedom from electrical interference, and ease of separation of sensor from processing electronics are some of the attractions of incorporating optical transduction methods into tactile sensors. The following illustrates two different fiber optic sensor designs, a proximity sensor and a tactile sensor.

Figure 14.5.4 illustrates the basic principle of fiber optic proximity sensor. Light from a light-emitting diode (LED) is passed down a fiber optic cable to illuminate any proximal objects. A second cable picks up any reflected light from illuminated objects within a detection zone and directs it onto a photodiode. This simple technique can be built into a finger. The finger can sense contacts perpendicular to the finger axis, radially, and also axial contact at the fingertip. Several fiber optic cable pairs can be evenly spaced around the fingers and incorporated into a gripping system. Figure 14.5.4 illustrates this transduction method for proximity sensing.

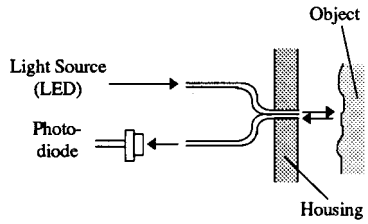

FIGURE 14.5.4 Optical proximity sensing.

Optical fibers are a type of dielectric waveguide. These waveguides channel light energy by "trapping" it between cylindrical layers of dielectric materials. In the most simple case, the fiber core is surrounded by a cladding which has a small refractive index. Light is lost from the core of a fiber when a mechanical bend or perturbation results in coupling between guided and radiation modes. The concept of monitoring light losses due to microbending can be found in several tactile sensor designs (Nichols and Lee, 1989; Tzou and Fukuda, 1992).

Piezoelectric/Pyroelectric Effect

The piezoelectric effect is the generation of a voltage across the sensing element when pressure is applied to it. Correspondingly, the pyroelectric effect is the generation of a voltage when the sensing element is heated or cooled. No external voltage is required, and a continuous analog output is available from such a sensor. Such sensors are most suited for sensing pressure changes or thermal variations. Figure 14.5.5 shows a design based on the piezoelectric effect for robotic applications (Fraden, 1993). The

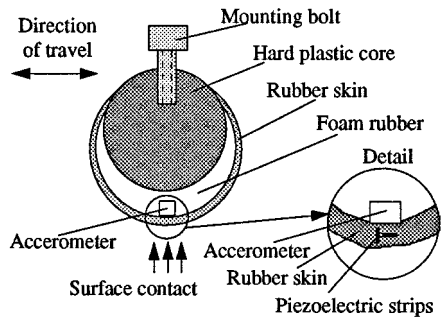

FIGURE 14.5.5 Schematic of piezoelectric sensor for a soft fingertip.

sensor includes piezoelectric strips directly interfaced with a rubber skin; thus the electric signal produced by the strips reflects movements of the elastic rubber which results from the friction forces.

Thermal Tactile Sensors

The thermal sensor (Nichols and Lee, 1989) is based on the detection of the change of thermal properties through contact of an object. The main function of the thermal sensor is to provide information about the material makeup of objects. The essential parts of each element of the thermal sensor are a heat source (such as a power transistor), a layer of material of known thermal conductivity (for example, copper) to couple the heat source to the touched object, and a temperature transducer (thermistor) to measure the contact-point temperature. The response time of the thermal sensor is relatively slow, typically in the order of several seconds. However, images representing the material constitution of the touching objects provide useful tactile data.

Force Sensors

Force sensors measure the force and represent its value in terms of an electrical signal. Examples of these sensors are strain gauges and load cells.

Strain Gauge-Based Force Sensor

A strain gauge is a resistive elastic sensor whose resistance is a function of applied strain or unit deformation. The relationship between the normalized incremental resistance and the strain is generally known as the piezoresistive effect. For metallic wire, the piezoresistance ranges from 2 to 6. For semiconductor gauges, it is between 40 and 200. Many metals can be used to fabricate strain gauges. Typical resistances vary from 100 to several thousand ohms. Strain gauges may be arranged in many ways to measure strains and are used typically with Wheatstone bridge circuits. As strain gauges are often sensitive to temperature variations, interfacing circuits or gauges must contain temperature-compensating networks.

Strain gauges are commonly used for six-degrees-of-freedom force/torque wrist sensors, force probes, flexural assemblies for force control, and micromotion detection. The Scheinman force-sensing wrist is a Maltese cross design, with one strain guage mounted on each of the 16 faces of the cross-webbings. The gauges are operated in eight voltage-divider pairs to measure distortions, and therefore forces, in six degrees of freedom in the hand coordinate system.

Other Force Sensors

Other methods include the vacuum diode force sensor, quartz force sensor, and piezoelectric force sensor. A piezoelectric sensor converts mechanical stress into an electric signal (Fraden, 1993). It is sensitive to changing stimuli only and insensitive to a constant force. As shown in Figure 14.5.6, the sensor consists of three layers where the PVDF film is laminated between a backing material (for example, silicon rubber) and a plastic film. When the PVDF is stressed, it results in a generation of electric charge

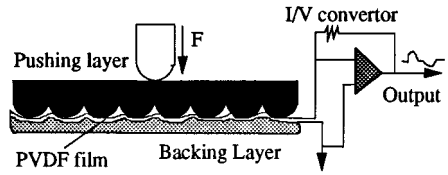

FIGURE 14.5.6 Piezoelectric force rate sensor.

flowing out of the film through a current-to-voltage (I/V) converter. The resulting output voltage is proportional to the applied force.

Figure 14.5.7 shows a typical structure fabricated by micromachining technology in a silicon wafer. As shown in the figure, the diode sensor has a cold field emission cathode, which is a sharp silicon tip, and a movable diaphragm anode. When a positive potential difference is applied between the tip and the anode, an electric field is generated which allows electrons to tunnel from inside the cathode to the vacuum. The field strength at the tip and quantity of electrons emitted (emission current) are controlled by the anode potential. When an external force is applied, the anode deflects and changes the field and the emission current.

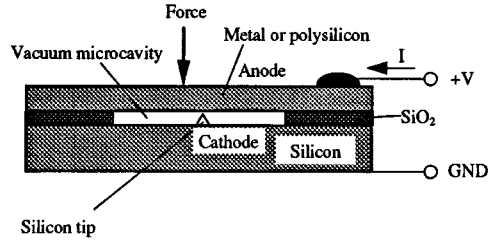

FIGURE 14.5.7 Schematic of a vacuum diode force sensor.

Figure 14.5.8 shows a quartz crystal force sensor. A quartz crystal is often used as a resonator in electrical oscillators. The basic idea behind the quartz force sensor's operation is that certain cuts of quartz crystal shift the resonant frequency when mechanically loaded.

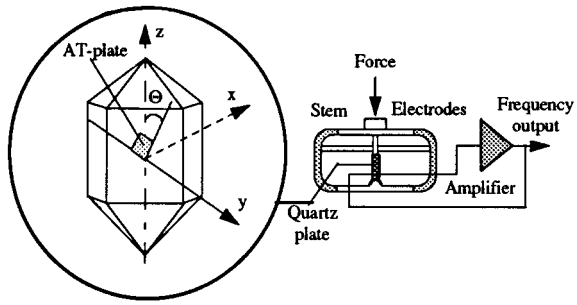

FIGURE 14.5.8 Quartz force sensor.

Vision

Many industrial tasks require sophisticated vision interpretation, yet demand low cost, high speed, accuracy, and flexibility. To be fully effective, machine vision systems must be able to handle complex industrial parts. This includes verifying or recognizing incoming parts and determining the location and orientation of the part within a short cycle time. Typical video-based vision systems conform to the RS-170 standard established in the 1950s, which defines the composite video and synchronizing signal that

the television industry uses. It specifies a standard frame rate for visual interpretation. The components required for building a video-based vision system generally include a video camera which outputs standard RS170 video signal, a frame grabber board which uses a flash analog-to-digital (A/D) converter to change the RS170 video signal into a series of n bit brightness values (gray levels) and fast memory components to store them, and a microcomputer which processes the images and computes the location and orientation of the part. See Ballard and Brown (1982) for information on vision processing techniques.

In addition to the error resulting from the timing mismatching between image acquisition hardware and the computer hardware, the RS170 video signal limits the readout of a complete frame at a rate of 30 fps (frames per second). An image of m rows by n columns has m × n *pixels* and so requires a substantial amount of memory and loading time. Among these m × n pixels, only a few carry the information on which a vision system will base a decision. This generally makes "frame grabbing" inherently wasteful.

Apart from the lack of appropriate hardware and the high equipment cost for robotic applications, a major problem often associated with the use of the RS170 video vision system is the excessive image processing time which depends on the illumination technique, the complexity of the geometry, and the surface reflectance of both the background and the objects to be handled.

Flexible Integrated Vision System

To overcome these problems, several vision systems were designed for robotic applications. Among these is a Flexible Integrated Vision System (FIVS) developed at Georgia Tech (Lee and Blenis, 1994), which offers performance and cost advantages by integrating the imaging sensor, control, illumination, direct digitization, computation, and data communication in a single unit. By eliminating the host computer and frame grabber, the camera is no longer restricted by the RS-170 standard and thus frame rate higher than 30 fps can be achieved.

Flexible Integrated Vision System Hardware. As shown in Figure 14.5.9, the central control unit of the flexible integrated vision system is a microprocessor-based control board. The design is to have all of the real-time processing performed using the microprocessor control board without relying on any other system or computer. Thus, it is desired to have the following features: (1) the microprocessor has an on-chip program memory and independent on-chip data memories. These memories must be externally expandable and accessible with zero wait states; (2) it has independent execution units which are connected by independent buses to the on-chip memory blocks. This feature provides the parallelism needed for high performance digital signal processing and high-powered computation of mathematically intensive algorithms. For these reasons, a digital signal processor (DSP) chip has been chosen.

The DSP-based control board is designed to communicate with several option boards in parallel to tailor the system for a number of applications. Each of these option boards is controlled independently by a programmable logic device (PLD) which receives a peripheral select signal, a read/write signal, and an address signal from the microprocessor control board. Typical examples of the option boards for the FIVS are the digital video head, a real-time video record/display/playback board, and an expandable memory board.

The video head consists of a m × n CCD array, the output of which is conditioned by high bandwidth amplification circuitry. The output is then sampled by a "flash" analog-to-digital converter (ADC). The DSP-based control board provides a direct software control of CCD array scanning and integration time, the intensity of the collocated illumination, and the real-time execution of a user-selectable vision algorithm imbedded in the EEPROM. In operation, the PLD decodes the control signals to initiate row shifts and column shifts in response to commands from the DSP-based control board. Particular row shifts and column shifts enable retrieving only a specific relevant area from an image. The PLD also provides control signals to ADC for performing the analog-to-digital conversion synchronized with row shifts, and enables the video buffer when the DSP reads or writes data to the VRAM.

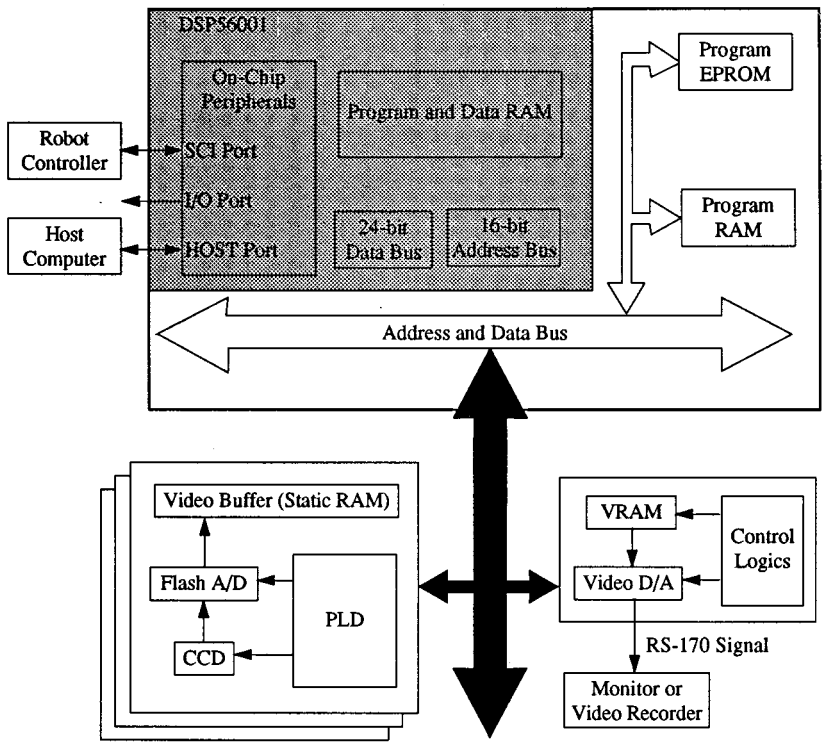

FIGURE 14.5.9 Schematic of a flexible integrated vision system.

Unlike conventional RS170-based systems which require pixel data to be stored in a video buffer before processing of pixel data can commence, the FIVS design provides an option to completely by-pass the video buffer and thus offers a means to process and/or to store the digitized pixel data by directly transferring the ADC output to the DSP. For real-time vision-based object tracking and motion control system applications, the scheme represents a significant saving in time and video buffer size required for processing an image. As an illustration, consider an image array of m × n pixels. The time needed to store the entire image (with no computation) in a memory at K MHz is (m × n)/K s and requires (m × n) bytes of memory. Typical array size of a CCD ranges from 200 × 160 to 4096 × 4096 of pixels. The corresponding video buffer and time required simply to store the entire image at a clock rate of 10 MHz would range from 32K btyes to 16 Mbytes and 3.2 to 1600 msec, respectively! Clearly, the option to completely bypass the video buffer offers a potentially usefu) solution to eliminate the frame storage prerequisite which is often required in conventional vision systems. Furthermore, this scheme completely eliminates the special hardware needed in acquiring the digitized pixel data for storage.

Flexible Integrated Vision System Imbedded Software. The vision system imbedded software includes the following functions. The first function is to give users the flexibility to control the CCD array scanning, integration time, and the intensity of the illumination. With the CCD under software control, partial frames can be “captured” instead of the customary full frame, reducing the cycle time required to capture and process an image. The ability to shift out partial frames is ideal for high-speed tracking applications where the approximate location is known from a prior image. By reducing the time to capture an image, the effective frame rate is increased. For example, shifting out 1/4 of an image can increase the frame rate up to 480 fps, not including the time required for illumination and image processing. This frame rate is 16 times the rate achievable from the RS-170 standard.

The second function is to offer an option to process the pixel data from the ADC directly without having to store the pixel data prior to processing. Although windowing process methods have been

suggested to perform object tracking under software control, these methods required that a partial window is stored before scanning can begin. The differences between the direct computation and the windowing process for object tracking are as follows: (1) in windowing process, the entire image must be stored and analyzed at least once before any subsequent windowing process can be performed in order to provide a reasonable estimate of the object location. Furthermore, if the initial field of view does not contain the object, this estimate must be repeated until an approximate area containing the object can be reasonably found. This prerequisite of storing the image is not necessary if the pixel data are directly processed; (2) after the initial estimate, a fixed window which must be sufficiently large in order to include the object in the field of view must be specified in the windowing process. In most conventional systems which output their ADC to the video buffer directly, a partial frame of the image as specified by the window must be stored. By providing a direct transfer the ADC output to the DSP and thus eliminating the windowing storing process, a significant fraction of time can be saved. This function provides an attractive feature to vision-based motion control applications.

The third function allows image processing to be performed in real time without a host computer. The algorithm that allows the user to customize the system for a specified task is preprogrammed in the EEPROM (electrically erasable programmable read only memory). Because it is impractical to preprogram every possible vision processing algorithm into the FIVS camera, it is desirable that the system can be reprogrammed easily. The main kernel provides a user interface whereby the user can customize the real-time processing for a particular task, from a library of algorithms. This function also provides an effective means to resolve software implementation issues prior to an on-line application. By previewing images of a sample part, the user may select an appropriate vision algorithm for an accurate computation of the location and orientation in real time. Once the algorithms and data are downloaded into the on-board EEPROM, the FIVS can function as an intelligent sensor and communicate directly with the robot controller without a host computer.

The fourth function, which incorporates a real-time display, allows the process controller to set up, to calibrate the vision system, or to analyze a failure mode (if any).

Illumination Considerations

Imaging sensors are characterized by their specific bandwidths or wavelengths of light which maximize the response of the sensor and will provide it an optimum operating environment. It is desired that the photodetector responds only to the light from the illumination source structured for the object but not that of ambient lighting. Otherwise, software compensation must be considered. To accomplish the objective, a typical sensor/illumination system design must consider the spectral matching of the camera imaging sensor/filter and a spectral illuminator while minimizing the effect of the ambient lighting.

Spectral Responsivity of Sensor. The two most commonly used camera imaging sensors are the charge-coupled device (CCD) and the charge injection device (CID). The CCD is responsive to wavelengths of light from below 350 nm (ultraviolet) to 1100 nm (near infrared) and has a peak response approximately at 800 nm. The CID offers a similar spectral response and has a peak spectral response about 650 nm. The relative response of a vidicon camera, however, depends significantly on the materials.

Spectral Characteristic of Typical Ambient Lighting. Depending on the spectral emissions of illumination sources used as general lighting in the factory environment, the influences of the ambient lighting can be effectively minimized or eliminated by means of spectral filtering. Gas discharge lamps generally have relatively high emission in the visible range and have little or no emission for wavelengths larger than 800 nm. Sun, tungsten lamps, and quartz-halogen-type lamps have a wide spectral emission.

Illumination Source. The spectral characteristics of three different spectral sources, namely, laser diodes, light-emitting diode (LED), and xenon strobes, are of particular interest since the spectral wavelengths of these sources well match the optimal response of the CCD and/or CID detectors. Pulsed GaAlAs laser diodes emit single frequency power in the 790- to 850-nm wavelength range. Irradiance at spectral wavelength in the range of 810 to 830 nm can also be produced from a xenon lamp. An

TABLE 14.5.2 Comparison Between Three Spectral Light Sources

Source	Wavelength (nm)	Unit cost (US $)	Life	Power
LED	570–630	1.00	5,000,000 hours (MTBF)	100 mW
Laser diode	790–840	200.00	250,000 hours (MTTF)	1 W (peak pulse power)
Xenon flashtubes	830–1000	10.00	1,000,000 flashes (0.3–4 flashes/sec)	25 W (500 V nominal)

AlGaAs LED is designed to concentrate the luminous flux into a narrow radiation pattern to achieve a narrow high peak intensity. A comparison of these sources is provided in Table 14.5.2.

Object and Background Reflectance. If the orientation of the parts can be characterized by the two-dimensional object silhouette and the environment can be structured, back lighting can be used to create silhouettes of the object. Alternatively, retroreflective materials (Lee and Blenis, 1994) can be used to create a unique background. Since most of the incident illuminance from the object is reflected or diffused away from the aperture, whereas that on the background surface is retroreflected, the object appears as a dark silhouette against a reliable bright-field background.

Retroreflective materials can be used as background in part presentation or as a landmark on parts. The choice clearly depends on the part design and manufacturing process. The most common retroreflective surface is in the form of sheeting due to its reliability and ease of application. Flexible retroreflective sheeting is made of countless microcube-corners or spheres enclosed in a weather-resistant transparent plastic film. Pigment or dye can be inserted into the film or the reflecting surface to reflect color. Four typical retroreflective sheetings are described as follows: (1) cube-corner retroreflective sheeting, (2) exposed glass beads, (3) enclosed glass beads, and 4) encapsulated glass beads. A detailed study of retroreflective sensing for robotic applications is given by Lee and Li (Lee and Blenis, 1994).

Vision Algorithms for Robotic Applications

Figure 14.5.10 illustrates a vision system for robotic part pickup applications (see also Section 14.9). Here the camera is mounted along with the gripper on the end effector mount of the robot. This allows complete freedom in positioning and orienting the camera for viewing. Placing the camera on the last link of a six-DOF robot enables the machine vision to view objects (parts) individually. The camera is oriented so that its line of sight is perpendicular to the plane on which the part is placed. However, at each position, the 3D position and orientation of the feature measured by the vision system are only relative to the vision sensor. The robot is driven by sensory information from the vision system as well as inputs from the off-line calibration.

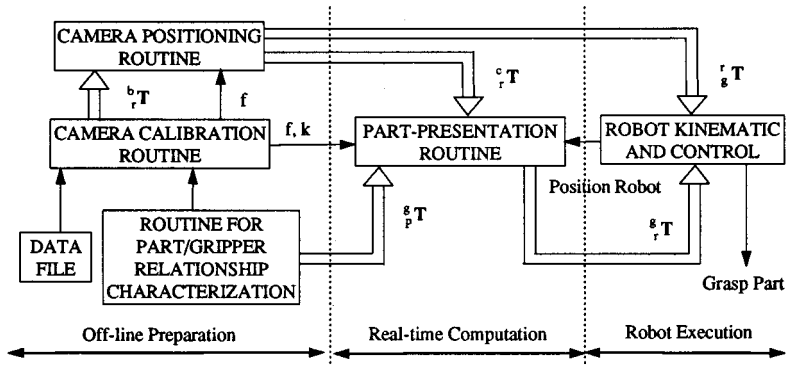

FIGURE 14.5.10 Vision system for robotic applications.

Thus, the basic components of the vision system for robotic part pickup include (1) system calibration, (2) image segmentation and feature extraction, and (3) communication protocol.

System Calibration. In order to determine the 3D position and orientation of the feature with respect to robot world coordinate, it is necessary to calibrate the relative homogeneous transformation between the two coordinate frames, one centered at the camera and the other at the gripper. Thus, the system calibration is to establish the relationship between the 3D world coordinates as seen by the robot and their corresponding 2D image coordinates as seen by the computer. The calibration algorithm consists of off-line calibrating the intrinsic parameters of the camera and the camera-gripper relationship and on-line calibrating the pallet location. The camera calibration technique originally established by Tsai and Lenz (1989) has been the basis for several later calibration routines.

Image Segmentation and Feature Extraction. Most existing industrial-vision systems and algorithms extract features from industrial objects against a high contrast background with controlled lighting. The processing of feature extraction usually begins by generating a binary image from the original gray-scale image by choosing an appropriate threshold. To eliminate noise caused by electromagnetic interference, and ignoring the other objects in the field of view, image segmentation is performed before the computation of the part location and orientation. An image segmentation algorithm is written to locate regions of pixels that are connected and to label each region (object) so that it can easily be picked out from the other regions in the image. After segmentation is complete, only the largest object in the image is examined for its features.

There are many practical methods for the identification of a given object in a scene. A part-recognition system consists of three major components, namely, feature extraction, object modeling, and matching. Most industrial parts-recognition systems are model-based systems in which recognition involves matching the input image with a set of predefined models of part. Models based on geometric properties of an object's visible surfaces or silhouette are commonly used because they describe objects in terms of their constituent shape features. Image features such as edge, corner, line, curve, hole, and boundary curvature define individual feature components of an image. Given a set of models that describes all aspects of all parts to be recognized, the process of model-based recognition consists of matching features extracted from a given input image with those of the models. There are many practical methods for identification of a given object in a scene. A tutorial on binary image processing for robot-vision applications is given by Kitchin and Pugh (1983). A more general comparative study of model-based object-recognition algorithms for robot vision is described by Chin and Dyer (1986).

Communication Protocol. To ensure data integrity during communications, DEC's Digital Data Communications Message Protocol (DDCMP) is used for communications with the vision system. DDCMP is an industrial standard communication protocol that is used to communicate with industrial robots. DDCMP ensures a reliable communications link with a minimum amount of overhead. DDCMP precedes all data transmissions with a header block describing the type of message and the length of any message data that follows.

Actuators

Actuators used for robotic manipulators can be broadly classified as follows: (1) electromechanical actuators, (2) fluid power actuators, and (3) new alternative actuators. Table 14.5.3 summarizes a further subdivision based on their operating principles. The choice of actuators for robotic applications depends on specific tasks. Relative comparisons to guide selection of common actuators are given in Table 14.5.4 and Figure 14.5.11, which shows the force vs. speed comparison for common actuators.

Direct-Drive Joint Motor

The direct-drive joint motor has been developed to eliminate the transmission mechanism between the motor and the links, thus eliminating friction and backlash introduced by gear motors. This results in an arm suitable for high-speed, fine torque control. A direct, drive design also allows for elegant

TABLE 14.5.3 Lower Power Actuator Principles

Electro-mechanical	Fluid power	Alternative concepts
Direct Current (DC) motor	Hydraulic actuators	Piezoelectric
Alternating Current (AC) motor	Pneumatic actuators	Magnetostrictive
Stepper motor		Electrochemical
Electromagnetic		Thermo-bimetal
Linear motor		Shape Memory Alloy
		Electrostatic

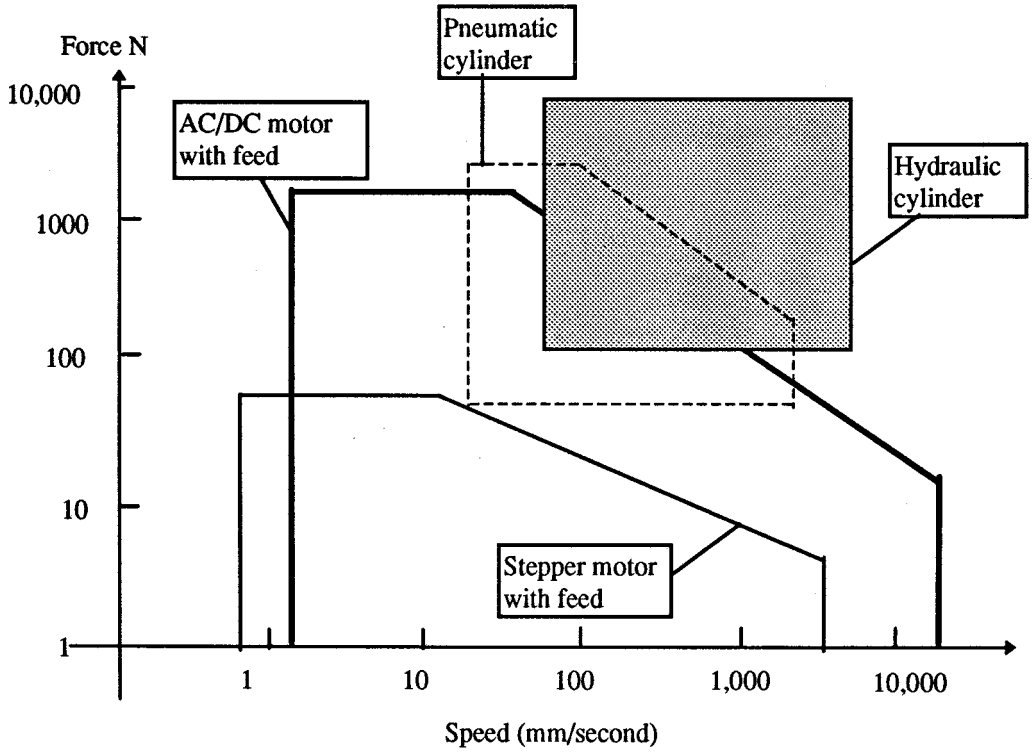

FIGURE 14.5.11 Force vs. speed for common actuators.

mechanical construction. All of the joints in a direct-drive arm are essentially identical in structure, consisting of a motor, a shaft encoder, bearings, and a housing. These components are mounted on a single shaft; a single bearing is used in the entire joint assembly. As a result, a direct drive joint generally has few but compact and more easily manufactured components than a gear-driven joint, an attractive feature for commercial production of arms.

Shape Memory Alloy (SMA) Wire

The properties of the shape memory alloy are associated with appearance and disappearance of martensite in the alloy structure. There are two kinds of martensites, namely, thermal martensite which is generated by cooling the shape memory alloy below martensite transition temperature, and stress-induced martensite which is generated by loading the stress on a shape memory alloy having an austenite structure. Shape memory effect (SME) is associated with the former, and superconductivity (SE) is associated with the latter. By making use of SME and SE, it is possible to use the shape memory alloy as an element of the actuator of a joint mechanism as shown in Figures 14.5.12 and 14.5.13. In Figure 14.5.12, mass 1 is driven toward the right side by heating the SMA wire A and cooling SMA wire B. Similarly, by reversing the direction of the heating and cooling, mass 1 can be made to move toward the left. An alternative SMA wire-actuated revolute joint using an ordinary spring is shown in Figure 14.5.13. The shape memory alloy joint mechanism has the advantage of being light in weight and simple. However, it generally has a relatively low efficiency and is slow in response.

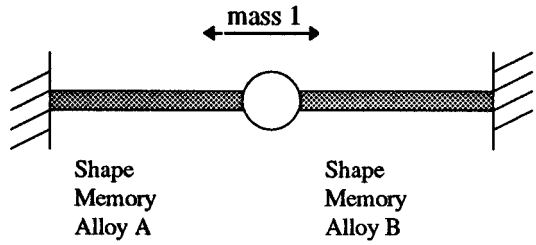

FIGURE 14.5.12 Model illustrating SME wire for joint mechanism.

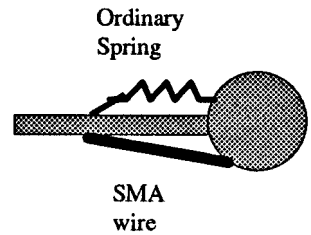

FIGURE 14.5.13 Schematic illustrating SME wire for revolute joint.

An increasing need for high performance robotic applications has motivated several researchers to direct their investigation efforts to new actuator concepts. In some applications such as high-speed plasma, water-jet and laser cutting, active joystick, and coordinate-measuring machines, the demands on workspace and the wrist force/torque are low, but the end effector must be oriented quickly, continuously, and isotropically in all directions. The performance of the popular three-consecutive-rotational-joints wrist, which possesses singularities within its workspace, is less than optimum. Several alternative designs have been developed, which present some attractive possibilities by combining pitch, roll, and yaw motion in single balljoint-like actuators. Among these design concepts are the spherical induction motor, the DC spherical servo motor, and the variable-reluctance (VR) spherical motor. Major developments for robotics are given as follows.

Spherical Induction Motor

In a spherical induction motor, three sets of windings are necessary to realize rotation about an arbitrary axis. The three windings are positioned to give rotations about the x, y, and z axes. By independently controlling the strength and phase of any two windings, one can realize a rotation vector at any point in the rotation plane of the two windings. Analyses of fields and torques in the spherical induction motor have been performed; however, realization of a prototype spherical induction motor remains to be

demonstrated. The mechanical design of a spherical motor is complex. Laminations are required to prevent unwanted eddy currents. Complicated three-phase windings must be mounted in recessed grooves in addition to the rolling supports for the rotor in a static configuration.

Spherical DC Servo Motor

The rotor of a spherical DC servo motor is a disk comprising a yoke with four permanent magnets attached to its periphery. The pivot bearing is constructed of three small radial ball bearings and has three DOF. Therefore, the rotor can incline and rotate around the three axes of Cartesian coordinates relative to the stator. The inclined and rotated angles are detected by rotary encoders attached to each axis. Three sets of windings are set at 30° apart around the z axis such that four electromagnetic force vectors can be obtained at the locations where the currents intersect the magnetic flux. They are controlled like three separated brushless motors. Although the DC spherical motor is characterized by its constructional simplicity, the range of inclination and the torque constant are rather limited.

Variable-Reluctance (VR) Spherical Motor

The structure of a VR spherical motor is shown in Figure 14.5.14, which consists of three subassemblies: a rotor, a stator, and a measuring system. The rotor is a smooth sphere in which m magnetic poles are embedded. The stator is a hollow sphere with n stator coils radially mounted on its inner surface. It also serves as a structure that holds together all the other functional elements which include the stator coils, the bearing, and the measurement system.

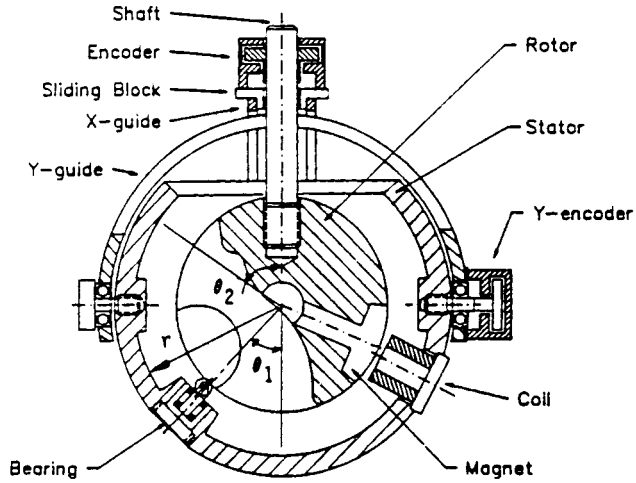

FIGURE 14.5.14 Schematic illustrating VR spherical motor.

In the operation of the VR spherical motor, the stator coils are energized individually using the control circuitry. A magnetic field is established which stores magnetic energy in the airgaps. The stored energy is a function of the relative position of the rotor and the stator. The motion of the spherical motor is thus generated as the rotor tends to move to a position such that the energy in the airgap is minimized. The VR spherical motor is characterized by the following features: (1) it offers a potential advantage of distributing the input power among several coils, each of which contributes a small fraction of the total mmf's required to generate a specified torque, and, thus, it allows a relatively low current per coil but a large surface area for heat dissipation; (2) there are multiple solutions to the selection of coil excitations, which allow an optimal electrical input vector to be chosen to minimize a preselected cost function.

As compared to its counterpart, a VR spherical motor has a relatively large range of inclination, possesses isotropic properties in motion, and is relatively simple and compact in design. The tradeoff, however, is that a sophisticated control scheme is required.

Multi-DOF Microactuators

Silicon exhibits very useful mechanical properties and its applications to microsensors and actuators have been extensively researched around the world. The fabrication of silicon-based components typically employs micromachining. Thin film and photolithographic fabrication procedures make it possible to realize a great variety of extremely small, high precision mechanical structures using the same processes that have been developed for electronic circuits. This technology has enabled the realization of many innovative microactuators operating on the basis of electrostatic to mechanical transduction.

14.6 Robot Programming Languages

Ron Bailey

The earliest industrial robots were simple sequential machines controlled by a combination of servo motors, adjustable mechanical stops, limit switches, and programmable logic controllers. These machines were generally programmed by a record and play-back method with the operator using a teach pendant to move the robot through the desired path. MHI, the first robot programming language, was developed at MIT during the early 1960s. It was an interpreted language which ran on a TX-O computer. WAVE, developed at Stanford during the early 1970s, was a general-purpose language which ran as an assembler on a DEC PDP-10 minicomputer. MINI, developed at MIT during the mid-1970s, was an expandable language based on LISP. It allowed programming in Cartesian coordinates with independent control of multiple joints. AL (Mujtaba, 1982), developed at Stanford, included some programming features of ALGOL and Pascal. VAL and VAL II (Shimano et al., 1984), developed by Unimation, Inc., was an interpreted language designed to support the PUMA series of industrial robots.

AML (A Manufacturing Language) (Taylor et al., 1982) was a completely new programming language developed by IBM to support the R/S 1 assembly robot. It was a subroutine-oriented, interpreted language which ran on the Series/1 minicomputer. Later versions were compiled to run on IBM-compatible personal computers to support the 7535 series of SCARA robots. MCL, developed by McDonnell Douglas, was an extension of the *APT* language (Automatic Programming of Tools) originally written for numerically controlled machine tools. RAIL, developed by AUTOMATIX, Inc., was an extension of Pascal designed to control robot welding and vision systems. Several additional languages (Gruver et al., 1984; Lozano-Perez, 1983) were introduced during the late 1980s to support a wide range of new robot applications which were developed during this period.

V+, developed by Adept Technologies, Inc., is a representative modern robot programming language. It has several hundred program instructions and reserved keywords. V+ will be used in the following sections to demonstrate important features of robot programming.

Robot Control

Program instructions required to control robot motion specify location, trajectory, speed, acceleration, and obstacle avoidance. Examples of V+ robot control commands are as follows:

MOVE	Move the robot to a new location
APPRO	Move to a location set back from a named position
DEPART_	Back away from the current location
DELAY	Stop the motion for a specified period of time
SPEED	Set the speed for subsequent motions
ACCEL	Set the acceleration and deceleration for subsequent motions
SINGLE	Limit motion of a joint
MULTIPLE	Allow full motion of the wrist joints
OPEN_	Open the hand
CLOSE_	Close the hand
RELAX_	Turn off air pressure to the hand

System Control

In addition to controlling robot motion, the system must support program editing and debugging, program and data manipulation, program and data storage, program control, system definitions and control, system status, and control/monitoring of external sensors. Examples of V+ control instructions are as follows:

EDIT	Initiate line-oriented editing
SEE	Initiate screen-oriented editing

STORE_	Store information from memory onto a disk file
LOAD	Read the contents of a disk file into memory
COPY	Copy an existing disk file into a new program
SPEED	Set the overall speed of robot motions
EXECUTE	Initiate execution of a program
ABORT	Stop program execution
DO	Execute a single program instruction
WATCH	Set and clear breakpoints for diagnostic execution
WHERE	Display current robot location
TEACH	Define a series of robot location variables
CALIBRATE	Initiate the robot positioning system
STATUS	Display the status of the system
TIME	Set and display current date and time
ENABLE	Turn on one or more system switches
DISABLE	Turn off one or more system switches

Structures and Logic

Program instructions are needed to organize and control execution of the robot program and interaction with the user. Examples include the following:

FOR	Execute a group of instructions a number of times
WHILE	Continue execution of a group of instructions until a condition is satisfied
DO	Execute a group of instructions until a condition is satisfied
IF	Control whether a group of instructions is executed
TYPE	Output a message to the terminal
ATTACH	Make the control pendant active
WRITE	Output a message to the manual control pendant
PENDANT	Receive input from the manual control pendant
PARAMETER	Set the value of a system parameter

Special Functions

Various special functions are required to facilitate robot programming. These include mathematical expressions and instructions for data conversion, manipulation, and transformation. Examples are as follows:

ABS	Absolute value
COS	Cosine function
SQRT	Square root
BCD	Convert from real to Binary Coded Decimal
DCB	Convert from binary to real
FRAME	Compute the reference frame based on given locations
TRANS	Compose a transformation from individual components
INVERSE	Return the inverse of the specified transformation

Program Execution

Organization of a program into a sequence of executable instructions requires scheduling of tasks, control of subroutines, and error trapping/recovery. Examples include the following:

PCEXECUTE	Initiate the execution of a process control program
PCABORT	Stop execution of a process control program

PCPROCEED	Resume execution of a process control program
PCRETRY	After an error, resume execution at the last step tried
PCEND	Stop execution of the program at the end of the current execution cycle

Example Program

This program demonstrates a simple pick and place operation.

```
 1  .PROGRAM move.parts()
 2  ; Pick up parts at location “pick” and put them down at “place”
 3  parts = 100                          ; Number of parts to be processed
 4  height1 = 25                         ; Approach/depart height at “pick”
 5  height2=50;
    Approach/depart height at “place”
 6  PARAMETER.HAND.TIME = 16             ; Setup for slow hand
 7  OPEN                                 ; Make sure hand is open
 8  MOVE start                           ; Move to safe starting location
 9  For i = 1 TO parts                   ; Process the parts
10  APPRO pick, height1                  ; Go toward the pick-up
11  MOVES pick                           ; Move to the part
12  CLOSEI                               ; Close the hand
13  DEPARTS height1                      ; Back away
14  APPRO place, height2                 ; Go toward the put-down
15  MOVES place                          ; Move to the destination
16  OPENI                                ; Release the part
17  DEPARTS height2                      ; Back away
18  END                                  ; Loop for the next part
19  TYPE “ALL done.”, /I3, parts, “parts processed”
20  STOP                                 ; End of the program
21  .END
```

Off-Line Programming and Simulation

Computer-integrated manufacturing operations require off-line programming and simulation in order to layout production facilities, model and evaluate design concepts, optimize motion of devices, avoid interference and collisions, minimize process cycle times, maximize productivity, and ensure maximum return on investment. Commercially available software (e.g., ROBCAD and SILMA [SILMA Inc., 1992]) provides support for 3D workable layouts including robots, end effectors, fixtures, conveyors, part positioners, and automatic guided vehicles. Dynamic simulation allows off-line creation, animation, and verification of robot motion programs. However, these techniques are limited to verification of overall system layout and preliminary robot program development. With support for data exchange standards (e.g., *IGES* [International Graphics Exchange Specification], *VDAFS* [Virtual Data Acquisition and File Specification], *SET* [Specification for Exchange of Text]), these software tools can pass location and trajectory data to a robot control program which, in turn, must provide the additional functions (operator guidance, logic, error recovery, sensor monitoring/control, system management, etc.) required for full operation.

14.7 Robot Dynamics and Control

Frank L. Lewis

This section deals with the real-time motion control of robot manipulators. In Section 14.8 are covered higher-level planning and control functions, including the generation of the prescribed trajectory that is assumed given in this section. Robot manipulators have complex nonlinear dynamics that might make accurate and robust control difficult. Fortunately, robots are in the class of Lagrangian dynamical systems, so that they have several extremely nice physical properties that make their control straightforward. In this section will be discussed several control techniques including computed torque (e.g., *feedback linearization*), classical joint control, digital control, *adaptive control*, *robust control*, *learning control*, *force control*, and teleoperation. More information may be found in Lewis et al. (1993). The advances that made possible this modern approach to robot control were made by Craig (1985), Slotine and Li (Slotine, 1988), Spong and Ortega (Spong and Vidyasagar, 1989), and others.

Robot Dynamics and Properties

A robot manipulator can have either revolute joints or prismatic joints. The latter are actuators that function like an automobile antenna, extending and contracting on a linear axis. The values of the angles, for revolute joints, and link lengths, for prismatic joints, are called the link variables, and are denoted $q_1(t)$, $q_2(t)$, …, $q_n(t)$ for joints one, two, and so on. The number of links is denoted n; for complete freedom of motion in space, six degrees of freedom are needed, three for positioning and three for orientation. Thus, most commercial robots have six links. We discuss here robots which are rigid, that is which have no flexibility in the links or in the gearing of the joints; flexible robots are discussed in the section on control of flexible-link and flexible-joint robots.

The dynamics of robot manipulators with rigid links can be written as

$$M(q)\ddot{q} + V_m(q,\dot{q})\dot{q} + F(\dot{q}) + G(q) + \tau_d = \tau \tag{14.7.1}$$

where $M(q)$ is the inertia matrix, $V_m(q,\dot{q})$ is the coriolis/centripetal matrix, $F(\dot{q})$ are the friction terms, $G(q)$ is the gravity vector, $\tau_d(t)$ represents disturbances, and $\tau(t)$ is the control input torque. The joint variable $q(t)$ is an n-vector containing the joint angles for revolute joints and lengths for prismatic joints. It is often convenient to write the robot dynamics as

$$M(q)\ddot{q} + N(q,\dot{q})\dot{q} + \tau_d = \tau \tag{14.7.2}$$

$$N(q,\dot{q}) \equiv V_m(q,\dot{q})\dot{q} + F(\dot{q}) + G(q) \tag{14.7.3}$$

where $N(q,\dot{q})$ represents a vector of the nonlinear terms.

The objective of robot control is generally to select the control torques $\tau(t)$ so that the robot follows a desired prescribed motion trajectory or exerts a desired force. Examples include spray painting, grinding, or manufacturing assembly operations. The position control objective can be achieved by first defining a desired trajectory $q_d(t)$, which is a vector containing the desired values vs. time $q_{d_i}(t)$ of each of joint of the manipulator. This desired trajectory vector $q_d(t)$ is determined in a higher-level *path planner*, based on a even higher-level task decomposition, and then fed to the real-time motion control system. This section discusses the real-time motion control problem assuming that $q_d(t)$, or a similar desired force vector, is given.

The robot dynamics in Equation (14.7.1) satisfies some important physical properties as a consequence of the fact that they are a Lagrangian system. These properties significantly simplify the robot control problem. The main properties of which one should be aware are the following.

Properties of Robot Arm Dynamics

P1 The inertia matrix $M(q)$ is symmetric, positive definite, and bounded so that $\mu_1 I \le M(q) \le \mu_2 I$ for all $q(t)$. For revolute joints, the only occurrences of the joint variables q_i are as $\sin(q_i)$, $\cos(q_i)$. For arms with no prismatic joints, the bounds μ_1, μ_2 are constants.

P2 The coriolis/centripetal vector $V_m(q,\dot{q})\dot{q}$ is quadratic in $\dot{q}$ and bounded so that $\|V_m\dot{q}\| \le v_B\|\dot{q}\|^2$.

P3 The coriolis/centripetal matrix can always be selected so that the matrix $\dot{M}(q) - 2V_m(q,\dot{q})$ is *skew symmetric*. This is a statement of the fact that the fictitious forces in the robot system do no work.

P4 The friction terms have the approximate form $F(\dot{q}) = F_v\dot{q} + F_d(\dot{q})$, with F_v a diagonal matrix of constant coefficients representing the viscous friction, and $F_d(\cdot)$ a vector with entries like $K_{d_i}\,\mathrm{sgn}(\dot{q}_i)$, with $\mathrm{sgn}(\cdot)$ the signum function, and K_{d_i} the coefficients of dynamic friction. These friction terms are bounded so that $\|F(\dot{q})\| \le v_B\|\dot{q}\| + k_B$ for constants v_B, k_B.

P5 The gravity vector is bounded so that $\|G(q)\| \le g_B$. For revolute joints, the only occurrences of the joint variables q_i are as $\sin(q_i)$, $\cos(q_i)$. For revolute joint arms the bound g_B is a constant

P6 The disturbances are bounded so that $\|\tau_d(t)\| \le d$.

P7 The nonlinear robot terms are *linear in the parameters* of mass and friction so that one can write

$$M(q)\ddot{q} + V_m(q,\dot{q})\dot{q} + F(\dot{q}) + G(q) = W(q,\dot{q},\ddot{q})\phi \tag{14.7.4}$$

where $W(q,\dot{q},\ddot{q})$ *is* a matrix of known robot functions and ϕ is a vector of mass and friction coefficient parameters, often unknown. The *regression matrix* $W(\cdot)$ can be computed for any specified robot arm.

The last property, P7, is especially useful in adaptive control approaches. The bounding properties are especially useful in robust control approaches. The *skew-symmetry* property P3 is vital for Lyapunov control proofs, which provide guaranteed tracking motion and often give the structure of the control loops. It essentially allows some very nice *linear systems techniques* to be used with the time-varying robot dynamics.

State Variable Representations and Computer Simulation

The nonlinear state-variable representation $\dot{x} = f(x, u)$, with $x(t)$ the internal state and $u(t)$ the control input, is very convenient for many applications, including the derivation of suitable control laws and computer simulation. Once the system has been put into state-space form, it can easily be integrated to obtain simulation time plots using, for instance, a Runge-Kutta integrator; many standard software packages have such integration routines, including MATLAB, MATRIX$_X$, and SIMNON.

It is supposed for convenience in this subsection that the disturbance $\tau_d(t)$ is equal to zero. There are three convenient state-space formulations for the robot dynamics in Equation (14.7.1). In the *position/velocity state-space form*, one defines the state as the $2n$-vector $x \equiv [q^T\ \dot{q}^T]^T$ and writes

$$\dot{x} = \begin{bmatrix} \dot{q} \\ -M^{-1}(q)N(q,\dot{q}) \end{bmatrix} + \begin{bmatrix} 0 \\ M^{-1}(q) \end{bmatrix} \tag{14.7.5}$$

which is in state-space form with $u(t) \equiv \tau(t)$.

For computer simulation purposes, the matrix inversion $M^{-1}(q)$ is required at every integration time step. For arms with simple dynamics, it is often possible to invert the inertia matrix analytically off-line, reducing the on-line computational burden. Otherwise, it is more suitable to solve Equation (14.7.2) for $\ddot{q}$, required by the integration routine, using least-squares techniques to avoid the inversion of $M(q)$.

An alternative *linear* state-space equation in the form $\dot{x} = Ax + Bu$ can be defined as

$$\dot{x} = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ I \end{bmatrix} u \tag{14.7.6}$$

with $u(t) \equiv -M^{-1}(q)\, N(q,\dot{q}) + M^{-1}(q)\tau$. This is known as the *Brunovsky Canonical Form.*

The third state-space formulation is the *Hamiltonian form,* which derives from Hamilton's equations of motion. Here the state is defined as the $2n$-vector $x = (q^T\ p^T)^T$, with $p(t) \equiv M(q)\dot{q}$ the *generalized momentum*. Then the state-space equation is

$$\dot{x} = \begin{bmatrix} M^{-1}(q)\, p \\ -\frac{1}{2}\left(I_n \otimes p^T\right)\frac{\partial M^{-1}(q)}{\partial q}\, p \end{bmatrix} + \begin{bmatrix} 0 \\ I_n \end{bmatrix} u \tag{14.7.7}$$

with the control input defined by $u = \tau - G(q)$ and $\otimes$ the Kronecker product (Lewis et al., 1993).

Cartesian Dynamics and Actuator Dynamics

Cartesian Dynamics

The dynamics in Equation (14.7.1) are known as the *joint-space dynamics*; they are expressed in the joint-space coordinates q. Cartesian coordinates referred to some frame, often the base of the robot manipulator, may be used to describe the position of the end effector of the robot arm. Denote the Cartesian coordinates of the end of the arm as $Y(t) = h(q)$, whose first three coordinates represent position and last coordinates represent orientation. The nonlinear function $h(q)$ gives the end effector Cartesian coordinates in termexcepts of the current joint positions q and is called the arm *kinematics transformation.* The *arm Jacobian* relates joint and Cartesian velocites and is defined as $J(q) \equiv \partial h(q)/\partial q$ so that

$$\begin{bmatrix} v \\ \omega \end{bmatrix} \equiv \dot{Y} = J(q)\dot{q} \tag{14.7.8}$$

where $v(t)$ is the linear velocity and $\omega(t)$ the angular velocity of the end effector. Both these velocities are 3-vectors. Differentiating this equation gives the *acceleration transformation* $\ddot{Y} = J\ddot{q} + \dot{J}\dot{q}$.

By differentiating Equation (14.7.1) one discovers that the dynamics may be written in Cartesian form as

$$\overline{M}\ddot{Y} + \overline{N} + f_d = F \tag{14.7.9}$$

where $\overline{M} \equiv J^{-T}MJ^{-1}$, $\overline{N} \equiv J^{-T}(N - MJ^{-1}\,\dot{J}\,J^{-1}\,\dot{y}\,)$, and the disturbance is $f_d \equiv J^{-T}\tau_d$. In the Cartesian dynamics the control input is F, which has three components of force and three of torque.

The important conclusion of this discussion is that the Cartesian dynamics are of the same form as Equation (14.7.2). Furthermore, it can be shown that the properties of the robot dynamics hold also in Cartesian form. Therefore, all the control techniques to be described in this section can be used for either the joint-space or the Cartesian dynamics.

Actuator Dynamics

The robot manipulator is driven by actuators which may be electric, hydraulic, pneumatic, and so on. Considering the case of electric motors it is direct to show that if the armature inductance is negligible, the dynamics of the arm plus actuators can be written as

$$\left(J_M + R^2M\right)\ddot{q} + \left(B_M + R^2V_m\right)\dot{q} + \left(RF_M + R^2F\right) + R^2G = RK_M v \tag{14.7.10}$$

where the robot arm dynamics are described by $M(q)$, $V_m(q,\dot{q})$, $F(\dot{q})$, $G(q)$, and J_M is the motor inertia, B_M is given by the rotor damping constant and back emf, and R has diagonal elements containing the

gear ratios of the motor/joint couplings. The control input is the motor voltage $v(t)$, with K_M the diagonal matrix of motor torque constants.

The important conclusion is that the dynamics of the arm-plus-actuators has the same form as the dynamics (Equation (14.7.1) and can be shown to enjoy the same properties of boundedness and linearityin-the-parameters. Therefore, the control methods to be described herein apply to this composite system as well. Similar comments hold for other sorts of actuators such as hydraulic. If the armature inductances of the electric motors are not negligible, then the arm-plus-actuators have a coupled form of dynamics such as those discussed in the section on control of flexible-link and flexible-joint robots. Then special control techniques must be used.

Computed-Torque (CT) Control and Feedback Linearization

For many years during the 1960s and 1970s the major techniques for robot dynamics control were based on the *computed-torque method*, which has many variants, including classical independent joint control. Recently, advanced mathematical techniques based on *feedback linearization* have been derived. For the rigid-link arms, these are equivalent.

It is assumed that the desired motion trajectory for the manipulator $q_d(t)$, as determined, for instance, by a path planner, is prescribed. Define the *tracking error* as

$$e(t) = q_d(t) - q(t) \tag{14.7.11}$$

and differentiate twice to see that the Brunovsky canonical form in Equation (14.7.6) can be written in terms of the state $x = [e^T \ \dot{e}^T]^T$ as

$$\frac{d}{dt}\begin{bmatrix} e \\ \dot{e} \end{bmatrix} = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix}\begin{bmatrix} e \\ \dot{e} \end{bmatrix} + \begin{bmatrix} 0 \\ I \end{bmatrix} u \tag{14.7.12}$$

with

$$u \equiv \ddot{q}_d + M^{-1}(q)\left(N(q,\dot{q}) - \tau\right) \tag{14.7.13}$$

A two-step design procedure now suggests itself. First, use linear system design techniques to select a feedback control $u(t)$ that stabilizes the tracking error system in Equation (14.7.12), then compute the required arm torques using the inverse of Equation (14.7.13), namely,

$$\tau = M(q)\left(\ddot{q}_d - u\right) + N(q,\dot{q}) \tag{14.7.14}$$

This is a *nonlinear feedback control law* that guarantees tracking of the desired trajectory. It relies on computing the torque τ that makes the nonlinear dynamics of Equation (14.7.1), equivalent to the linear dynamics of Equation (14.7.12), which is termed *feedback linearization.*

Selecting proportional-plus-derivative (PD) feedback for $u(t)$ results in the *PD computed-torque controller*

$$\tau = M(q)\left(\ddot{q}_d + K_v\dot{e} + K_p e\right) + N(q,\dot{q}) \tag{14.7.15}$$

and yields the tracking error dynamics $\ddot{e} = -K_v\dot{e} - K_p e$, which is stable as long as the derivative gain matrix K_v and the proportional gain matrix K_p are selected positive definite. It is common to select the gain matrices diagonal, so that stability is ensured as long as all gains are selected positive.

The PD computed-torque controller is shown in Figure 14.7.1, which has a *multiloop structure*, with a nonlinear inner feedback linearization loop and an outer unity-gain tracking loop. Note that there are actually n outer loops, one for each joint. In this figure, $\underline{q} \equiv [q^T \ \dot{q}^T]^T$, $\underline{e} \equiv [e^T \ \dot{e}^T]^T$, $\underline{q}_d \equiv [q_d^T \ \dot{q}_d^T]^T$.

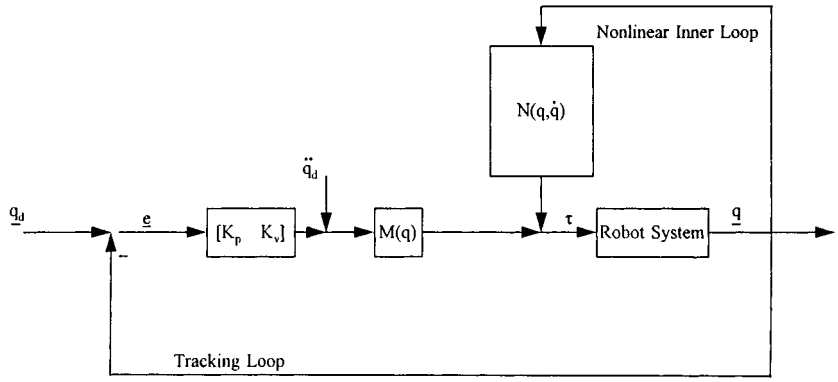

FIGURE 14.7.1 PD computed-torque controller.

To improve steady-state tracking errors, n integrators can be added, one to each joint controller, to place an integrator in the outer tracking loop in the figure. In fact, selecting $u(t)$ *as* a proportional-plus-integral-plus-derivative controller yields the *PID computed-torque controller*

$$\begin{aligned} \dot{\varepsilon} &= e \\ \tau &= M(q)\left(\ddot{q}_d + K_v\dot{e} + K_p e + K_i\varepsilon\right) + N(q,\dot{q}) \end{aligned} \tag{14.7.16}$$

which has its own dynamics and gives stable tracking as long as the integral gain K_i is not chosen too large.

Example 14.7.1 (Performance of PD and PID Computed-Torque Controllers)

The sort of performance to be expected from PD and PID CT controllers is illustrated here. It is desired for a 2-link robot arm to follow, in each of its joints, sinusoidal trajectories $q_d(t)$ with period of 2 sec.

Ideal PD CT Control. Since CT is theoretically an exact cancellation of nonlinearities, under ideal circumstances the PD CT controller yields performance like that shown in Figure 14.7.2, where the initial tracking errors go to zero quickly, so that each joint perfectly tracks its prescribed trajectory. In this figure are shown the plots for joint 1 tracking error $e_1(t)$ and joint 2 tracking error $e_2(t)$.

PD CT Control with Constant Unknown Disturbance. Now a constant unknown disturbance is added to the robot arm. As shown in Figure 14.7.3, the PD controller now exhibits steady-state tracking errors of $e_1 = -0.01$ rad, $e_2 = 0.035$ rad.

PID CT Control. If an integral term is now added to the outer loop to achieve PID CT control, even with a constant unknown disturbance, the simulation results look very much like the original plots in Figure 14.7.2; that is, the integral term has reduced the steady-state tracking errors to zero. □

A class of computed torque-like controllers is given by selecting

$$\tau = \hat{M}\left(\ddot{q}_d - u\right) + \hat{N} \tag{14.7.17}$$

where $\hat{M}, \hat{N}$ are approximations, estimates, or simplified expressions for $M(q)$, $N(q,\dot{q})$. An example is the *PD-gravity controller*

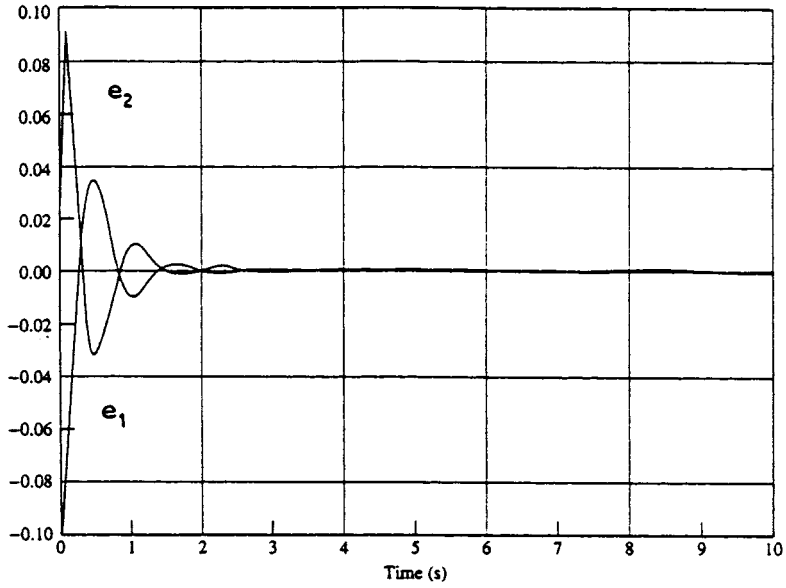

FIGURE 14.7.2 Joint tracking errors using PD computed-torque controller under ideal conditions.

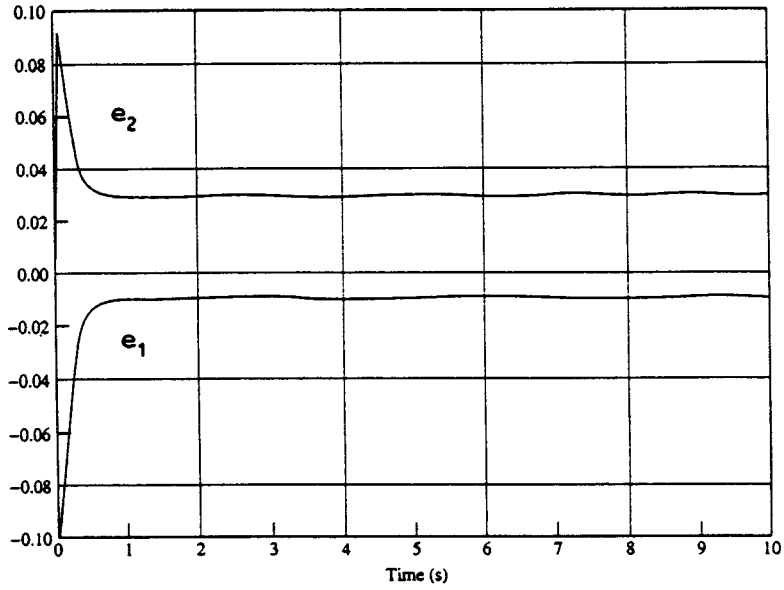

FIGURE 14.7.3 Joint tracking errors using PD computed-torque controller with constant unknown disturbance.

$$\tau = K_v\dot{e} + K_p e + G(q) \tag{14.7.18}$$

which selects $\hat{M} = I$ and only includes the gravity nonlinear terms, so that it is very easy to implement compared to full CT control. This has been used with good results in many applications.

If $\hat{M}, \hat{N}$ are selected, not as the actual inertia matrix and nonlinear terms, but only as approximations or simplified values, it is not always possible to guarantee stable tracking. In fact, the error dynamics of Equation (14.7.12) are then driven by *modeling mismatch errors*, which can degrade or even destabilize the closed-loop system.

Another computed torque-like controller is *PID classical joint control*, where all nonlinearities of the robot arm are neglected and one selects simply

$$\dot{\varepsilon} = e$$
$$\tau = K_v \dot{e} + K_p e + K_i \varepsilon \tag{14.7.19}$$

with the gain matrices diagonal, so that all the joints are decoupled. A PD classical joint controller is shown in Figure 14.7.4, which may seem familiar to many readers. The same figure may be drawn for each joint. In this figure, $d(t)$ represents the neglected nonlinear coupling effects from the other joints, and r *is* the gear ratio. The motor angle is $\theta(t)$ and $q(t)$ *is* the joint angle. The effective joint inertia and damping are J and B, respectively.

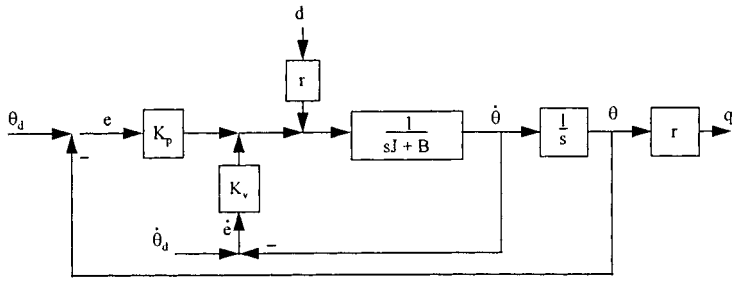

FIGURE 14.7.4 PD classical joint controller.

The simplified classical joint controller is very easy to implement, as no digital computations are needed to determine nonlinear terms. It has been found suitable in many applications if the PD gains are selected high enough, particularly when the gear ratio r is small. Unfortunately, if the gains are selected too high, the control may excite vibratory modes of the links and degrade performance. Moreover, practical applications often benefit by including additional terms such as gravity $G(q)$, desired acceleration feedforward $\ddot{q}_d(t)$, and various additional nonlinear terms.

Example 14.7.2 (Performance of PD-Gravity and Classical Joint Controllers)

The sort of performance to be expected from PD-gravity and classical joint controllers is shown in this example It is desired for a 2-link robot arm to follow, in each of its joints, sinusoidal trajectories $q_d(t)$ with period of 2 sec.

PD-Gravity Controller. The joint 1 and 2 tracking errors are shown in Figure 14.7.5. Note that the errors are small but not exactly zero, a reflection of the fact that the nonlinear coriolis/centripetal terms are missing in the controller. However, the DC error is equal to zero, since gravity compensation is used. (The gravity terms are effectively the "DC terms" of the robot dynamics.)

Classical PD Controller. The sort of behavior to be expected from classical (independent joint) control is illustrated in Figure 14.7.6. In this figure, the tracking errors are nonzero, but using large-enough PD gains can often make them small enough. Note that the DC error is no longer equal to zero; the offset is due to ignoring the gravity terms. □

Another important CT-like controller is the PD *digital controller* given by

$$\tau_k = M(q_k)\left(\ddot{q}_{d_k} + K_v \dot{e}_k + K_p e_k\right) + N(q_k, \dot{q}_k) \tag{14.7.20}$$

where the control input can only be computed at the *sample times*, $t_k = KT$, with T the sample period and k taking on integer values. Digital control is usually required in modern applications, as robot control

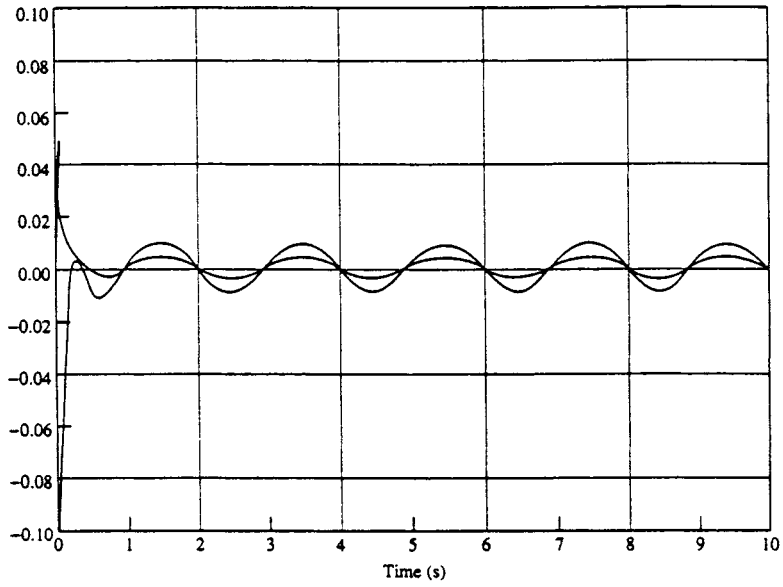

FIGURE 14.7.5 Joint tracking errors using PD-gravity controller.

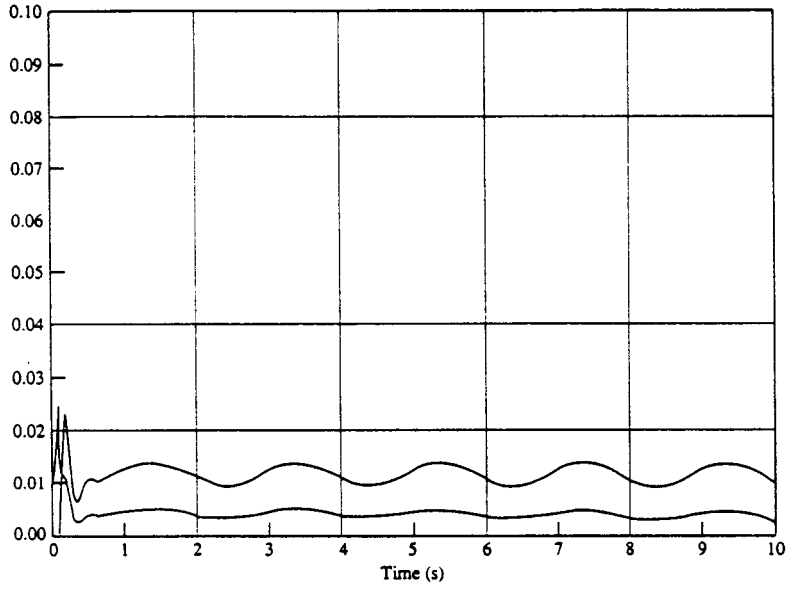

FIGURE 14.7.6 Joint tracking errors using classical independent joint control.

laws are generally implemented using microprocessors or digital signal processors. Unfortunately, the stability of robot digital controllers has not been generally addressed, so that the traditional approach relies on designing continuous-time controllers, meticulously proving stability, then sampling "fast enough" and holding one's breath.

In practice there are many other problems to be faced in robot controller implementation, including actuator saturation, antiwindup compensation, and so on. See Lewis et al., (1993).

Example 14.7.3 (Performance of Digital CT Controllers)

The performance of digital robot controllers has several idiosyncrasies of which one should be aware. In this example, it is desired for a 2-link robot arm to follow, in each of its joints, sinusoidal trajectories $q_d(t)$ with period of 2 sec.

Digital CT Controller. Using a sample period of T = 20 msec yields the tracking error plots shown in Figure 14.7.7. There the performance is quite good for the specific choice of PD gains. The associated control input for joint 2 is shown in Figure 14.7.8.

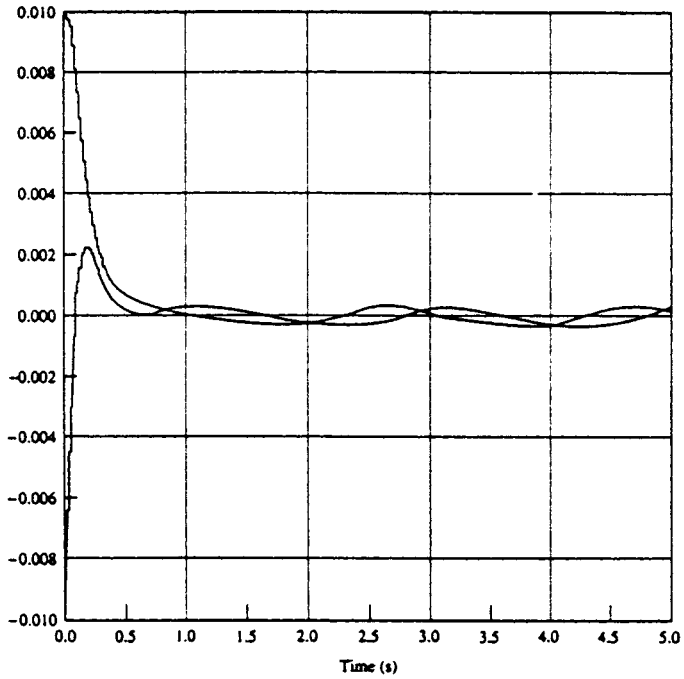

FIGURE 14.7.7 Joint tracking errors using digital computed-torque controller, T = 20 msec.

Limit Cycle of Digital Robot Controller. Unacceptable behavior in digital robot controllers can be due to integrator windup problems, selecting too large a sample period, selecting too small a sample period (so that there is not enough time to perform all control calculations in each period), or the ocurrence of *limit cycles*. If the sample period is selected as T = 100 msec, everything seems acceptable according to Figure 14.7.9, where the tracking errors are somewhat increased but still small. However, Figure 14.7.10 shoves the control torque for link 2, which has now entered a limit cycle-type behavior due to too large a sample period. □

Adaptive and Robust Control

Computed-torque control works very well when all the dynamical terms $M(q)$, $V_m(q,\dot{q})$, $F(\dot{q})$, $G(q)$ are known. In practice, robot manipulator parameters such as friction coefficients are unknown or change with time, and the masses picked up by the arm are often unknown. Moreover, computing nonlinear terms is difficult to do without exotic microprocessor-based hardware. Therefore, in applications simplified CT controllers that do not compute all nonlinear terms are used (e.g., classical joint control). These methods rely on increasing the PD gains to obtain good performance. However, large control signals may result and stability proofs of such controllers are few and far between. Adaptive and robust control techniques are useful in such situations to improve upon the performance of basic PD control

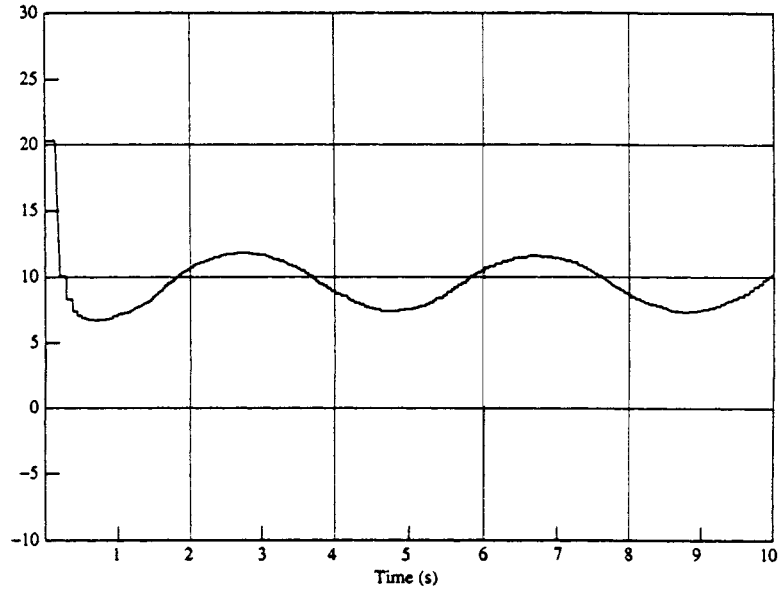

FIGURE 14.7.8 Joint 2 control torque using digital computed-torque controller, T = 20 msec.

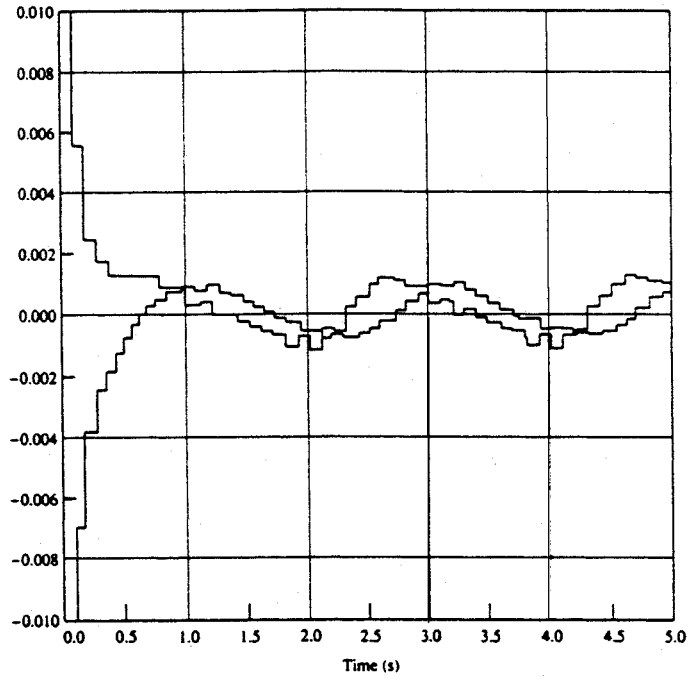

FIGURE 14.7.9 Joint tracking errors using digital computed-torque controller, T = 100 msec.

techniques, providing good performance that can be mathematically proven and so relied upon in applications. Such advanced techniques also extend directly to more complicated control objectives such as force control for grinding, polishing, and so on where straight PD methods are inadequate.

There are many sorts of adaptive and robust controllers (Lewis et al., 1993). A unifying design technique is presented here that extends as well to intelligent control using neural network and fuzzy

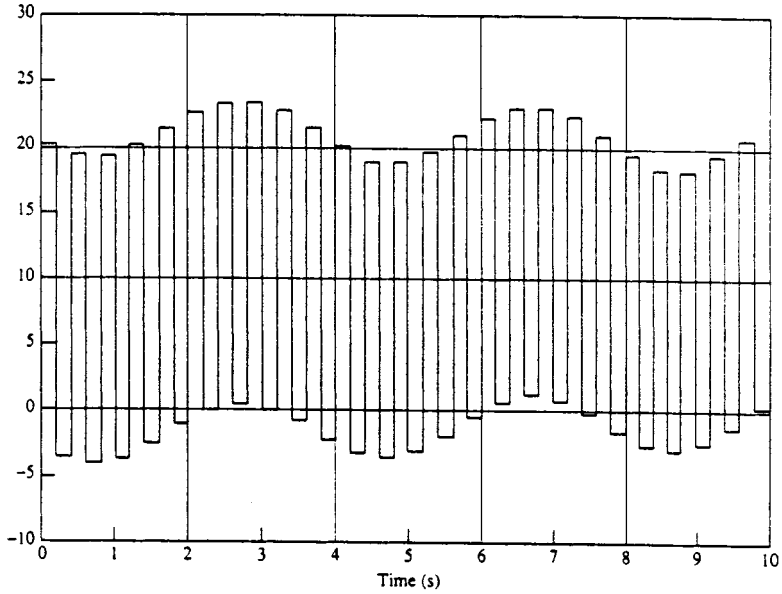

FIGURE 14.7.10 Joint 2 control torque using digital computed-torque controller, T = 100 msec.

logic techniques. Thus, given the desired trajectory $q_d(t)$, define the tracking error and *filtered tracking error* $r(t)$ by

$$e = q_d - q \tag{14.7.21a}$$

$$r = \dot{e} + \Lambda e \tag{14.7.21b}$$

with Λ a positive definite design parameter matrix. Common usage is to select Λ diagonal with large positive entries. Then Equation (14.7.21b) is a stable system so that $e(t)$ *is* bounded as long as the controller guarantees that the filtered error $r(t)$ *is* bounded.

Differentiating Equation (14.7.21b) and invoking Equation (14.7.1), it is seen that the robot dynamics are expressed in terms of the filtered error as

$$M\dot{r} = -V_m r + f(x) + \tau_d - \tau \tag{14.7.22}$$

where the *nonlinear robot function* is defined as

$$f(x) + M(q)\left(\ddot{q}_d + \Lambda\dot{e}\right) + V_m(q,\dot{q})\left(\dot{q}_d + \Lambda e\right) + F(\dot{q}) + G(q) \tag{14.7.23}$$

Vector x contains all the time signals needed to compute $f(\cdot)$ and may be defined, for instance, as $x \equiv [e^T\ \dot{e}^T\ q_d^T\ \dot{q}_d^T\ \ddot{q}_d^T]^T$. It is important to note that $f(x)$ contains all the potentially unknown robot arm parameters, except for the $V_m r$ term in Equation (14.7.22), which cancels out in the proofs.

A general sort of controller is now derived by setting

$$\tau = \hat{f} + K_v r - v(t) \tag{14.7.24}$$

with $\hat{f}$ an *estimate* of $f(x)$, $K_v r = K_v \dot{e} + K_v \Lambda e$ an *outer PD tracking loop*, and $v(t)$ an auxiliary signal to provide robustness in the face of disturbances and modeling errors. The estimate $\hat{f}$ and robustifying

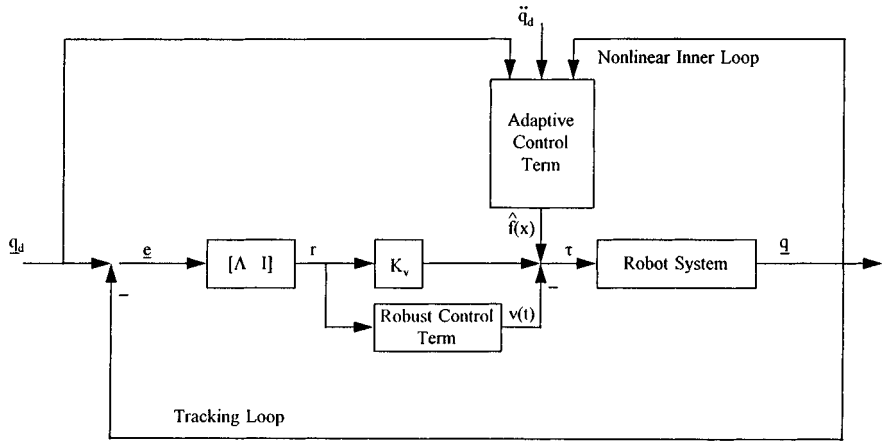

FIGURE 14.7.11 Adaptive filtered error controller.

signal $v(t)$ are defined differently for adaptive control, robust control, neural net control, *fuzzy logic control*, etc. The multiloop control structure implied by this scheme is shown in Figure 14.7.11.

Adaptive Controller

Using nonlinear stability proofs based on Lyapunov or passivity techniques, it can be shown that tracking error stability can be guaranteed by selecting one of a variety of specific controllers. One such is the adaptive controller shown in Figure 14.7.11 and described by the equations

$$\begin{aligned} \tau &= W(w)\hat{\phi} + K_v r \\ \dot{\hat{\phi}} &= \Gamma W^T(w) r \end{aligned} \tag{14.7.25}$$

where Γ is a tuning parameter matrix, generally selected diagonal with positive elements. Matrix $W(x)$ is the (known) regression matrix chosen such that $f(x) = W(x)\phi$, with all the unknown parameters placed into the vector ϕ; $W(x)$ must be computed off-line in a design phase for the specific robot arm to be controlled (Lewis et al., 1993). In the adaptive controller, the second equation represents the internal dynamics of the controller, where the estimate $\hat{\phi}$ of the unknown parameter vector is produced by dynamic on-line tuning. The robot control input $\tau(t)$ *is* then given in terms of $\hat{\phi}$ by the first equation. Though it need not be computed to produce the control inputs, the estimate of the nonlinear function is given by $\hat{f}(x) = W^T(x)\hat{\phi}$.

The adaptive controller shown in Figure 14.7.11 has a multiloop structure with an outer PD tracking loop and an inner nonlinear adaptive loop whose function is to estimate the nonlinear function required for feedback linearization of the robot arm.

Robust Saturation Controller

Another filtered error controller is the robust saturation controller

$$\begin{aligned} \tau &= \hat{f} + K_v r - v \\ v &= \begin{cases} -r\dfrac{F(x)}{\|r\|}, & \|r\| \geq \varepsilon \\ -r\dfrac{F(x)}{\varepsilon}, & \|r\| < \varepsilon \end{cases} \end{aligned} \tag{14.7.26}$$

where $\hat{f}$ is an estimate for $f(x)$ that is not changed on-line — for instance, a PD-gravity-based robust controller would use $\hat{f} = G(q)$, ignoring the other nonlinear terms. In computing the robust control term $v(t)$, ε is a small design parameter, $\|\cdot\|$ denotes the norm, and $F(x)$ is a known function that bounds the uncertainties $\|f - \hat{f}\|$. The intent is that $F(x)$ is a simplified function that can be computed even if the exact value of the complicated nonlinear function $f(x)$ is unknown.

Variable Structure Robust Controller

Another robust controller is the *variable structure robust controller*

$$\tau = \hat{f} + K_v r - v$$
$$v = -\big(F(x) + \eta\big)\mathrm{sgn}(r) \tag{14.7.27}$$

where sgn(·) *is* the signum function and $F(x)$ *is* a known function computed to bound the uncertainties $\|f - \hat{f}\|$. The design parameter η is selected as a small value. This controller takes advantage of the properties of sliding mode or variable structure controllers to provide its robustness.

In adaptive controllers the primary design effort goes into selecting a dynamic estimate $\hat{f}$ that is tuned on-line. By contrast, in robust controllers, the primary design effort goes into selecting the robust term $v(t)$. An advantage of robust controllers is that they have no dynamics, so they are generally simpler to implement. On the other hand, adaptive controllers are somewhat more refined in that the dynamics are learned on-line and less control effort is usually needed. Furthermore, in adaptive control it is necessary to compute the regression matrix $W(x)$, while in robust control it is necessary to compute the bounding function $F(x)$.

Example 14.7.4 (Performance of Adaptive and Robust Robot Controllers)

This example illustrates the sort of performance to be expected from adaptive and robust controllers. In this example, it is desired for a 2-link robot arm to follow, in each of its joints, sinusoidal trajectories $q_d(t)$ with period of 2 sec.

Adaptive Control. In adaptive control, the controller dynamics allow for learning of the unknown parameters, so that the performance improves over time. Typical plots are like those in Figure 14.7.12, where the errors start out large but then converge to zero, and the parameter (mass) estimates converge to constant values.

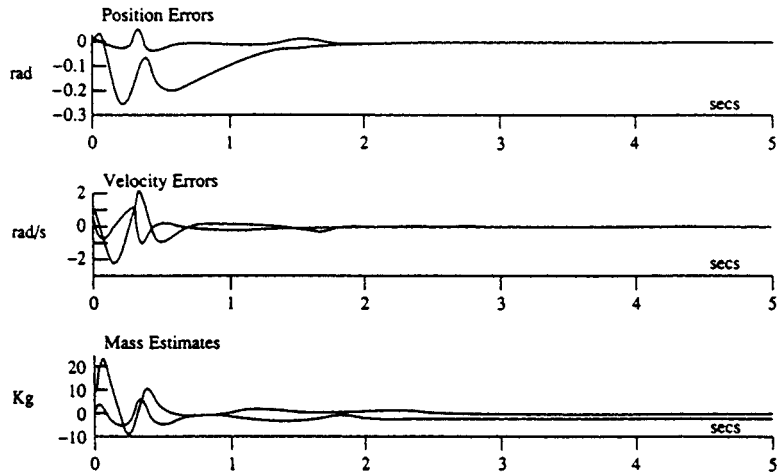

FIGURE 14.7.12 Typical behavior of adaptive controller.

Robust Control. In typical robust controllers, there are no controller dynamics so that the performance does not improve with time. However, with good designs (and large-enough control gains) the errors are bounded so that they are small enough. Typical plots are like those in Figure 14.7.13, where the errors are always small, though nonzero, but do not become smaller with time. □

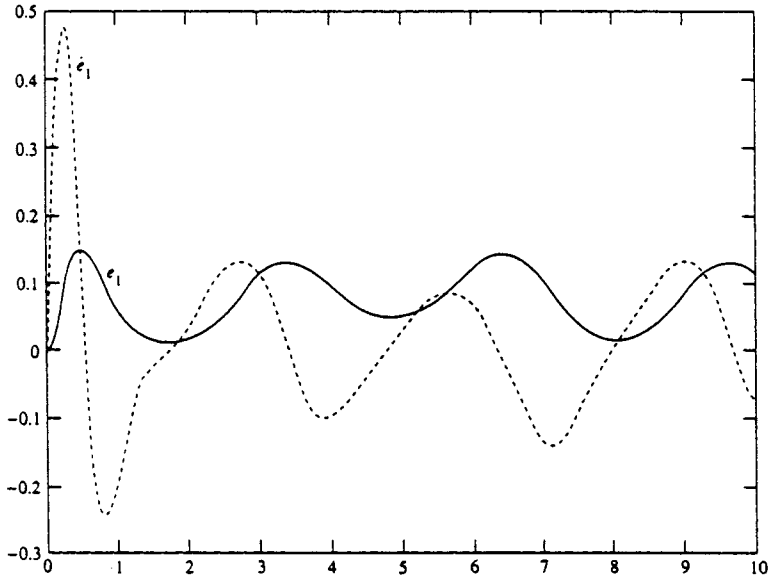

FIGURE 14.7.13 Typical behavior of robust controller.

Learning Control

In many industrial applications robot manipulators are used to perform the same task repeatedly, such as in spray painting, short assembly operations, component insertion, and so on. In such repetitive motion situations, information from one iteration can be recorded and used to improve the performance on the next iteration. This is termed repetitive motion learning control. Using the filtered error approach of the section on adaptive and robust control, it is direct to derive the learning controller of Sadegh et al. for the robot arm in Equation (14.7.1).

Let $\ell = 1, 2, \ldots$ denote the iteration number of the trajectory repetition. Then, using information from the $(\ell - 1)st$ iteration, the controller for the ℓth iteration is given by

$$\begin{aligned} \tau_\ell &= \hat{f}_\ell + K_v r - v \\ v &= -\left(K_p e + K_s \|e\|^2 r\right) \\ \hat{f}_\ell &= \hat{f}_{\ell-1} + K_L r \end{aligned} \tag{14.7.28}$$

where the filtered error is $r = \dot{e} + \Lambda e$, $e = q_d - q$, with $q_d(t)$ the specified trajectory to be followed repeatedly. The gains K_v, K_p, K_s are positive diagonal design matrices, and K_L is a positive diagonal learning gain matrix. The function $\hat{f}_\ell$ is a learning term that uses its value on the previous iteration to improve on an estimate for a nonlinear function appearing in the error analysis.

Control of Flexible-Link and Flexible-Joint Robots

If the robot arm has flexible links, flexible joints, or fast motor dynamics, the control schemes just discussed must be modified. There are two basic cases to consider: *flexible-link robots* and flexible-joint robots; fast motor dynamics can be considered a special case of the latter.

Flexible-Link Robots

In the case of flexible-link robots, the links have significant vibratory modes that cannot be neglected. In this case one may perform an analysis using, for instance, the Bernoulli-Euler model, obtaining an infinite dimensional (partial differential equation) model, which can then be truncated to a finite dimensional (ordinary differential equation) model using, for instance, assumed mode shape techniques. The result is a model such as

$$\begin{aligned} M_{rr}\ddot{q}_r + M_{rf}\ddot{q}_f + V_{rr}\dot{q}_r + V_{rf}\dot{q}_f + F_r(\dot{q}_r) + G_r(q_r) &= B_r\tau \\ M_{fr}\ddot{q}_r + M_{ff}\ddot{q}_f + V_{fr}\dot{q}_r + V_{ff}\dot{q}_f + K_{ff}q_f &= B_f\tau \end{aligned} \tag{14.7.29}$$

which describes the coupling between the rigid modes $q_r(t)$ and the flexible modes $q_f(t)$. In these equations, the quantities M, V, F, G are defined basically as in Equation (14.7.1) and K_{ff} is a matrix of flexible mode stiffness constants.

The complete dynamics are now described by the vector $q = [q_r^T \; q_f^T]^T$. The control objective is to control the link-tip positions to follow a desired trajectory $q_d(t)$ while making small the flexible modes q_f. In the pinned-pinned modes shape method, for instance, the link-tip positions are given by $q_r(t)$. The major problem is that there are now *more degrees of freedom in* $q(t)$ *than control inputs available in* τ. This complicates the control problem greatly; however, a key property is that the matrix B_r is *nonsingular* in flexible-link manipulators.

It can be shown by using a singular perturbation approach, followed by the filtered error approach of the section on adaptive and robust control, that all the basic controllers just described can be used for flexible-link arms if an *additional inner control loop* is added for vibration management. That is, to the control toque $\tau(t)$ generated by Equation (14.7.24), is added the boundary-layer correction (fast) control term, manufactured by an inner loop, given by

$$u_F = -\frac{K_p}{\varepsilon^2}q_f - \frac{K_d}{\varepsilon}\dot{q}_f + \frac{K_p}{\varepsilon^2}\bar{q}_f \tag{14.7.30}$$

where ε is a small parameter (determined according to the time-scale separation imposed by the elements of the stiffness matrix K_{ff}). The slow manifold term $\bar{q}_f$ is a function of the slow control $\bar{u}$ (which is found as before), the variable $q(t)$, and some system parameters. It is possible to avoid measurements of the flexible mode rates $\dot{q}_f$.

Flexible-Joint Robots

The case of flexible-joint robots is in some ways the "dual" problem to that of flexible links. The dynamics of a robot arm driven by motors through rigid joints are given by Equation (14.7.10) for which the controllers described in previous subsections can be used. The dynamics of a robot arm driven by motors through joints with flexibility that is not negligible are given by

$$\begin{aligned} M\ddot{q}_r + V_m\dot{q}_r + F_r(\dot{q}_r) + G_r(q_r) &= K_J(q_f - q_r) \\ J_M\ddot{q}_f + B_M\dot{q}_f + F_M(\dot{q}_f) + K_J(q_f - q_r) &= v \end{aligned} \tag{14.7.31}$$

where $q_r(t)$ is the robot joint variable vector, $q_f(t)$ are the motor angles, and quantities are defined as per the discussions on Equations (14.7.1) and (14.7.10). It is assumed for simplicity that the gear ratio is $R = 1$. The stiffnesses of the joint motor couplings are on the diagonals of the joint stiffness matrix K_J.

The flexible-joint controller problem can be confronted using either a singular perturbation approach (work by M. Spong) or a *backstepping* approach. Using backstepping, it is found that the same basic structure of controller can be used as in Figure 14.7.30, but now the controller has multiple loops, with two adaptive systems required. The extra loop arises since the control input $v(t)$ controls directly the motor angles, which provide indirectly an input into the arm dynamics to control $q_r(t)$, the quantity of actual interest.

Force Control

In many industrial applications it is desired for the robot to exert a prescribed force normal to a given surface while following a prescribed motion trajectory tangential to the surface. This is the case in surface finishing etc. A hybrid position/force controller can be designed by extension of the principles just presented.

The robot dynamics with environmental contact can be described by

$$M(q)\ddot{q} + V_m(q,\dot{q})\dot{q} + F(\dot{q}) + G(q) + \tau_d = \tau + J^T(q)\lambda \tag{14.7.32}$$

where $J(q)$ *is* a Jacobian matrix associated with the contact surface geometry and λ (the so-called "Lagrange multiplier") is a vector of contact forces exerted normal to the surface, described in coordinates relative to the surface.

The prescribed surface can be described by the geometric equation $\phi(y) = 0$, with $y = h(q)$ the Cartesian position of the end of the arm and $h(q)$ the kinematics transformation. The constraint Jacobian matrix $J(q) \equiv \partial\{\phi[h(q)]\}/\partial q$ describes the joint velocities when the arm moves on the surface; in fact, the normal velocity is $J(q)\,\dot{q} = 0$. According to the implicit function theorem, on the surface $\phi(q) = 0$ one may find a function $\gamma(\cdot)$ that $q_2 = \gamma(q_1)$, where the reduced variable $q_1(t)$ corresponds to motion in the plane of the surface and $q_2(t)$ represents dependent variables. The robot, constrained for motion along the surface, satisfies a *reduced-order* dynamics in terms of $q_1(t)$. Defining the extended Jacobian $L(q_1) \equiv [I^T\ \partial\gamma^T/\partial q_1]^T$, the relation of q_1 to the full joint variable q is given via $\dot{q} = L(q_1)\,\dot{q}_1$. For further details see McClamroch and Wang (1988) and Lewis et al. (1993).

The hybrid position/force control problem is to follow a prescribed motion trajectory $q_{1d}(t)$ tangential to the surface while exerting a prescribed contact force $\lambda_d(t)$ normal to the surface.

Define the filtered motion error $r_m = \dot{e}_m + \Lambda e_m$, where $e_m = q_{1d} - q_1$ represents the motion error in the plane of the surface and Λ is a positive diagonal design matrix. Define the force error as $\tilde{\lambda} = \lambda_d - \lambda$, where $\lambda(t)$ is the normal force measured in a coordinate frame attached to the surface. Then a hybrid position/force controller has the structure

$$\tau = \hat{f} + K_v L(q_1) r_m + J^T\left[\lambda_d + K_f\tilde{\lambda}\right] - v \tag{14.7.33}$$

This controller has the basic structure of Figure 14.7.11, but with an inner force control loop. In this controller, the nonlinear function estimate inner loop $\hat{f}$ and the robustifying term $v(t)$ can be selected using any of the techniques mentioned heretofore, including adaptive control, robust control, intelligent control, and so on. A simplified controller that may work in some applications is obtained by setting $\hat{f} = 0$, $v = 0$, and increasing the PD motion gain K_v and force gain K_f.

Teleoperation

In teleoperation, a human operator conducts a task, moving a master robot manipulator and thus defining motion and force commands. The master is connected through a communication channel to a slave robot manipulator in a remote location whose purpose is to mimic the master, thus performing the commanded motions and exerting the commanded forces on its environment. A typical teleoperation system is depicted in Figure 14.7.14. Task performance is enhanced if the human operator has information on the contact force being exerted by the slave manipulator. A convenient way of providing this information is to "reflect" the contact force to the motors on the master so the operator can feel a resistive force indicative of the contact force.

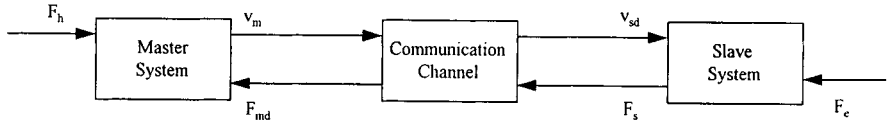

FIGURE 14.7.14 Typical robotic teleoperation system.

To focus on the issues peculiar to teleoperation, one can consider simplified dynamics for the master and slave arms given, respectively, by

$$M_m \dot{v}_m = F_h + \tau_m \tag{14.7.34}$$

$$M_s \dot{v}_s = -F_e + \tau_s \tag{14.7.35}$$

where the human operator input torque is F_h and the contact force exerted by the slave is F_e. In actual systems, one should include the nonlinear coriolis, centripetal, friction, and gravity terms (see Equation (14.7.1)), so that a preliminary feedback linearization (computed torque control) is needed to get the dynamics in this simplified form. Moreover, the Jacobians associated with the force inputs should also be considered (see Equation (14.7.32)).

The control problem is to provide motor control torques τ_m, τ_s so that the slave velocity $v_s = \dot{q}_s$ equals the commanded (master) velocity $v_m = \dot{q}_m$ and the environmental contact force F_e is proportional to the commanded force F_h (there could be a desired force amplification). In Figure 14.7.14, F_s *is* the sensed force resulting from the contact force F_e, the reflected force provided to the master robot is F_{md}, and v_{sd} is the desired velocity command for the slave. A straightforward control scheme for teleoperation is given by

$$\begin{aligned} \tau_m &= -K_m v_m - F_{md} \\ \tau_s &= -K_s v_s + F_s - \alpha_f F_e \end{aligned} \tag{14.7.36}$$

where K_m, K_s are positive master and slave control gains and α_f *is* a positive force gain. The selection of τ_s closes a local force control loop around the slave manipulator.

The key to successful control now lies in the appropriate definition of F_s, F_{md}, and v_{sd}. A naive definition of the sensed force is $F_s = F_e$, the contact force. It has been observed in experiments that this definition is unsuitable and results in instability. Therefore, a *coordinating torque* F_s is defined based on the slave velocity error $e_s(t) \equiv v_{sd}(t) - v_s(t)$ so that

$$\begin{aligned} \dot{\varepsilon} &= e_s = v_{sd} - v_s \\ F_s &= K_p e_s + K_i \varepsilon \end{aligned} \tag{14.7.37}$$

Though it may seem odd to define F_s in terms of the velocity error, it can be shown that, taking into account the impedance relationship of the environment, $F_e = Z_e v_s$, this definition makes the coordinating torque dependent on the contact force F_e. In fact, this definition results in the *passivity* of the slave dynamics referred to the variables (v_s, F_s).

Now, it can be shown that stable teleoperation results if one selects

$$F_{md} = F_s$$
$$v_{sd} = v_m \tag{14.7.38}$$

Unfortunately, if there is any delay in the communications channel, this simple scheme is doomed to failure and results in unstable control. One technique for repairing this problem is to remove the force reflection and let the operator rely on transmitted visual information to infer the contact forces. In practical applications, this can result in the exertion of excessive forces that break tools and fixtures.

It has been shown in Anderson and Spong (1989) that if there is a time delay T in the communications channel, one may modify the controller as shown in Figure 14.7.15 to obtain stable teleoperation regardless of the magnitude of T. In this figure N is a positive scaling factor introduced since the force and velocity signals may differ by orders of magnitude. This modification makes all blocks in the diagram *strictly passive*, so that stability can be shown using circuit analysis techniques. The teleoperation controller with time delay compensation is given by the torques Equation (14.7.36), the coordinating torque in Equation (14.7.37), and the modified reflected force and slave velocity commands given by

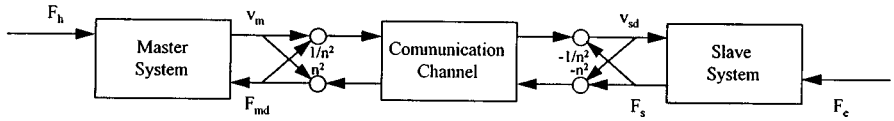

FIGURE 14.7.15 Passive robotic teleoperation system using active control.

$$F_{md}(t) = F_s(t-T) + n^2\left[v_m(t) - v_{sd}(t-T)\right]$$
$$v_{sd}(t) = v_m(t-T) + \frac{1}{n^2}\left[F_{md}(t-T) - F_s(t)\right] \tag{14.7.39}$$

It is noted that in this modified controller, part of the reflected force is derived from the slave velocity error and part of the slave velocity command is derived from a force error term.

14.8 Planning and Intelligent Control

Chen Zhou

The previous section dealt with servo-level joint control of robot manipulators. This section deals with higher-level functions of planning and control, including generation of the prescribed joint trajectories that are required for servo-level control. Robots are designed to accomplish various tasks such as spot welding in assembly, part loading in material handling, or deburring in processing. A task consists of a series of complex motions of various joints and the end effector. The execution of robot tasks is controlled by robot programs. Robot programming can be classified into three levels: (1) joint level, (2) manipulator level, and (3) task level (see Leu, 1985). At the joint and manipulator levels, a task is decomposed into a set of explicit paths. The robot program is essentially a series of move statements to instruct the robot to pass through a sequence of paths. The programming at these two levels involves tedious specification of points, paths, and motions.

The difficulties involved at the first two levels of programming led to research and development for task level programming. At the task level, a robot program is a sequence of goals or objective states of the tasks, such as inserting a peg or deburring an edge. Due to the omission of explicit path and kinematic instructions by the programmer, the robot must know its configurations, its environment and the goal locations, such as the location of materials, as well as the obstacles within the envelope. The robot controller has to construct a set of collision-free paths that are optimized in terms of time, motion, or other control characteristics.

Task planning is a process in which the detailed motion control involved in a task (or a subtask) is determined by software or algorithms. The objectives can include proper grasp configurations, collision-free paths, minimum travel distance, minimum travel time, and avoidance of *singularities*. In a singular configuration, the robot may lose a degree of freedom or lose the ability to provide designed power. For complex tasks, task decomposition can be performed to provide more specific control of the robot. *Path planning* is a process of finding a continuous path from an initial robot configuration to a goal configuration without collision. It is a very important component in task planning.

Task planning includes several special cases. First, errors can occur during execution of a task. Various sensors have been developed to detect error conditions. Since the occurrence of an error is random, there is uncertainty associated with task planning when error and error recovery are concerned. Second, multiple robots are often used in robotic applications. The simplest case involves two arms. An important issue in two-arm task planning and control is the coordination of the two arms. Third, in robotic manufacturing cells, robots must coordinate with other equipment in the cell and the control of the robot can often affect the performance of the entire cell. Therefore, cell control is also discussed in this section. At the end of this section, we also mention artificial intelligence as applied to planning and man–machine interface.

Path Planning

Path planning involves finding a continuous path from an initial robot configuration C_{init} to a goal configuration C_{goal} without collision. Figure 14.8.1 illustrates an example of path planning in two-dimensional space. The small rectangular object represents a *mobile robot* or an end effector of a manipulator, and the other objects represent the obstacles within the working envelope. The dashed line shows the path of the center point of the robot. The four small rectangles show the orientation of the robot at the initial, goal, and two intermediate configurations.

Often, the collision-free path is not unique. In addition to avoiding collision, one can also add requirements for smoother motion, shorter traveling distance, shorter traveling time, or more clearance from the obstacles. Therefore, path planning can also involve optimization with respect to certain performance measures.

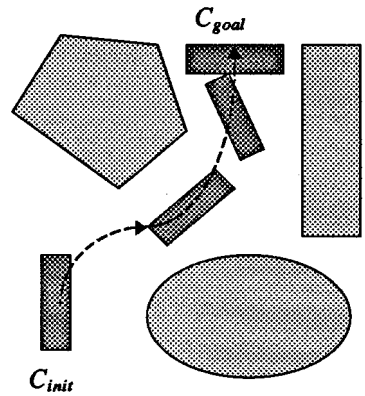

FIGURE 14.8.1 Illustration of path-planning problem.

The abstract model of the path-planning problem can take different forms depending on the application characteristics. It can be in two dimensions or in three dimensions. The concern can be the end effector alone or the entire robot arm. The end effector can be considered as a solid body or an infinitesimal point. Different considerations can have significant implications on the solution methodology and complexity. In this handbook, we will only discuss the simplest cases in which a point end effector in two-dimensional space is concerned. The readers are referred to Latombe (1991) for more complex procedures.

Road Map Approach Based on Visibility Graph

The road map approach is one of the earliest path-planning methods. The obstacles are modeled as polygons. A *visibility graph* is a nondirected graph. The nodes of the graph are the vertices of the polygons, the initial point and the goal point. The links of the graphs are straight-line segments that connect a pair of nodes without intersecting with any obstacles. A reduced visibility graph for the example is shown in Figure 14.8.2. A reduced visibility graph does not contain links that are dominated by other links in terms of distance. The elliptical obstacle is approximated by a hexagon. In the visibility graph, all the paths consisting of successive links that connect C_{init} to C_{goal} represent semicollision-free paths. The coarse line represents one of these paths. The use of the term "semicollision free" is due to the fact the path may actually contact an obstacle. It is clear that the path is not unique. In the example the possible paths can be $C_{init}\,AC_{goal}$, $C_{init}\,BC_{goal}$, or $C_{init}\,CD_{goal}$. Some offer shorter travel distances while others offer smoother paths. This method can be extended to include circular end effector and obstacles which have lines and arcs as boundaries.

Road Map Approach Based on Voronoi Diagram

For the same problem described above, one can create a *Voronoi diagram* based on the vertices and line segments of the obstacles and the working envelope and use this graph to generate a collision-free path. A Voronoi diagram is a diagram that consists of lines having equal distance from the adjacent objects. Obviously, the Voronoi diagram does not touch the obstacles and can provide collision-free paths. A Voronoi diagram in a polygonal space with polygonal obstacles is composed of straight line segments and parabolas. When both adjacent object segments are straight lines or vertices, the segment of the Voronoi diagram is a straight line. When one object segment is a point while the other is a line segment, the segment of Voronoi diagram is a parabola. Two additional links need to be created to connect the C_{init} and C_{goal} to the Voronoi diagram. Any set of links that connects C_{init} and C_{goal} through the diagram represents a collision-free path. Unlike the road map approach based on visibility graph, this approach tends to maximize the clearance between the robot and the obstacles. For the characteristics and creation of the Voronoi diagrams, the reader is referred to Okabe et al. (1992).

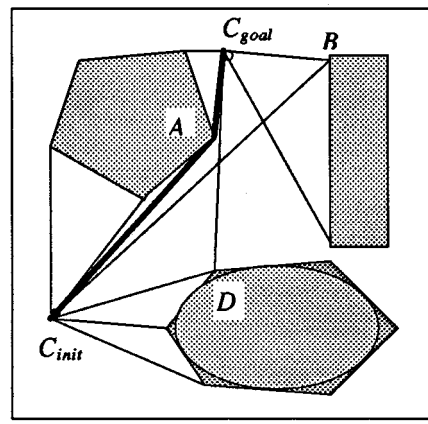

FIGURE 14.8.2 Road map method based on visibility graph.

Cell Decomposition Approach

In the *cell decomposition* approach, the robot free space is decomposed into simple connected geometric shapes, or cells such that a path can be generated between any two points within a cell. When Euclidean distance is used (as when using a Cartesian robot), convex polygonal cells satisfy this requirement. The simplest way to generate cells is the line sweeping method. An example in which the work envelope and the obstacles are polygons is shown in Figure 14.8.3. The two shaded areas are obstacles. In this example, the decomposition is done by sweeping a vertical line across the work envelope. A cell is formed whenever a vertex is encountered by the sweeping line. After decomposition, a *connectivity graph* is constructed. A connectivity graph is a nondirected graph. The nodes of the graph are the cells. If two cells share a common edge, they are connected and a link is drawn between the two nodes. The existence of a collision-free path can be found by searching the connectivity graph to see if there exists a path that connects two nodes containing C_{init} and C_{goal}. If such a path exists, one can construct collision-free paths by determining paths in the cells and connect the paths in adjacent cells.

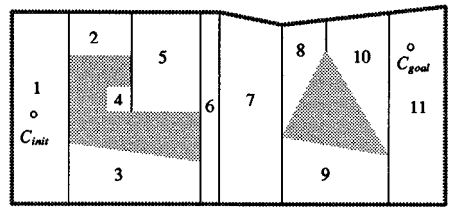
Apparently, the path and decomposition are not unique. One can select different paths and decompositions to optimize other measures. Figure 14.8.3(d) shows another possible decomposition of the same space.

Potential Field Approach

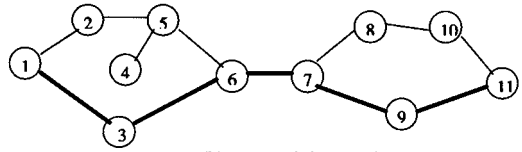
The idea of the *potential field* method is to represent the robot work space as a potential field which has peaks and a valley. The valley is at the goal configuration, while the peaks are at the location of the obstacles. The robot, represented by an article, will roll naturally away from the peaks and toward the valley in such a terrain. Mathematically, this is done by creating an artificial potential field with peaks as obstacles and a valley as the goal, and by using a search procedure to plan a descending path to the valley. The artificial potential field is composed of an attractive potential with its lowest point as the goal configuration, and a repulsive potential for each of the obstacles. An example is shown in Figure 14.8.4. The dimension of the robot envelope is 10 wide and 10 high. Here *ZG* is the attractive potential function, *ZR* is the repulsive potential function for all obstacles, and *Z* is the combined potential function. In this example, the attractive potential function *ZG* is a parabolic well:

$$ZG(x,y) = \frac{A}{2}\left[\left(x - G_x\right)^2 + \left(y - G_y\right)^2\right] \tag{14.8.1}$$

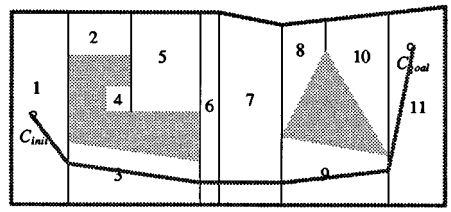
where *A* is a constant used to adjust the magnitude of the attractive field, G_x = 2 and G_y = 1 are the coordinates of C_{goal}. *ZR* represents three cylindrical obstacles with diameters 2, 1, and 1, respectively.



(a) cell decomposition



(b) connectivity graph



(c) a possible collision free path.

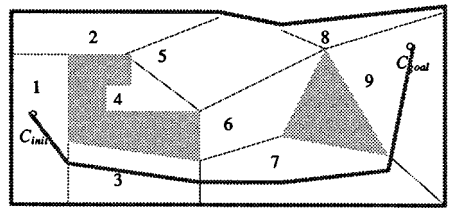


FIGURE 14.8.3 Cell decomposition method.

The center location of the three obstacles are at (2, 5), (7, 7), and (6, 3). Let ZR_i be the obstacle repulsive fields of i^{th} cylindrical obstacle. The repulsive function for i^{th} obstacle is

$$ZR_i(x,y) = \begin{cases} \dfrac{B_i}{2}\left[\dfrac{1}{\sqrt{\left(x-R_{x,i}\right)^2+\left(y-R_{y,i}\right)^2}} - C_i\right] & \text{if } \dfrac{D_i}{2} \ge \sqrt{\left(x-R_{x,i}\right)^2+\left(y-R_{y,i}\right)^2} < D_i \\ Z_i & \text{if } \sqrt{\left(x-R_{x,i}\right)^2+\left(y-R_{y,i}\right)^2} \le \dfrac{D_i}{2} \\ 0 & \text{otherwise} \end{cases} \tag{14.8.2}$$

where B_i is a constant for the adjustment of the height of i^{th} peak, D_i is the diameter of the i^{th} cylindrical obstacle, and $R_{x,i}$ and $R_{y,i}$ are the center coordinates of the cylinder. The characteristic of this function

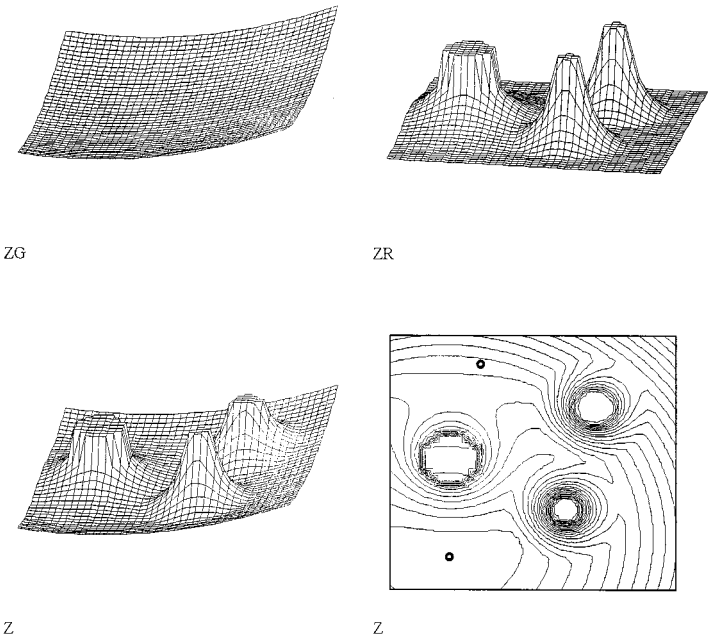

FIGURE 14.8.4 Potential field method example.

is that the potential at any point with distance more than twice the diameter of the closest obstacle is zero. Also, the potential inside the obstacle is a constant and equal to the potential at the boundary of the obstacle, where C_i is a constant to accomplish the former and the Z_i is a constant for the latter. The total potential is the sum of all the terms:

$$Z = ZG + \sum_{i=1}^{3} ZR_i \tag{14.8.3}$$

There are several techniques for potential guided path planning. The simplest is the depth first planning. In depth first planning, a prespecified step δ is predefined. The path will be found iteratively using

$$\begin{aligned} x_{n+1} &= x_n + \delta \frac{\partial Z(x_n, y_n)}{\partial x} \\ y_{n+1} &= y_n + \delta \frac{\partial Z(x_n, y_n)}{\partial y} \end{aligned} \tag{14.8.4}$$

where x_0 and y_0 are at C_{init}. Depth first planning is very fast for certain situations but may cause trapping some local point in others.

Error Detection and Recovery

In the execution of a task, errors can occur. The errors can be classified into several categories: hardware error, software error, and operational error. The hardware errors include errors in mechanical and electrical mechanisms of the robot, such as failure in the drive system or sensing system. Software errors can be bugs in the application program or control software. Timing with cooperative devices can also

be called software error. The operational errors are the errors in the robot environment that are external to the robot system such as jamming of parts or collision with obstacles.

The sensors used in error detection can be classified into several categories: tactile sensors for sensing contact and existence, proximity sensors for sensing location or possible collision, force/torque sensors for sensing collision and jamming, and vision for sensing location, orientation, and existence.

The occurrence of an error normally causes interruption of the normal task execution. Error recovery can be done at three levels. At the lowest level, the task is not resumable. Upon detection of an error, the task is interrupted automatically. The error must be corrected manually and the task must start again manually. At the second level, the task can be resumed. Upon detection of an error, the error can be corrected manually and the task can be continued from the point where the error occurred. At the third level, upon detection of an error, the error will be corrected automatically and the task execution is continued. Figure 14.8.5 shows an example of error and recovery in an insertion task.

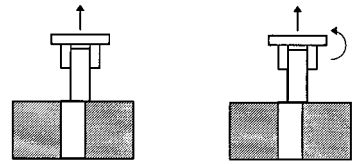

FIGURE 14.8.5 Jamming error detection and recovery.

In this insertion example, a peg is misaligned with the hole. The misalignment can be caused by wrong location of the fixture, wrong positioning of the peg before pickup, etc. The jamming error can be detected by a vertical force sensor in the gripper. At the lowest level, this can be used to trigger an emergency stop and an alarm. An operator can withdraw the gripper, remove the peg, and start the cycle again. At the second level, the operator can correct the problem and continue the insertion after the error condition is corrected. At the third level, additional sensory information is required. For example, additional force sensors can be used to identify the jamming torque. The torque information can be used to redirect the end effector to put the peg in the hole correctly. Since the occurrence of error is random in nature, the incorporation of error recovery introduces uncertainty into task planning. Artificial intelligence methods are often employed in error recovery.

Two-Arm Coordination

Many robotic applications require multiple arms, such as lifting heavy weights in handling or assembling two components that require simultaneous motion. In such applications, a special planning and control issue is the coordination of two arms. Figure 14.8.6 shows an example of two-arm application. In two-arm applications, two arms form a closed chain. Each arm acts as a constraint on the other and can have different contributions to the motion of the part. In terms of constraints, one or both arms can have rigid grasps. Two arms may also be controlled to remain in contact at a point, along a line, or on a surface. In terms of control, two-arm coordination can rely on a master/slave relationship, a push/pull relationship, or other relationships. In the master/slave relationship, one arm is controlled in force mode (master) while the other is controlled in position mode (slave). These constraints and control relationships require different controls from both controllers. Please see Hayati et al. (1989) for more discussion.

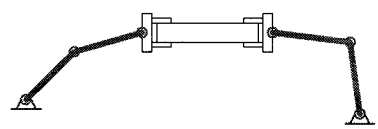

FIGURE 14.8.6 Two-arm coordination.

Workcell Control

Robots are used in many workcells for machine loading/unloading, assembly, part *kitting*, packaging, etc. The task planning associated with workcell control has its unique characteristics. A robot in a workcell often interacts with other resources in the cell such as a machine, a conveyor, a fixture, or a container. These interactions often require exact coordination. The coordination is done based on the clocks or interlocks implemented through *discrete inputs* (DI) and *discrete outputs* (DO). A DO is a binary signal that can be set in one of the two states and a DI is a binary sensing that can detect one of the two possible states from a DO.

In a flexible robotic manufacturing cell, alternative actions often exist for robot control, such as which assembly task to perform first, or which machine to serve first. The ordering of these different alternatives can directly affect the utilization, throughput, and other measures of the cell. Due to its discrete nature, the cell control optimization problem is combinatorial in nature and expands rapidly with problem size. As a result, dispatching rules in scheduling are often employed as rules in rule-based cell controllers.

Additional concerns in cell control relate to two commonly used terms in production system control: *blocking* and *deadlock* (or *locking*). Blocking is a condition in which material cannot be transported to its next location because of a temporary resource unavailability. This can cause the waste of capacity of the current machine. Deadlock is a condition in which two resources mutually require the service of the other but neither can provide the required service at the current state. Therefore, the system will be deadlocked. Examples of blocking and locking are given in Figure 14.8.7.

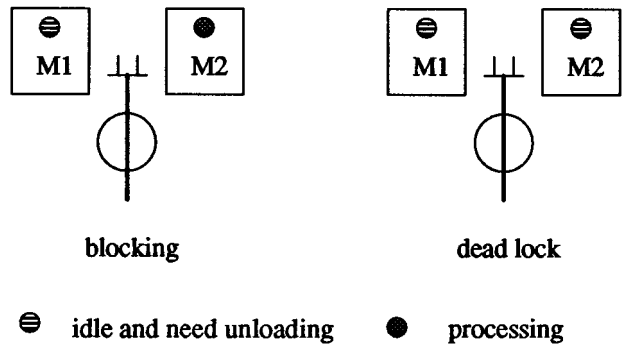

FIGURE 14.8.7 Example of blocking and locking.

In the figure on the left, the part on M1 needs to be transported to M2. However, M2 is in processing state and therefore the part in M1 has to wait for its completion. In the figure on the right, both parts on M1 and M2 are finished and need to be transported to the other machine. Suppose the robot has a single end effector; it is not able to transport either part to the other machine. One possible solution to blocking and deadlock problems is to add buffers. In the example, if a buffer location is added to the cell, the blocking and deadlock can be temporarily resolved. However, the addition of buffers to a cell can increase the cost of the cell and the complexity of the control. The real-time solution to blocking and deadlock problems lies in the identification of possible blocking or deadlocks and prevents them from occurring. Blocking or deadlock avoidance and system optimization are combinatorial in nature. The number of states expands exponentially with the number of states for each resource and number of part types. Therefore, rule-based systems and AI techniques find wide acceptance in cell controls.

Planning and Artificial Intelligence

Artificial intelligence (AI) is a branch of computer science studying the characteristics associated with human intelligence such as reasoning, acquiring knowledge, applying knowledge, and perceiving the environment. Path or task planning is the application of reasoning, knowledge acquisition, and perception

of the environment. Therefore, robot planning is closely related to the study of AI and certain AI techniques can be applied to robot planning and control. Some of the areas of research in AI that apply to robotic planning are problem solving, expert systems, learning, and machine vision.

The methodologies in path planning can be considered as problem solving. In assembly, when multiple components are assembled with precedence requirements, AI techniques can also be applied. Expert systems or rule-based systems solve problems in a discrete space domain based on rules derived from experts or other sources. Finally, machine vision has enjoyed a rapid increase in robotic applications. Machine vision can acquire complex environment information rapidly. Various algorithms can be used to extract useful path planning information such as locations of obstacles, end effectors, tools, etc. and can be used in real-time robot motion control. The reader is referred to Winston (1984) for more AI discussion.

Man-Machine Interface

Robots can commonly be programmed or controlled through teach pendants or a computer. A teach pendant is a small key pad that allows the user to move the robot, record positions, and enter simple programs. Modern robots are also accompanied by programming and control software that runs in microcomputers or workstations. The software environment often includes an editor, menu-driven robot control, and diagnostic utilities. More intelligent robot control programming is commonly supported in this environment than is available through the teach pendant.

Control programs can also be generated off-line. In *off-line programming*, the spatial configuration of the robot and work environment is modeled in the computer. A programmer is presented with a 2D or 3D world model of the robot and its environment graphically. The programmer will specify the locations and paths in this model rather than working with a real robot. Off-line programming has the potential to improve robot productivity and simplify the procedures of creating complex robot programs.

14.9 Design of Robotic Systems

Kok-Meng Lee

For manufacturing in which the manufacturing facility is concerned with similar volumes of production and a wider range of parts, the assembly line/mass production method is often not cost effective. It is often desirable to group equipment units together into workcells that can, in composite, perform an entire family of related operations on the product. The work-in-progress enters the workcell, remains while several functions are performed, and then leaves the workcell.

The individual equipment units that are used in the workcell (for both processing and materials handling) can consist of combinations of manual, semiautomatic, and fully automated equipment. However, in this section, the term "workcell" refers to a grouping of the robot and its peripheral equipment to assemble any of a large variety of products with little or no human intervention, driven by electronically designed data. An assembly robot is a comparatively simple mechanism whose function is to position parts and tools in the space of its work volume accurately. It is a comparatively low-cost machine of high precision of positioning and great reliability. Its simplicity, however, excludes the possibility of human-type actions like form recognition and its prehensile tools are very far from having the number of degrees of liberty a human hand has. If we concede that an assembly robot can by no means compete with a human being in a complex task, we also have to acknowledge that an assembly robot is capable of executing monotonous tasks with consistently high precision, thereby increasing the quality of the product. It can also keep up a fast production line indefinitely. Recognizing this difference between a human and a robot is essential in the design of a robotic system.

The remainder of the section is organized as follows. A set of design considerations for designing an assembly robot workcell is first presented. Layouts for a typical robotic workcell are then discussed. Experience so far has shown that in most instances, it is a feeder that fails in the workcell, not the robot. Feeding methods must be carefully considered when designing a workcell and are discussed at the end of the section.

Workcell Design and Layout

Design Considerations

Assembly systems can be broadly classified as manual, fixed, and flexible systems in relation to the complexity of the product to be assembled and to the production volume as shown in Figure 14.9.1. Flexible robotic workcells are typically used for less complex products at low or medium production volume, while for increasing product complexity, the cells designed for a single-purpose task can be linked into assembly lines. Apart from product volume and complexity, the design of the robotic workcell depends on several factors: namely, number of part types, end-of-arm tooling exchange, as well as product design.

Number of Part Types. A typical workcell consists of a robot and its peripherals made up of part-presentation mechanisms, feeders, conveyor, and end-of-arm tooling. For a small number of part types, parts are presented to the robot by feeders or magazines. As these take up space, only a limited number of different parts can be fed to one robot. In mechanical assembly normally a maximum of five to six different parts can be presented in this way.

To extend the robot's accessibility to a large number of parts, mechanized component feeding systems can be mounted on data-driven carousel conveyors spaced around the robot, each with a fixed dispensing point within reach of the robot gripper. The carousel can accommodate up to several hundred positions onto which magazines, tapes, or other modular dispensing systems can be attached. With multiple programmable carousels, the robot can access several thousand different parts. The application of the mechanized carousel is useful when only a few of each part type from thousands of styles may be used. Other alternatives are (1) kitting, in which all components to be assembled are kitted in a loosely

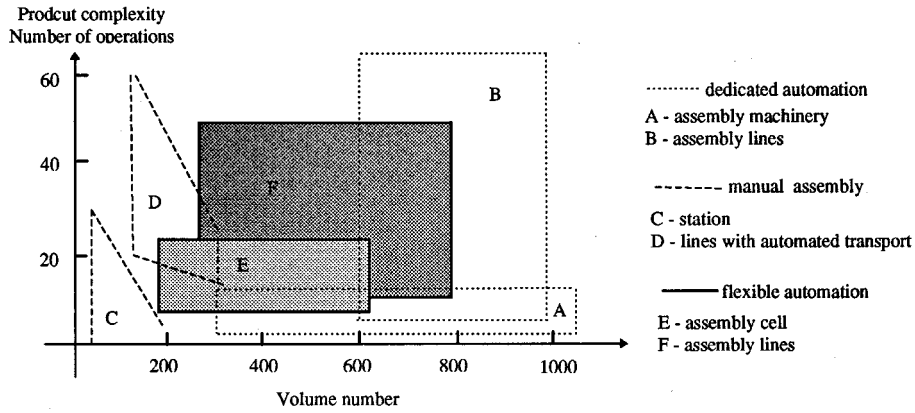

FIGURE 14.9.1 Classification of assembly systems.

palletized waffle pack, and followed by more accurate location using standard machine vision; and (2) the use of accurate totes for robot handling.

End-of-Arm Tooling Exchange. Many systems use different gripper exchange systems in order to cope with different parts. Tool exchanges are often considered as "nonproductive" since they do not contribute to assembly operations. The exchange is serially coupled to the assembly operations. This means that the cycle time increases due to the extra time needed for pickup and drop-off for tool changes as well as travel time between the assembly point and the end-of-arm tooling station. In order to reduce time loss due to the gripper, exchange should be minimized and/or in parallel with other activities, and the distance between pick-up point and assembly point should be very short. This problem could be avoided if a fast-revolving gripper head is used provided that space, weight, and cost of the revolving head do not pose a problem. Alternatively, the pallet carries batch-specific equipment such as grippers, fixtures, and end-of-arm tooling and can be presented to the robot on a conveyer in a similar fashion as the parts.

Product Design. Product design for flexible automation cells includes the following criteria: task operations based on flexible assembly cells for specific product families which must be able to assemble the variants of these product families using programming, fast changeover from one product to another within a flexible assembly cell, and reuse of standard elements for new assembly tasks

In addition to product complexity and volume, two other criteria should be considered in the construction of flexible assembly cells. First, since only a few products are generally suitable for fully automatic assembly, manual working processes are often essential with a large number of products. Flexible assembly cells must be constructed so that manual work stations can be included following ergonomic principles. Second, since the type-specific peripheral costs will increase in relation to the number of individual parts in the product to be assembled, part-specific feeders must be minimized for the economic use of flexible assembly cells.

Workcell Layout

Workcell design and layout in a flexible automation system depend on the nature of the manufacturing processes, the product design, and the material handling system as a whole. The manufacturing systems are classified as electronic product assembly, subassembly of electrical and mechanical components, and kitting cell for large-scale manufacturing.

Electronic Product Assembly. Flexible workcells are commonly used for the assembly of integrated circuit boards (PCB), where a combination of interchangeable part-feeding mechanisms are used to present parts to robots. Since a majority of the processes involved are carried out in the linear, vertical plane, robots of SCARA or gantry construction are best suited for these assembly tasks. The workcell

consists of a robot and its peripherals made up of part-presentation mechanisms, feeders, conveyor, and end-of-arm tooling.

Figure 14.9.2 shows the organization of a typical workcell for assembly of a family of circuit boards (Decelle, 1988), which is a part of the in-line component insertion, inspection, and repair assembly line. Circuit boards to be assembled are secured on panels and flow through the workcell on a conveyor. Each of the circuit boards is characterized by a bar-coded serial number that permits product tracking, data collection, and testing through the assembly. Boards requiring assembly are positioned over an elevator mechanism in the workspace of the robot. The mechanism lifts the board slightly and uses the tooling holes on the panel to locate the circuit board. Two digital signals interface the conveyor to the workcell — one signals the robot that the board is ready for assembly and the other signals the conveyor to index the board to the next workcell. Components are fed to the robot by using feeders. The feeder singles out components to a walking-beam mechanism that transfers parts through lead-cutting, lead-straightening, and lead-verification operations and on to the lead-locating nest for robot pickup. The activities of the robot and its peripherals in a workcell are coordinated by a host computer. The workcell is set up and monitored through the host computer. Through the host computer, the operator provides the workcell the code to be assembled, the components in the feeders, and the configuration of the feeders.

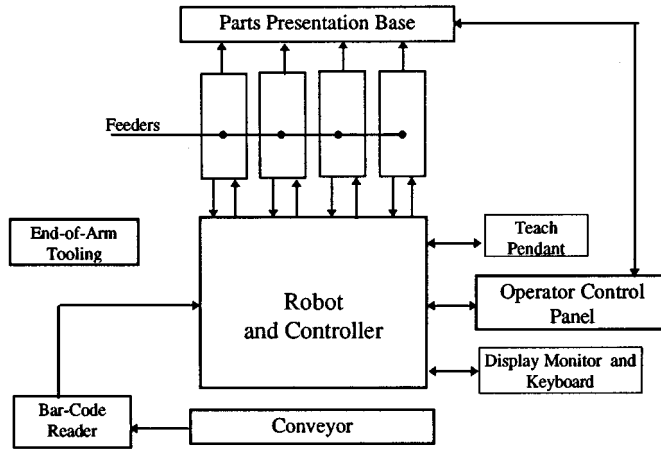

FIGURE 14.9.2 Workcell for elctronic assembly.

Subassembly of Electrical and Mechanical Components. Unlike PCB assembly, packaging and designs of small electrical and mechanical components are generally nonstandardized. Thus, the problem of automated flexible assembly workcells lies in the presentation of parts and the degree of flexibility of assembly of small components often involves both product design and layout considerations extensively.

Figure 14.9.3 shows a self-contained flexible workcell for assembly of small mechanical parts with a circular indexing table. Modular part-feeding equipment such as vibrator feeder bowls and special-purpose trays are placed around the indexing table to feed and to orient small components to the robot. Typical mechanical operations such as riveting, screwing, welding, inserting, pressing, and so on are achieved through quick changeover end-of-arm tooling. The circular indexing table arrangement is advantageous where end-of-arm tooling changes are necessary for handling different parts. It allows changes of end-of-arm tooling to take place while other operations are continuing.

With complex products, assembly in a single flexible assembly cell is not always feasible. In this case, a flexible assembly line can be designed to link self-contained independent workcells (Figure 14.9.3) so that they can be engaged or disengaged as required to allow adaptability in connection with product model change. Alternatively, standard carriers or pallets can be used to present a large number of different part-types to a robot. Each pallet carries a large number of identical parts, unoriented but

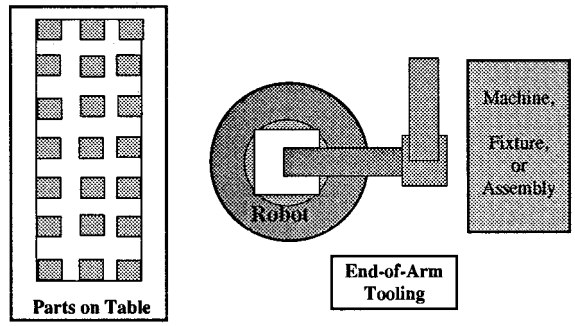

FIGURE 14.9.3 Typical single-purpose workcell.

with the right side up, and placed on a flat board. Standard machine vision was used to detect the orientation of the parts.

Kitting Cell for Large-Scale Manufacturing. In the field of large-scale manufacturing such as automobile manufacturing, engine assembly, and machining processes, where the setup time of specialized tools for each task is excessive, the work is generally distributed into several cycle zones. As an example, actual cutting time (production time) represents a value between 5 and 20% of average machine utilization time that includes nonproductive time accountable by workpiece load/unload, too) change/setting, and workpiece inspect.

To avoid a high level of wear and tear on tools due to constant conversion, the cycle zone is commonly divided into individual operating cells which may be interconnected in series, parallel, or a combination of series and parallel. A typical workcell (Figure 14.9.3) consists of a robot, a part-feeder, an end-of-arm tooling section, and the manufacturing process. The parts are contained in a regularly spaced pallet, which are transported by means of an automated guided vehicle (AGV) or a conveyor to the loading tables and are fed to process by the robot. The most common approach in automated part presentation for machine loading is the use of specially designed pallets for each part family to maintain sufficient position accuracy for a completely preprogrammed robot picking.

In the case of assembly, purchased parts or parts to be processed are kitted onto one kit tray in a single location. Kitting is the process of taking parts from bulk and placing them on a kit tray, which is an organized group of parts. Concentrating the material delivery system and its control to one area is the main benefit of the kitting cell. In addition to efficient use of floor space by eliminating duplicate equipment at each assembly cell, the feeders and tooling are universal — the same equipment is being used all the time for all parts, thus maximizing utilization while minimizing capital expense. The material delivery equipment is eliminated at the assembly cycle times. Also, having all the parts for an assembly on a carrier permits changes in the process route during machine downtime or blockages.

Figure 14.9.4 shows a layout of the kitting cell. An overhead gantry takes bins of parts and dumps them in the appropriate feeders (indicated in Figure 14.9.4 as F1, … F7). The feeders fill the lanes with an initial quantity and replenish them as parts are kitted. The parts come to rest in nests at the end of the feeder lanes. Here the vision system verifies the correct part family, performs some quality checks, and determines the position and orientation for the robot to pick the parts. Should the vision reject the part, the nest will dump the part and a new part will be fed in for an inspection. Using a quick changeover gripper, multiple parts are kitted onto a tray. Once all the parts are on the kit tray, the tray is indexed to the inspection station for verification that all parts are placed. The robot takes the completed kit tray and places it on the assembly conveyor to an idle station, ready to be picked up by an AGV.

Part-Feeding and Transfers

The term “part-feeding” refers here to feeding workpieces from pallets using a preprogrammed robot for subsequent processes such as machining or assembly. The cost to feed parts to a robot for either

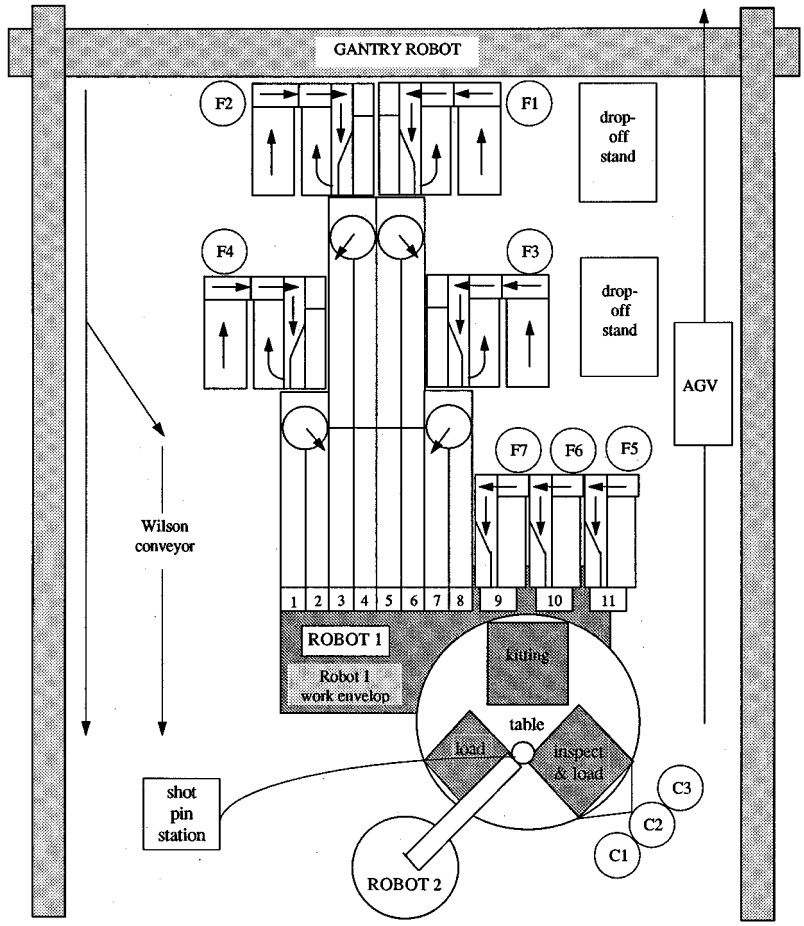

FIGURE 14.9.4 Schematics of the kitting cell.

machine loading or assembly in a flexible manufacturing system (FMS) has often been underestimated, which may comprise as high as two thirds of the overall investment and is usually the source of a large percentage of work stoppages and defects. A general review of existing *mechanical part feeders* can be found in Lee (1991).

The basic kinds of part-feeding may be classified as follows: (1) mechanical feeders which are designed to feed and to orient the parts-dedicated part-feeding apparatus, (2) dimensionally dedicated pallets which are specially designed for each part family to maintain the position/orientation, and (3) machine vision.

Mechanical Feeders

The commonly used mechanical feeders for robotic assembly are bowl feeders, vibratory feeders, and programmable belt feeders. For large volume manufacturing, the employment of the dedicated mechanical part-feeding apparatus may be justified. However, mechanical feeders consume a lot of room around the workcell, often fail due to jamming, and, most significantly, generally require retooling when a component is changed or tool wear is caused by jamming.

Vibratory Bowl Feeders. Vibratory bowl feeders (Boothroyd and Dewhurst, 1985) are most commonly used as mechanical feeders for robotic assembly. The basic component of a bowl feeder consists of a

vibratory bowl, a rotating disk, and an orienting track. Parts to be fed to the robot are separated into a single line and oriented to move to feeding end. These feeders, in general, are not designed to be easily converted to feed new part types. The cost of the bowl feeders can be broadly divided into two parts: special purpose equipment cost and general purpose equipment cost. Typically, changeover would involve replacing the bowl, orientation track, feed track, and escapement, which contribute to special-purpose equipment cost. Only the vibratory drive unit could be reused. This general-purpose portion of the feeder is approximately 30% of the feeder cost.

One way to lower the cost of the bowl feeder per part is to deliver different parts to a robot assembly station using multiple layer vibratory bowl feeders. A multilayer bowl feeder has several bowls mounted in stacked fashion, and in each bowl a different kind of part is stored. The design of multipart vibratory feeders aims at reducing the cost of the vibratory feeders by sharing the general-purpose hardware cost over several parts and by reducing the special-purpose tooling cost. Two basic forms are available: bowl type and in-line type.

To change over this multipart vibratory feeder to other part types, the orienting tracks must be replaced. An effective way to reduce wear is to separate the function of orienting from feeding. The function of the multilayer vibratory feeders is to restrict feeding parts to a separation unit. Parts of several different types are fed but not oriented from a vibratory feeder. In most cases, the workpieces must be held by a mechanical pusher against a pair of orthogonal datum planes on a relatively flat surface with the "right side up." A machine vision system is then used to locate and/or to sort the orientation of the parts using two-dimensional binary images, which is a great deal easier to store and to process.

Vibratory Belt Feeders. In vibratory belt feeders, parts are fed by a vibratory conveyer belt (Boothroyd and Dewhurst, 1985). The principle of the vibratory belt feeder is to produce a vibratory motion on the surface of the brushplate. The motion is obtained by pulling the brushplate sharply down and back and then allowing it to spring up and forward. This action, repeated at high speeds (approximately 3600 times per minute at 60 Hz power supply), produces a definite vibrating movement on the brushplate surface, permitting parts to be conveyed in a smooth and easily controlled manner.

The orienting systems used on these belt feeders may be a mechanical device, an optical sensor, or a vision system. A machine vision system is often used to locate and/or to sort the orientation of the parts using two-dimensional binary images. A line-scan camera is commonly used to create the silhouettes of the workpieces, and in some cases the product designs can be reviewed to simplify the vision algorithm and to reduce the system cost. Since a robot gripper can grasp parts from a queue on the feeder itself, belt feeders do not require any special-purpose tooling for feed track or escapement and thus offer several advantages over the vibratory bowl feeder for robotic assembly

Dimensionally Specific Pallets

One of the most common approaches is the use of specially designed trays or totes for each part family to maintain sufficient accuracy for a completely preprogrammed robot picking. A particular form of these dimensionally precise feeders is known as tape-and-reel for feeding parts of relatively small sizes, which can be placed on tapes of standard width. For some devices that are large, heavy, ceramic, or have fragile leads, tapes are very expensive and impractical.

In general, the dimensionally specific pallets are well suited for large volume production where changes of part types are not frequent. The operational cost of the design-specific pallets includes packaging costs for transport, construction cost for pallet alignment, and engineering cost for new pallet designs.

Vision-Based Flexible Part-Feeding

For flexible manufacturing, where a large variety of product sizes and component types are encountered, the part-feeding system must have the ability to adapt to a changing product design without costly hardware redesign or time-consuming software reengineering. This need has been addressed as a general industrial vision-based bin-picking problem by several authors.

In manufacturing automation applications, the processing speed of acquiring and analyzing an image must be comparable to the speed of execution of the specific task. The attempt to duplicate human

perception by obtaining a three-dimensional detailed image of the part often calls for time-consuming computation and does not necessarily determine the location and orientation of a given part with the accuracy required for successful part acquisition by the robot. Moderate location inaccuracies pose no difficulty for human operators since they use vision, hand-eye coordination, and sense of touch to locate and correctly load the part.

However, if the orientation of the parts can be characterized by the two-dimensional object silhouette, retroreflective materials can be used as a background in generic part presentation (Lee and Li, 1991). Most surfaces on objects exhibit a combination of diffuse and specular reflection. A point on an ideal diffuse-reflecting surface appears equally bright from all viewing directions. Surfaces covered with papers and matte paints may be considered as reasonable approximations. An ideal specular reflector is one that reflects any incident light ray as a single ray in the same plane as the incident ray and the surface normal. The basic principle of the retroreflective vision sensing is to structure the surface reflectance of the pallet or the landmarks so that it is much brighter than objects generally characterized by diffuse or specular surfaces. In practice, a number of nonpredictable factors such as measurement noise, the uniformity of the surface reflectivity, and the uniformity of illumination, which occur on both the object and the background, can be eliminated by a relatively simple technique. If part design can be modified, brightly illuminated retroreflective landmarks can be intentionally created on objects for location tracking. Low cost landmarks could be incorporated in design by using retroreflective liquid paints on existing features. Alternatively, generic landmarks can be constructed by applying solid glass beads on the reflected surface of standard fastening devices such as screw heads.

14.10 Robot Manufacturing Applications

John W. Priest and G. T. Stevens, Jr.

Product Design for Robot Automation

Identifying automation opportunities early in product design is important because product design requirements to facilitate robotic manufacturing are often unique and must be integrated early in the product design process. Some overall manufacturing problems for using robots and some design solutions to resolve these problems are listed in Table 14.10.1.

TABLE 14.10.1 Design Solutions for Robots

Problems in Utilizing Robotics	Design Solutions to Assist Production
Location accuracy and repeatability	Design for vertical assembly; use chamfered edges for mating surfaces; tolerance leeway for mating parts
Part feeding and orientation	Design parts which can be easily fed, provide notches, guide pins, or slots for part orientation; select parts from vendors that will deliver in easy-to-feed packaging
Programming robot and associated equipment	Design simplification; use common parts for different products, part reductions; part families
Application problems with fasteners (screws, washers, and nuts)	Minimize the use of all fasteners; utilize snap fits where possible
Downtime caused by jams and misfeeds due to poor part quality	Select vendors that produce high-quality parts

Rossi highlighted the product designer's role in robotics stating this problem (Rossi, 1985):

> Often designs are made in such a fashion that one cannot access a certain area with a robot. Humans can get around obstacles and operate within those designs easily, but robots cannot because they are not quite as flexible as human beings. I think that this is the single most important item that has kept us from being further along than we are. What happens is that users try to apply a robot to something that's been designed without robotic assembly in mind. They usually run into a problem. Either the robot cannot handle it at all or the users find that they have got to put a lot of additional engineering design into a particular workcell, or perhaps into an end effector, in order to get around the problem. All this does is add to the price tag, and cost is very much in consideration when one is trying to sell these systems. A situation arises where robots are no longer attractive because of all the additional things that need to be done.

In summary, the product must be designed for the manufacturing process and the robot. For more information, the reader should review Boothroyd (1994), Bralla (1986), Priest (1988), and Tanner (1994). Table 14.10.2 shows some design rules for robotic assembly.

TABLE 14.10.2 Design Rules for Robotic Assembly

Product should have a base part on which to build assemblies in a top-down, straight-line motion direction
Base should be stable and facilitate orientation
Parts should be able to be added in layers
Use guide pins, chamfers, and tapers to simplify and self-align the layering of parts
All parts should accommodate handling by a single gripper and be comparable with popular feeding methods
Sufficient access is available for the gripper
Avoid the use of bolt-and-nut assembly
Parts should be able to be pushed or snapped together; when screws are necessary for repair, they should all be the same size
High quality parts are used
Vendors deliver parts that are compatible with the selected part feeder mechanism

Economic Analysis

Economic analyses for robotic applications are similar to those for any manufacturing equipment purchase and usually use minimum annual revenue requirements, present value methods, or break-even analyses. Since robots are a flexible method of automation, a unique aspect of robotics is manufacturing's ability to reuse the robot after its initial production run for other applications in later years. For many companies, this subsequent use of the robot can be shown in the economic evaluation. Some other unique benefits in robotic economic analysis that may be included are improved quality, higher precision, ability to run longer shifts, and reduced floor space. Unfortunately, some unique disadvantages of robot analysis are software integration complexity, inability to respond quickly to product design changes, and process reliability.

In general, there are several situations where robots are more likely to make economic sense. These are

A. Sufficient volume to spread investment costs over many units
   1. High volume
   2. Stable product design
   3. Multishift operations
B. Robot is used on more than one product
   1. Limited number of different products on same production line
C. Part handling problems occur when performed manually
   1. Parts that are very large, heavy, or bulky
   2. Parts that are very fragile or easily damaged
   3. Parts that are extremely small
D. Extremely difficult manufacturing process without using robot or automation
   1. Many processes, especially in electronics, cannot be performed without robots or some type of automation
E. Safety and health concerns of process
   1. Safety and health costs can be significant

The type of data concerning the robot system that is required for an economic analysis is shown in Table 14.10.3.

TABLE 14.10.3 Economic Cost and Savings for Robot Applications

Investment costs
Robot purchase price — for many applications this is a much smaller part of the costs than expected (25 to 45%)
Other equipment (part feeders, conveyors) — this includes the cost of hardware interfaces
Design of end effector, special fixtures, and other equipment — most applications require the design of a unique end effector and special fixtures
Software design and integration — can be a much higher cost than expected due to the complexity of interfacing different equipment controllers
Installation including facility modifications — usually a small cost for robot system
Technical risk — this is the risk of whether the system will perform up to the specifications in areas such as performance, quality, precision, etc.
Operating costs
Training — costs of training operators, engineering and maintenance personnel
Product design changes — cost required to modify the robotic software and hardware when design changes or modifications are made to the product
Operating, utilities, and maintenance — typical costs found for most manufacturing equipment
Savings
Direct labor — labor savings caused by the robotic system
Ergonomic and health — benefits of lower number of job injuries, workers compensation costs, and compliance with OSHA regulations
Quality — improved quality may result due to lower scrap and waste
Precision — robots can often perform tasks at a much higher precision (i.e., lower variability) than manual operations resulting in fewer defects and better product performance

Cost Justification for Robots

In this section an example of a robot justification study is presented. This example uses the discounted cash flow method resulting in the calculation of a rate of return (often referred to as the internal rate of return).

The rate of return, R, is defined by Equation (14.10.1) as

$$0 = \sum_{j=0}^{n} \frac{X_j}{(1+R)^j} = \sum_{j=0}^{n} X_j (P/FR, j) \tag{14.10.1}$$

where

X_j = the net total cash flow for year j
n = number of years of cash flow

Basically, the rate of return, R, is the interest rate that makes the sum of the discounted cash flows equal zero.

The net cash flows, X_j, in Equation (14.10.1) can be defined by Equation (14.10.2):

$$X_j = (G - C)_j - (G - C - D)_j (T) - K + L_j \tag{14.10.2}$$

where

G_j = gross income (savings, revenues) for year j
C_j = the total costs for year j exclusive of book (company depreciation and debt interest)
D_j = tax depreciation for year j
T = tax rate (assumed constant)
K = total installed cost of the project (capital expenditure)
L = salvage value in year j

A numerical example is now presented using the data given in Table 14.10.4. The values in Table 14.10.4 should not be considered representative. They are used only for example purposes.

TABLE 14.10.4 Data for Numerical Example

Project costs	
Purchase price of robot	= $40,000
Cost of end effector	= $10,000
Software integration	= $20,000
Cost of part feeders	= $10,000
Installation cost	= $ 4,000
	$84,000
Yearly operating costs	= $10,000
Yearly savings	
Labor	= $60,000
Quality	= $10,000
Tax rate	= 40%

The first question that must be answered is, what is the capital recovery period (life of the economic study)? In this example 3 years is used. The next question is, what is the yearly tax depreciation? This example uses MACRS (3 years). Therefore, the percentages used to determine the yearly tax depreciation amounts are those given in Table 14.10.5. It should be noted that Table 14.10.5 implies there are 4 years of tax depreciation. This is because the MACRS system uses a half-year depreciation convention. In this example, it is assumed there is sufficient taxable income from other operations that allow the use of the depreciation amount in year 4. In this example, the salvage value is assumed to be zero.

TABLE 14.10.5 MACRS Percentages

Year	Percentage
1	33.33
2	44.45
3	14.81
4	7.42

Using Equation (14.10.2), it is now possible to generate the cash flows shown in Table 14.10.6.

TABLE 14.10.6 Net Cash Flows

EOY	K&L	G	C	D	X
0	$84,000	—	—	—	84,000
1		$70,000	$10,000	$27,997	47,199
2		70,000	10,000	37,338	50,976
3		70,000	10,000	12,440	40,976
4	L = 0	—	—	6,224	2,490

Some sample calculations follow:

$$x_0 = -\$84,000$$

$$x_1 = (70,000 - 10,000) - (70,000 - 10,000 - 27,997)(.40)$$

$$= \$47,199$$

$$x_4 = -(-6224)(.40)$$

$$= \$2,490$$

With the cash flows in Table 14.10.6 the rate of return can be determined using Equation (14.10.1):

$$0 = -84,000 + 47,199(P/FR,1) + 50,935(P/FR,2) + 40,976(P/FR,3) + 2,490(P/FR,4) \qquad (14.10.3)$$

To determine R in Equation (14.10.3), a trial-and-error solution is required. Assuming 20%, the right-hand side of Equation (14.10.3) gives $15,619 and with 25%, it is $–17,262. Therefore, the rate of return, using linear interpolation, is

$$\begin{array}{cc} 20\% & \$15,619 \\ R & 0 \\ 25\% & -17,262 \end{array}$$

$$R = 20 + \frac{15,619}{32,881}(5)$$

$$= 22.38\%$$

This rate of return (22.38%) is now compared to a minimum acceptable (attractive) rate of return (MARR). If R ≥ MARR, the project is acceptable. Otherwise, it is unacceptable. It is pointed out that the definitions of cash flow and MARR are not independent. Also, the omission of debt interest in Equation (14.10.2) does not, necessarily, imply that the initial project cost (capital expenditure) is not

being financed by some combination of debt and equity capital. When total cash flows are used, the debt interest is included in the definition of MARR as shown in Equation (14.10.4).

$$\text{MARR} = k_e(1-c) + k_d(1-T)c \tag{14.10.4}$$

where

k_e = required return for equity capital
k_d = required return for debt capital
T = tax rate
c = debt ratio of "pool of capital" used for current capital expenditures

In practice, it is not uncommon to adjust (increase) k_e and k_d for project risk and uncertainties in the economic climate. There are other definitions of cash flow definitions (equity and operating) with corresponding MARR definitions. A complete discussion of the relationship between cash flow and MARR definitions is given in Stevens (1994).

Assembly

Assembly is projected to be the largest area of growth for robots. Key design goals for robotic assembly are to ensure high-quality parts, minimize the use of fasteners and cables, and provide accessibility so that parts can be easily fed and oriented by automated equipment. Designing to facilitate the use of robotics requires a review of their capabilities. Although assembly robots are often shown as stand-alone equipment, they require considerable amounts of support tooling and auxiliary equipment. These include part feeders, end effectors, special fixturing, and a material handling system. Except in the case of robots with vision or special sensors, parts with which the robot will interact must be precisely located and oriented. This may require additional tooling or special vendor packaging.

Assembly is defined as the combining of two parts into one entity. This combining process may include (1) the use of mechanical fasteners (i.e., screws, snap fits, rivets, etc.); (2) joining processes such as welding, brazing, soldering, etc.; (3) application of adhesives; (4) the simple process of placing two parts together to be joined together later.

Robotic assembly is the use of robots to perform one of these assembly processes. A typical set of tasks for robotic assembly using mechanical fasteners might be

1. Go to location (x_1, y_1, z_1) and grasp part A (assumed to be properly positioned and oriented).
2. Place part A in a fixtured assembly position (x_2, y_2, z_2, including proper orientation).
3. Go to location (x_3, y_3, z_3) and grasp part B (assumed to be properly positioned and oriented).
4. Place part B on part A (x_4, y_4, z_4) including proper orientation.
5. When an additional process is needed, fasten or join part A to part B using process tooling.

As can be seen in this simple list of tasks, developing robotic assembly system focuses on getting the parts to be assembled in the proper position and orientation and the combining process itself. Because of this, the rest of this section will describe the parameters of these two aspects: part feeding and presentation and the combining process.

Part Feeding and Presentation

Robot assembly requires the robot to go to a predefined location and grasp a part. The part may be positioned and oriented or it may not. Since a positioned and oriented part is preferred, part-feeding methods that can perform this task are desired. The most popular types are

1. Vibratory bowl feeders
2. Pallets and trays
3. Specialized feeders
4. Special vendor packages

5. Conveyors

Vibrating bowl feeders are one of the most popular methods due to the large number of parts that it can feed and its cost effectiveness. Pallets, in turn, are popular for many electronic parts and fragile parts where the part cannot withstand the forces found in a vibrating bowl feeder. Specialized feeders are those feeders that are usually designed for a particular type of part. These can include tube feeders, magazine feeders, and slides. Vendors can often provide parts in specialized shipping packages which keep the parts in the proper position and orientation. Finally, when the parts are delivered by conveyor, special fixturing and stops can often be placed on the conveyors to position/orient the part.

When the part is not positioned or oriented, additional sensors must be added to the system. Commonly used sensors are

Machine/robotic vision
Simple sensors such as photodiodes
Tactile/touch sensors

Robotic vision is becoming more popular in assembly as their purchase, software integration, and installation costs continue to decrease. Although most robot manufacturers offer vision systems as an option, they are still an expensive addition to the system. Simple on/off sensors can be used in certain cases when only limited data are required. Tactile sensors can sometimes be used to touch/feel the part to identify specific features of the part or to recognize its location.

Combining Process

After the parts are placed together, the combining process will often require the robot to perform some process operation. This can include an additional equipment such as a fastening gun for a screw, adhesive applicator and pump for a bonding operation, or a solder gun for soldering. Most robot manufacturers can offer equipment for the various types of assembly processes.

For more information on robotic assembly, the reader should review Asfahl (1992), Groover (1986), Klafter et al. (1989), and Sandler (1991).

14.11 Industrial Material Handling and Process Applications of Robots

John M. Fitzgerald

Replacing humans with robots to perform processes has often led to failure. The reason is that the robots are often mechanically capable of the manipulation while being incapable of process planning and control. Thousands of robot installations have failed because replacing the manual method with the automatic method lacked adaptability to process related variation. The human operators had been using their cognitive abilities to do the job. A vast majority of successful robot implementations past and present have a very important common aspect: repeated execution of fixed programs with little or no on-line modification of path or position.

Process robot planning and programming still usually require the efforts of highly skilled technicians. Often, complex programs cost too much and take too long. Continuously controlling and varying path manipulation parameters for real-time process control is difficult. Many processes are not known well enough to describe their control algorithmically. In a few applications sensors are becoming more common for adapting robot plans to changes in the environment. Setup, seam tracking, positioning, conveyor tracking, and now automatic programming for painting and finishing are becoming practical as sensor costs and computation costs continue to decline.

In this section robotic material handling and process applications are presented from an automation system perspective focusing on the robot's manipulation functions. Manipulation is considered a manufacturing material transformation and a transportation process factor. Programming and control are viewed as the means of integrating robot manipulation as part of the manufacturing process. The reader who is interested in a specific application is encouraged to first review the relevant process technology sections of this book.

Implementation of Manufacturing Process Robots

Manipulation as a Process Requirement

The starting point of automation system design is a thorough understanding of the process to be automated. Implementation of a process robot requires a focus on manipulation as a process factor. The pose and path requirements of the process are independent of the manipulator used.

It is useful to conduct a static spatial analysis of manipulation requirements and then examine the mechanical and dynamic requirements when designing or selecting a process robot manipulator.

A spatial description of the relative positions and orientations of the workpiece and tool during processing provides the basis for describing the required manipulation. *Tool poses* are graphed in an appropriate reference frame, usually the frame of the workpiece, or in the case of machine loading, the work holding fixture may be used. Path requirements are secondary for these applications. The path taken does not affect the process. For *continuous path processes* entire paths must be graphed or mapped. If continuous analytical descriptions of the path are not available, a sampling of discrete points along the required path can be used to represent the space occupied by the path. The result in both cases is a Cartesian mapping of spatial requirements of pose and path. A description of the pose and path precision requirements should be included. Next the mechanical and dynamic requirements are defined. Payload and force reactions at each position and along the path must be understood. Other important dynamic requirements such as acceleration and power should be quantified. The manipulation requirements are the basis for design and selection of both the robot arm and the controller.

Manipulation Capability of Process Robots

The basic mechanical capability of the robot mechanism to perform the manipulation work is determined by its mechanical structure, kinematic configuration, and drive mechanism. There are several applications including painting, palletizing, spot welding, and arc welding for which specific types of robot arm

designs have evolved driven by process needs. Although predisposed by design to perform a particular process, these robots have no innate process capability and are not guaranteed to perform in a specific application. Specifications of gross robot performance characteristics such as reach, *repeatability*, accuracy, and payload are usually readily available from their manufacturers. A well-defined set of process manipulation requirements when compared with published robot specifications usually isolates the field of mechanically qualified candidates. It is more difficult to characterize and evaluate a robot's capability for complex motion. The exact working of the robot's trajectory generation software is usually not known by end users and can only be evaluated by indirect testing. Acceleration and load capacity are usually specified, and there are some standard methods for specifying path performance, but the robot's dynamic behavior and performance are difficult to measure. Specific performance testing is usually required to prove manipulability for process robot applications.

Integration of Manipulation Control and Process Control

Achieving manipulator and process control integration depends upon robot programming and external data access. For any given application the required motion execution may be possible, but programming may be too difficult to be practical. Establishing that the robot is capable of coordinated motion can be done by reviewing the specifications or by conducting motion tests. As an illustration of the importance of programmability consider, for example, a situation in which a complex series of twisted curves define a robot tool path. If two robots with identical kinematic structure and joint trajectory generation capability differ in their programming in that one is capable of executing paths following user-defined mathematical functions and the other is only capable of executing paths defined by closely spaced taught poses, the difference in programming effort could easily amount to hundreds of hours. For each application encountered the programming methods must be assessed to determine if the required motion is programmable in a practical sense.

Access by process robot programs to external data is becoming more important. Although most process robots now work without any external process feedback, this is beginning to change rapidly with the development of improved low cost sensor systems and methods. Virtually all robots are capable of discrete digital and analog signal input and output. Most may also be equipped with standard serial and parallel communication capacity. If sensor information is to be used for set-up positioning or real-time path adjustment, the robot controller must have the communication and control to convert data into information that can be used to modify path and position commands. In cases of extreme path complexity, path planning systems external to the robot controller may be needed to create the paths. Testing will verify the ability of the robot controller to accept and execute externally generated motion sequence data.

Industrial Applications of Process Robots

Palletizing and Depalletizing

Many products are packaged in boxes of regular shape and stacked on standard pallets for shipping. Robots are commonly used to palletize and depalletize boxes because they can be programmed to move through the array of box positions layer after layer. Although palletizing is more common than depalletizing, there is no major functional difference in the manipulation requirements. Transport distances of several feet are common. Stack heights usually do not exceed 5 ft. Payload weight can be in excess of 100 lb. When standard servo-driven joint actuators are used accuracy and repeatability will usually be far better than the required box positioning precision.

Palletizing typically requires four axes of controlled motion — three for translation and a fourth for yaw to orient the box. Cylindrical coordinate robots are favored in palletizing because they have large vertical lift and a compact footprint allowing more of the floor area in the workspace for conveyors and pallets. When larger workspace is needed gantry robots must be used. Continuous duty cycles are not uncommon and robot power is important for maximizing throughput. The most technically demanding aspect of system design is the gripper. Vacuum grippers are popular for lifting boxes by their tops, but other more complex gripping methods are sometimes needed. Payloads must be carefully positioned

with respect to the robot's wrist and other links to balance gravitational and dynamic loading. Load shifting during high acceleration moves can result in dropping or mislocating the box.

Palletizing position arrays are usually taught or programmed relative to a corner or keystone box position as a reference so that the entire array can be shifted by redefining that one position. Programs are simple and easily modified to adapt to changes in box dimensions. Monitoring is done by checking the state of discrete proximity and vacuum sensors. A proximity sensor mounted on a gripper will indicate if an object is at an expected location; or the same simple proximity sensor may be used to stop the robot in the correct location to pick up a box from a stack of unknown height when the top of the box is encountered. Vacuum pressure switches are often used to verify acquisition by suction cup. A simple proximity switch can be used to signal the presence of an expected package at the pick-up point. With careful timing and additional sensor inputs, items can be transported to and from moving conveyors.

Packaging

Packaging is often a combination of palletizing and assembly-type actions. A collection of objects which may not be identical are inserted into a box or other container. The robot may also be required to assemble, place dunnage, seal, or mark the package. Insertion may simply require positioning the pack item over the opening of the package and dropping it. Boxes most often are supplied partially assembled, printed, and folded flat. Usually human operators or a special machine will open and prepare the box for packing; rarely will the robot be used for this purpose. Often the robot can be used to place cardboard layer separators, foam, or cardboard holding forms and other protective dunnage in the box. Finally, sealing and marking operations may be performed by the robot. Pack items may require complicated assembly-type motions such as rotations and curved moves to clear other packed items.

Three to six axes of motion may be needed. Packing items with a variety of sizes, shapes, and other varying physical properties into one package have the potential to complicate motion and tooling requirements. Grippers can be designed with multiple functions or they can be designed to be exchanged by the robot at tool storage racks. When material throughput is high, a single robot may be dedicated to each pack item. Simple programming methods are employed such as teach programming. Discrete sensors are useful for monitoring grip status of pack items.

Machine Tending: Loading and Unloading

Forges, stamping process, some machine tools, and molding machines are now commonly tended by robots. Historically these types of machines have been loaded by human operators. Now these jobs are considered to be too arduous and hazardous. An important benefit of robotic machine loading is improved product quality resulting from consistent machine cycles. Robots eliminate the inconsistencies of human-paced loading and as a result the cycle can be precisely repeated. For heated molding, stamping, and forging processes, part formation and release are sensitive to the thermal state of the machine. If a machine is left open for loading for differing amounts of time each cycle, significant cooling variations result in potential sticking and geometric flaws. When robots are used, the process can be tuned to the consistent robot loading cycle.

Machine loading is usually more demanding than other material handling applications because part orientation and placement are critical and may require locating mechanisms such as tooling pins and pads and/or sensor logic to guarantee interface between the robot and the serviced machine. Accuracy is usually not an important factor because the loading stations are permanently located in the robot workspace, but repeatability requirements may be as small as several thousandths of an inch. Payloads can range from a few ounces to several hundred pounds. Grippers for machine loading may also require tooling pins and pads to locate and orient parts and to mate precisely with the machine's part holding fixture. The gripper may dock with the holding fixture and then transfer the part when loading clearances are very tight.

The entire range of robot types, sizes, and configurations is used for machine tending. Articulated arm robots are needed when dexterous manipulation is required to transport parts through the maze of clamps and spindles and other protrusions and obstacles found on some machines or when part orientation

must change for loading. Applications where the robot is dedicated to loading a single part into a single machine in high volume production are not uncommon. Position programming is usually done by teaching. It is common to monitor discrete sensors in the gripper and the loaded machine to insure proper loading before cycling the process machine.

Sorting

Discrete parts are often sorted during production, usually as a condition of transfer to the next production station. The sort characteristics are usually distributed in some unpredictable manner so that individual inspection and handling are required. The diflference between sorting and other transfer or loading robot applications is that the disposition of the part is based on information gained during the sort. The robot must have the programming functions to support multiple preprogrammed path execution triggered by the logical sort outcome conditions.

Part Dipping

Many processes require controlled manipulation of parts temporarily submerged in some working fluid or coating material. Some common part dipping processes are the following.

Investment Casting. Intricately shaped and often delicate wax forms are coated with a slurry of stucco material which cures to form a mold. Later the wax is melted and drained from mold which can then be filled with molten metal. The dipping motion must be carefully controlled to prevent trapping bubbles and distorting the wax shape.

Solder Pretinning. Electrical contact pads and component leads are coated by dipping in molten solder as a preliminary step to assembly and soldering of the connections. A temperature-dependent flux reaction is required to achieve wetting by the solder so the robot must hold the component submerged in molten solder for a precise delay period. Speed of withdrawal is a major process variable for controlling the coating thickness of solder.

Conformal Protective Coating. Some electrical and mechanical components are dipped in liquid polymers to seal out moisture, air, and contamination. The viscosity of the polymer and the speed of insertion into the fluid must be controlled so that flow into small features occurs without trapping bubbles of air. Once submerged the component may be reoriented to several poses and to allow air bubbles to escape.

Quenching. Heat treating is a commonly used method of improving alloy properties. Various fluids are used as cooling baths. Controlling insertion and manipulation is important for control of cooling rate.

Dipping processes require precision of part insertion and withdrawal so velocity and acceleration must be programmable and repeatable. The stirring requirements may require the use of a two- or three-axis wrist in addition to the translation motion axes. Grippers may require special cleaning or cooling capability either on board or at service stations located conveniently in the robot's reach.

Resistance Spot Welding

Robotic spot welding (see Figures 14.11.1 and 14.11.2) is the most pervasive robot application in the automotive industry. Resistance spot welds are formed by tightly clamping steel pieces together with opposing contact electrodes and then passing a large amount of current through the joint, welding the metal while producing a spray of molten sparks along with loud noise. Then the joint is held momentarily until the weld solidifies. Welds are made at discrete positions by moving the robot-mounted gun to pretaught poses. The spot welding process parameters, pressure and temperature, are controlled with the separate gun controller. Weld location and therefore positioning of the gun are critical.

Dexterity, payload, and quickness are critical operational requirements for spot welding robots. Gun pose repeatability is critical for consistently locating weld joints. Access to joint locations is limited because both electrodes must reach the weld site while maintaining clearance between gun frame and workpiece edges. Large articulated arm robots are typically used for most spot welding applications because of the dexterity needed and because the weight of the welding gun and associated robot-mounted

FIGURE 14.11.1 Six-axis articulated arm robots spot weld automobile bodies on a transfer line. (Courtesy of Nachi Robotics, Ltd.)

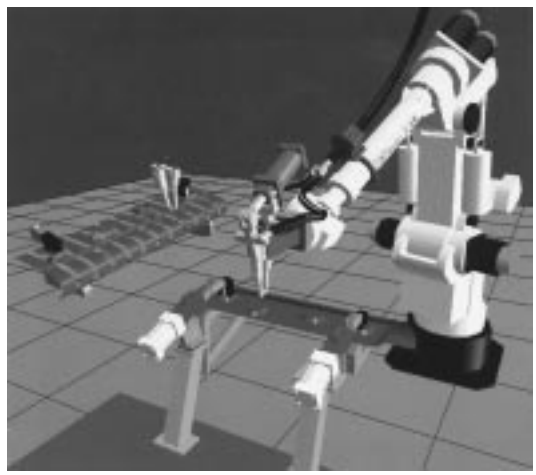

FIGURE 14.11.2 Spot welding operation simulated in off-line programming environment. (Courtesy of Deneb Robotics, Inc.)

apparatus often exceeds 200 lb. Fixed cycle programs are typical which may require several man-months to develop and less than a minute to execute. The robot spot welding path position names, path order, and control logic can be developed off-line, but lack of robot positioning accuracy characteristic of large articulated robots requires the weld positions for each individual robot to be taught by posing and recording them manually. This takes advantage of the robot's repeatability which is often orders of magnitude better than its accuracy. Unfortunately, when a robot that has been teach programmed is replaced by another robot, even an identical model, hours or days of teaching will be required to bring the replacement robot on line. Practical new PC-based calibration methods which eliminate this problem by effectively improving accuracy are now becoming commercially available.

Drilling

Hole drilling is a precision machining process. Most robots cannot hold a drill spindle rigidly enough to overcome the drilling reactions and most robots cannot generally move in a precise enough straight line to feed the drill. Drilling robots use special drilling end effectors which locate and dock onto the work piece or a fixture. The robot wrist and arm must be compliant and forceful enough to hold the drilling end effector firmly into location against the fixture or workpiece. Drilling end effectors have a spindle motor and a feed mechanism which execute a separately controlled drilling cycle while the robot holds the end effector in position.

The robot's only contribution to the process is to move the drilling end effector into its docking or holding place. Drilling robots have been used most successfully in the aerospace industry because airframe structures require thousands of holes to be placed precisely and in complex orientations. Manipulability requirements for drilling are similar to those for spot welding. The drilling end effector weight will tend to be less than a welding gun but tool holding force and reach usually impose the requirement for large robots.

Fastening

Robots are commonly used for applying threaded fasteners in the automobile industry for fastening wheels, and in the electronics industry for screwing components to circuit boards and circuit boards into chassis. Robots are also used for riveting in airframe fabrication.

Fastening is an end effector position-and-hold application. The robot does not follow the threaded fastener as it turns and travels into place; the end effector uses a slide or cylinder for that purpose. Automatic nut runners and screwdrivers and the associated hardware feeding apparatus are broadly available. Since a human is no longer operating the fastening tool other means of process control are needed. Usually fastener angular displacement, longitudinal displacement, and torque can be monitored and correlated with signatures or patterns characterized for specific fastener joints. Manipulator arm and control system requirements are similar to other position-and-hold applications. Very large torque may be encountered. Torsion bars or other static mechanisms are often needed to prevent the arm from being torque loaded.

Inspection

Robot inspection involves relative part/sensor manipulation to compare, measure, or detect a physical characteristic of the objective workpiece. Sensors used in robotic inspection include chemical detectors, computer vision systems, infrared detectors, sonar, laser radar, radiation detectors, capacitive proximity sensors, touch probes, X-ray cameras, particle/photon detectors, thread probes, and go-no go gauges. Robot inspection applications cover the range of manipulation from end effector position-and-hold to continues in-contact path motion. In some cases the kinematic structure of the robot is used as a spatial measuring device by incorporating surface sensors or probes in the last link as robot end effectors (Figure 14.11.3). The forward kinematic solution of the joint angle measurements sampled at a contact pose give the position in Cartesian space of the contact point. If the manipulator is stationary during the measurement then the robot's Cartesian positioning error must be added. If the robot is calibrated the error may be almost as small as the repeatability (0.001 to 0.020 in. for most industrial servo-driven

arms). If the arm is moving while measurements are made significant error may be added because of delay in sampling the manipulator joint positions.

FIGURE 14.11.3 Robots inspect pick-up truck body prior to final assembly. (Courtesy of Fanuc Robotics, N.A.)

Programming considerations are critical because robot inspection often requires data collection at a huge number of discrete positions. When CAD data are available, off-line programming of inspection may be possible, particularly for position and sense-type inspections. Sensor tool pose requirements can be quickly and accurately defined in the CAD environment and the pose data transformed into robot workspace coordinates. When hundreds or thousands of inspection poses are required manual teach programming may be too time consuming and cost prohibitive, especially when a mix of different parts must be inspected.

Paint and Compound Spraying

Paint spraying is a major application in the automotive industry. Painting booths are hazardous because the paint material is often toxic, carcinogenic, and flammable. Human painters often wear required protective clothing and breathing equipment. The paint fan projecting from the arm-mounted spray gun must be manipulated smoothly along paths that are often curved and complex.

Most robots used for painting are especially designed for that purpose. They usually have large reach, small payloads, and repeatability is usually larger than that of other types of robots and may exceed ±0.010 in. Painting robots are typically six DOF articulated arms, often with supplemental axes to pitch the paint gun and to traverse alongside a moving line. The potential for ignition of solvents and suspended particles may require taking precautions to eliminate ignition sources associated with the sparking of motors and other electrical components. Until brushless DC motors became commonly available for robot actuation virtually all painting robots were hydraulic because of the motor sparking problem. Lead-through teaching (also called teach-playback) is typical for painting. Off-line programming of painting is becoming more popular and some special software packages are available. Figure 14.11.4 shows an image from a simulation used in validating painting robot motion programs. Some compound spraying is done with smaller general-purpose robots, for example, spraying of protective coatings in the electronics industry. Circuit boards may require unexpected dexterity in order to point the spraying nozzle correctly to coat board features.

Compound Dispensing

Compound dispensing refers to laying a bead of fluid material on a surface. Application examples include caulking car bodies, sealing windshields, placing solder masking on circuit boards, gluing subassemblies,

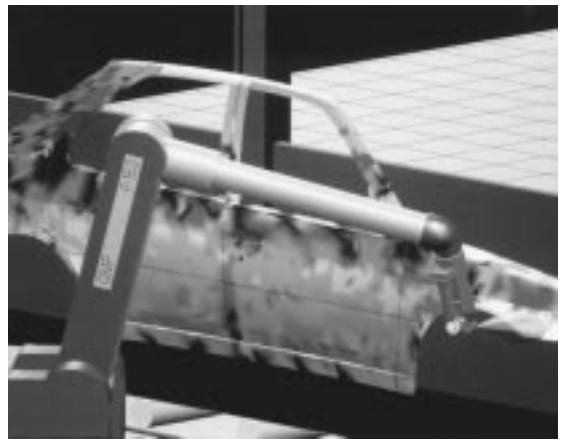

FIGURE 14.11.4 Painting operation simulated in off-line programming environment. Estimated paint thickness is illustrated by shading. (Courtesy of SILMA, Inc.)

solder paste dispensing, and decorating candies and cakes. Precision of placement and amount is critical. Smooth controlled paths are often essential. Position accuracy and tool path velocity accuracy are both important requirements.

All types and configurations of robots are used for dispensing. Many applications require only three DOF. When obstructions must be maneuvered around to gain access to the dispense locations, five or six DOF are needed. Payloads are usually small. Dispense speed may be limited by either the robot's ability to track a path at high speeds or by the dynamics of the dispensing process. In automotive applications the fixed cycle mode of operation is common. A robot program to lay a bead of sealer along the edge of a windshield is a taught path requiring good dynamic path repeatability of the robot. In electronic circuit board fabrication and decorating cakes, each workpiece may have a different dispense pattern; teaching paths are not practical in this situation. Some method of off-line programming must be used.

Cutting

Many engineering materials are produced and supplied as stacked or rolled flat plates or sheets. Further fabrication can require forming and/or cutting these materials into precise shapes. Robots are frequently used to manipulate a variety of cutting tools along paths that are often complex and curved. Many cutting processes are also used to produce fine features such as holes and slots. Common robotically manipulated cutting processes are listed below.

Laser. Molten metal heated by collimated intense light is blown away by a gas jet. Most common use is for thinner metals (0.50 in. or less) and on a variety of other thin materials.

Waterjet. A high velocity water jet is formed by forcing very high pressure water through a small orifice in the range of 0.008 to 0.040 in., which can cut a variety of nonmetals.

Abrasivejet. After a high velocity water jet is formed it passes through an abrasive mixing chamber where abrasive particle are entrained in the jet. A variety of metals and other tough and hard materials can be precisely cut; many materials can be cut with good control up to 1.0 in. thick. Cut thickness in excess of 6.0 in. has been reported.

Plasma Arc. Molten metal heated by an electric arc is blown away by a gas jet. Plasma arc cutting is commonly used to cut patterns in plate steel.

Router. A rotary cutter is most often piloted either on the workpiece or a guide fixture for precise trimming or chamfering edges of plate and sheet material.

Knife. A variety of knife types, some ultrasonically assisted, are employed to cut mostly nonmetals.

The cutting tool path and pose must be precisely controlled to achieve accurately patterned piece parts. The demands on manipulator performance are primarily determined by the interaction of desired part geometry, material thickness, and material properties. Feed rate, tool stand-off, beam, jet, and arc angle are all cutting process control variables which must be adjusted to material characteristics for good results. An extreme case of cutting manipulator performance demand is the combination of thin easily cut material with complex shape, and small geometric tolerance. This requires high speed coordinated motion of five or more axes which must be kept on track. This translates to a requirement for high performance servo-control elements in order to achieve high rates of mechanical response and joint angle position and velocity precision. Some type of advanced programming method such as a CAD/CAM may be required for high part mix applications. When extreme precision and complexity are required, as in many aerospace applications, precision fixtures incorporating tool guides may be used to force the tool path to repeat with near-zero deviation. In the case of contact tools such as routers and wheel knives the end effector must be capable of bearing preload forces applied in excess of the tool reaction forces to eliminate tool bounce-induced path errors.

Equipment and tooling for many of the robotic cutting processes may be complex and expensive. End effectors can easily cost tens of thousands of dollars and require difficult and cumbersome wiring and plumbing. Routing of laser wave guides and high pressure tubing for water jets from power source to robot end effector requires skill and experience in both design and installation.

The majority of cutting robots are three-axis natural Cartesian machines specially designed to cut flat sheet materials. Cutting speed and accuracy performance are aided by their easily calculated kinematics and easily predicted dynamics. Path planning and path generation are also simplified with flat parts. CNC is commonly used, and many automatic nesting and path programming software systems are readily available. There is some use of tool position sensors for part location during setup. In-process sensor-based tracking for edge cutting has been implemented with success, but is rare. Several five-axis gantry-style machines have been implemented for cutting complex aerospace materials including impregnated broadcloth patterns and composite wing skins. Articulated arm robots may be used when less precision is needed, as in trimming automobile carpet or making cut-outs in large plastic moldings.

Arc Welding

Arc welding is a metal joining process that uses intense heat produced by an electric arc between an electrode and the metal parts being welded. The weld pool and arc are always shielded by inert gas or a chemical vapor. In gas metal arc welding (sometimes called metal inert gas welding), which is the most common robotic arc welding, an electrode of filler metal wire is fed through a gun into the weld pool site as the robot manipulates the gun along the weld path. The hazards of arc welding include: intense ultraviolet, visual band and radio frequency radiation, toxic fumes, and noise. The pose (position and orientation) of the welding gun with respect to the joint or seam is a major arc control parameter. The feed rate of the gun is important in control of penetration and other weld characteristics. Unlike spot welding, manipulation is an arc welding process control variable.

Most arc welding robots operate in fixed cycle mode, which means they execute or play back a programmed sequence. If assemblies are presented to the robot with consistent seam geometry, then the path can be taught once, stored, and then executed repeatedly for each assembly. Given that all other relevant process variation is within accepted limits, the system will produce satisfactory output. However, weld seam position and seam shape variations may influence the process, especially in larger assemblies. When there is variation in the upstream sizing, cutting, fit-up, and jigging of weld assemblies, the location and orientation of the weld seam will vary. Also, as the weld progresses, localized thermal expansion and residual stresses can force seam distortion. A range of methods for adapting the robot system to these variations exists, from correcting pretaught path plans at setup time, through actively altering robot motion in “real time.” A sustained high level of academic and commercial research and development effort has resulted in practical methods of automatic weld seam tracking and process control.

Rapid deployment in recent years is a direct result of sensor integration for seam tracking Seam tracking methods correct the path to compensate for errors in location and orientation of the welding tip based on sensor data. Commonly used sensors include mechanical probes, computer vision, laser edge detection and ranging, and arc current and voltage. Because of the extreme environment of the region surrounding an active welding tip, sensors are often housed in protective chambers. Typically the errors are measured and calculated in a convenient reference frame in the three-dimensional workspace of the robot system, the same space in which the tool path is described. In some cases the error is measured by tool-mounted sensors relative to the moving reference frame of the tool. The preprogrammed path is then shifted by mathematical transform in the reference frame of the tool. An important aspect of seam tracking is the use of sensors to detect the sides of the weld channels as boundaries for automatic side-to-side weaving. This is usually done with "through-the-arc" sensing in which arc current is monitored as an indicator of clearance between the welding tip and the channel edge. While tracking in the direction of the seam, transverse motion commands are given so that the tip approaches one edge until the edge is sensed and then the motion is commanded in the direction of the other edge. Weld penetration, filler deposit amount, and weld bead shape can be controlled in-process by variable control of the welding speed or feed rate. Arc welding robot systems which use sensors to adjust the robot path in real time (computation is fast enough to respond to sensor data with useful path adjustments) are among the most advanced or intelligent robotic applications found in practical industrial use.

Robots used for arc welding must be capable of precisely executing taught paths. Motion must be smooth and precisely controlled. Velocity control is important but the speeds required are not high, 2 in./sec, while welding is faster than most applications require. Higher velocities are important to reduce cycle time for applications with lengthy arc-off motion. Welding robots must have good reach and dexterity. Five DOF is required as a minimum and six DOF adds to gun maneuverability. There is normally no forced contact with the weld seam and the welding gun's weight is usually less than 20 lb, so robot payload requirements are light. If real-time path altering is required, the robot's motion generation functions must have programmable interfaces with the sensor systems. The robot's controller must have a means of accepting data and manipulating it for use with high level functions in the robot's native programming language.

Finish Machining

Few material-forming processes produce finished parts. Most machining operations leave burrs and sharp edges. Large aircraft wing skins are milled by three-axis terrace cutting leaving small steps which must be blended to prevent fatiguing stress concentrations. Complex curved surfaces like ship propellers and aircraft landing gear are machined with rounded milling tools which leave a pattern of tool marks which must be ground off. Cast parts require gate and sprue removal and deflashing. Many parts must have their surfaces conditioned for appearance or subsequent plating and coating operations. Stamping and forging of automobile door panels and engine components leave "imperfections" which are finished out by hand. Die cast surfaces of hardware for door handles, faucets, furniture, and appliances are ground and polished. Finishing removes material to reduce waviness, reduce roughness, remove burrs and sharp edges, and to remove flaws. Manipulation is a finish machining process control variable. Tool pose, applied pressure, feed rate, and tool path must be controlled. Smaller parts are finished using fixed-floor or bench-mounted tool stands. For larger work pieces the finishing tool is mounted on the robot. Finish machining is very demanding of the manipulator because continuous path control is required while maintaining contact between part and tool.

Medium- to large-sized robots are usually required for surface finishing because end effector weight and tool reaction force are additive when calculating payloads. A further margin of payload is usually required to offset the fatiguing effects of vibration and cyclic loading from tool reactions. Tool point positioning accuracy is less important than tool orientation and feed rate. In general, higher rates of surface curvature will require greater robot path precision. Six DOF robots are often required. Edge machining tool paths are constrained by burr geometry, finishing tool characteristics, end effector geometry, and part geometry. A single part may have edge features in several directions and orientations.

The robot may require an assortment of different tools and a tool changer to reach all edges. If these measures do not allow access then multiple setups may be needed to present all features for finishing.

Most robotic surface finish machining applications use compliant abrasive processes. Force control is required in some applications to keep tool pressure constant. Force controllers are most often incorporated in the end effector or in the tool stand. Figure 14.11.5 shows a robot equipped with a force-controlled finishing end effector using a servo-controlled pneumatic actuator that is capable of applying consistent tool pressure. Through-the-arm robot force-control is available from some robot manufacturers, but its usefulness is limited to applications requiring slow feed rates because of slow mechanical response.

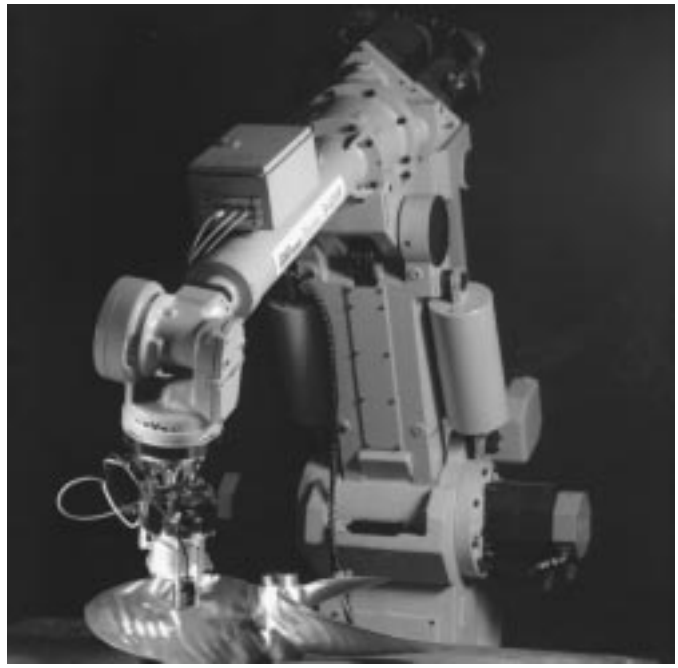

FIGURE 14.11.5 Robot equipped with force-controlled end effector grinds tool marks from ship propellor. (Courtesy of The Automation and Robotics Research Institute, The University of Texas at Arlington.)

Path planning and programming of edge and surface finishing for complex-shaped parts can be very difficult and time consuming. Both tool position and tool pose are critical in obtaining the correct tool contact area. Tedious paths programmed using the teach method require hundreds of hours to develop because of the large number of taught points. Generating the path control sequence is a major problem in manufacturing operations which produce a variety of complex-shaped parts. An example is in polishing large asymmetric-shaped aircraft skin panels. A more difficult automation problem is robotic spot finishing of flaws and other anomalous regions of the part surface when their location and extent are not known before set-up time. The reason is that the paths must be planned, generated, and executed on-line. This type of motion generation system requires part modeling and computational functions not available on most robot controllers. Figure 14.11.6 shows an operator digitizing a part surface to be modeled in preparation for automatic path generation by the PC.

14.12 Mobile, Flexible-Link, and Parallel-Link Robots

Kai Liu

This section will discuss nonstandard robots, including mobile robots, lightweight flexible-link robots, and parallel-link robots. These robots are often more suitable than standard serial-link commercial robots for certain applications.

Mobile Robots

Traditionally, standard robots are fixed in position. They are mounted on a rigid base and bolted to the floor so that they can withstand the forces and torques applied when the arm manipulates objects. However, fixed-base robots cannot cope with a large variety of applications in which a robot will operate in large and unstructured domains. A special type of manipulator, that is, a mobile robot, is often required in these applications.

In tomorrow's flexible manufacturing system (FMS) environment, mobile robots will play an important role. They will transport parts from one workstation to others, load and unload parts, remove undesired objects from floors, and so on. In addition to indoor mobile robots, there are some other outdoor occasions where mobile robots may take on heavy responsibilities. Examples include construction automation, military missions, handling of harmful materials, hazardous environments, interplanetary exploration, and so on.

Classifications of Mobile Robots

Mobile robots can be classified by driving mechanism as wheeled mobile robots, legged mobile robots, and treaded mobile robots. Some other types of mobile robots, for instance, the *underwater mobile robots*, the *autonomous aerial mobile vehicle*, and so on, are also available but are not included in this discussion.

Wheeled Mobile Robots. Mobile robots using wheels for locomotion are called *wheeled robots*. Two driving configurations are used in today's wheeled mobile robot — steer-drive and differential-drive. The former uses two driving wheels to make the vehicle move forward and backward. The heading angle is controlled by an independent steering mechanism. Since the driving action is independent of the steering action, the motion control of the vehicle is somewhat simplified. However, due to physical constraints, this configuration cannot turn in a very small radius. This shortcoming makes it less attractive in some industrial applications. Differential-drive configuration mobile robots, on the other hand, have two independent driving wheels positioned at opposite sides of a cart base, arranged parallel to one another. Their speeds can be controlled separately. Thus, by appropriately controlling the speed of each driving wheel, this mechanism is able to drive the vehicle forward and backward, as well as steer its heading angle by differential speed commands. Even though this configuration requires a somewhat more complex control strategy than the steer-drive configuration, its capability of making small-radius turns, even making turns on-the-spot, makes it the first choice in many industrial applications.

Some commercial wheeled mobile robots include the *CyberGuard Autonomous Survelliance Robot* manufactured by Cyberworks Inc., Canada; *B12 Mobile Robot Base* manufactured by Real World Interface, Inc., Dublin, NH; *LabMate Mobile Robot Platform* manufactured by Transitions Research Corporation, Danbury, CT; and *R-20 Mobile Robot* manufactured by Arrick Robotics, Euless, TX.

Legged Mobile Robots. While most mobile robots use wheels for locomotion because of the simplicity of the moving mechanism design and control, some other mobile robots use legs for locomotion. These types of mobile robots are called *legged robots.* The primary advantages of legged robots include their ability to traverse rough terrain with good body stability and minimal ecological damage. In order to maintain good stability, it is sufficient that at any time there are three points in contact with the ground. Therefore, most legged robots use at least four legs, or even six or eight legs. As long as the legged mobile robots' center of gravity is within the triangle formed by the three contact points, stability is

guaranteed. Compared with the wheeled robots, the control of legged robots is much more difficult. Much has been learned about multilegged locomotion from studies of balancing and hopping on a single leg. In particular, biped running can be viewed as successive hopping on alternating legs, since both legs never contact the ground simultaneously. Some examples of legged mobile robots include *ODEX I* manufactured by Odetics.

Treaded Mobile Robots. Another type of mobile robot, the treaded robot, moves much like a tank. An example of the treaded robot is the *ANDROS MARK V* manufactured by REMOTEC, Inc. at Oak Ridge, TN. It is something of a hybrid between a walking and a rolling vehicle. *ANDROS* can ascend/descend 45° stair/slopes by lowering its front and rear auxiliary tracks. It has all-terrain capabilities that are ideal for performing missions in rough outside terrain or in rubble-strewn, damaged buildings.

Sensors and Measurements

To navigate in unknown and unstructured areas, the mobile robot must have the capability of sensing the real world, extracting any useful information from the data acquired, and interpreting the information to understand the environment surrounding it, especially the situation in front of it. Several sensor systems for mobile robot navigation have been reported in the literature (Elfes, 1987). Of these, stereo vision systems and active rangefinding devices are the most used sensor systems. The former extracts range information from pairs of images to build a 3D world map. However, due to the high computational expense — a 3D map may require 1 min to generate — stereo vision systems have not to date been generally used for real-time navigation control. Active rangefinding devices do not suffer from this problem because they can deliver range information directly

Two kinds of rangefinding devices are available: laser rangefinders and ultrasonic range transducers. Even though laser rangefinders can provide fast response with high resolution, a relatively long measurement range, and high measurement precision, the required systems structure and configurations are very complicated, which makes the system itself very expensive. On the other hand, sonar systems are simple and low cost (probably orders of magnitude less expensive than laser-based systems), though the measurements have lower resolution and lower precision.

Determining range by means of sonar systems is a simple process. A short burst of ultrasonic sound is first transmitted by an ultrasonic range transducer, then an echo is expected to be received by the same transducer. If in a reasonable time period no reflected signal is detected, it is assumed that there are no objects in the area of interest. Otherwise, the time for round-trip propagation is determined and the distances to any objects are calculated. The transducer yields a 3-dB full angle beamwidth of 50 KHz at approximately 12 to 15°, depending on the signal frequency and transducer diameter. Thus, to scan the whole area surrounding the mobile robot, at least 24 to 30 transducers, of which the transmit/receive axis lies in the same horizontal plane, are needed.

Vision systems, also sometimes useful in robot sensing, usually consist of one or more video cameras and an image processor. The vision system can provide the richest source of information, which is, in fact, needed in certain applications such as road following, object identification, and so on.

Feedback from rotary and linear actuators used in wheeled and/or legged mobile robots is provided by position sensors and/or velocity sensors. This information is then processed for estimating position and orientation of the mobile robot in world coordinates.

By far the most commonly used position sensor is the *optical encoder*, which uses marks to indicate position. The typical encoder has a track for each binary digit of information. The encoder is mounted on the servo motor. When the motor rotates certain degrees, the absolute rotation position of the axis can be read from the digital output of the encoder. The resolution of the encoder is equal to $(360/2^n)$ degree, where n is the number of tracks. If an 8-track encoder is used, then a 1.4°/step resolution can be attained.

Other types of position sensors used in mobile robot systems include synchros, resolvers, potentiometers, linear variable differential transformers (LVDT), rotary variable differential transformers (RVDT), amplitude-modulated laser radars, and laser interferometers.

Conventional servo design requires that the servo controller include a "velocity term" in its transfer function. Without the velocity term, a servo system will usually exhibit an undamped, resonant behavior and can be highly unstable. In principle, the signal from a joint position sensor can be electronically differentiated to obtain joint velocity. However, if the joint position sensor has a noisy output, differentiating the position sensor signal can effectively magnify the noise sufficiently to make the servo system unstable or unreliable. To overcome this difficulty, several velocity sensors are available for directly measuring the joint velocity. A *DC tachometer* system consists of a voltage meter (or a current meter) and a small DC generator (sometimes called a "speed-measurement generator"). The latter is usually constructed with a permanent-magnet stator and a multipole wound armature. The armature is connected directly to the rotating shaft of the servo motor which is used to drive the manipulator joint. When the small permanent magnet DC generator rotates with the servo motor, its output voltage (when driving a high-impedance load) varies in proportion to the rotation speed of the armature. Voltage output variations can then be translated into speed changes or used as a feedback signal to control the robot arm velocity.

Supplementary position and orientation information can also be supplied by inertial guidance sensors, terrestrial magnetic field sensors, or inertial reference systems (IRS).

Navigation

Autonomous navigation of mobile vehicles has been studied by many researchers. In Elfes (1987), a sonar-based navigation system for an autonomous mobile robot working in unknown and unstructured environments was developed. The workspace is classified into "probably empty regions," "somewhere occupied regions," and "unknown regions" based on the interpretation of the data obtained from the sonar system. In this scheme, as more and more data are received, the first two regions may increase, and the uncertainty of these regions also decreases. It is reported that after a few hundred readings, a sonar map covering a thousand square feet with up to 0.1-ft position accuracy can be made. Another navigation scheme uses a stereo vision system to control a mobile base autonomously operating in a complex, dynamical, and previously unknown environment. A pair of stereo cameras is mounted on the mobile base to generate a symbolic world model. Based on this model, the desired trajectories are specified for the driving motors.

Although the schemes described above work well in specific environments, path planning and navigation control are always separated into two isolated issues. The path planning mechanism designs a smooth path from an initial position to a goal position by providing profiles of position and velocity, or profiles of position and heading angles, in Cartesian space. It assumes that perfect knowledge of the system dynamics and the environments is always available and that the position and orientation of the vehicle are measurable absolutely. After the desired trajectories have been designed, the navigation mechanism will take charge of driving the mobile robot to follow the prescribed trajectory as closely as possible. Even though each mechanism may work well through closed-loop control, the whole navigation system is an open-loop system. Static path planning strategies do not provide the essential adaptability necessary for coping with unexpected events. The success of navigation control depends mostly on the accuracy of absolute measurements of position, velocity, orientation, and their rates of change. All of these must be measured in (or transformed to) Cartesian space. This is a very expensive and difficult job.

Other possible closed-loop navigation control schemes use intelligent control techniques, for instance, fuzzy-logic control. In such a control scheme, the path-planning mechanism and trajectory-following mechanism are often integrated, not separated. The path is planned dynamically and is always up-to-date. All the information that the system needs to know such as "where is the goal (the dock)," "what is the required final orientation (the docking angle)," "what is the present orientation (the present heading angle)," "what is the present distance between the car and the goal," "what is the present distance between the car and any obstacles," "what is the safe turning radius (the minimum curvature radius)," and so on is easily captured through sensing the environment surrounding the car using onboard sensors (e.g., sonar) that yield relative information.

The advantages of such intelligent control strategies are evident. They unite navigation and maneuvering into a single set of algorithms. Full and accurate knowledge of the system dynamics is not required. The only knowledge needed are the correlations between the control actions (acceleration, steering, etc.) and the performance ("behaviors") of the system. The absolute measurement of the position and velocity in Cartesian space is not required. Only information about relative locations is necessary, and this is always available. Tight coupling between sensor data and control actions provides the adaptability necessary for coping with unexpected events. Actually, there is no path planning to be performed; the driving mechanism reacts immediately to perceived sensor data as the mobile robot navigates through the world.

Flexible-Link Robot Manipulators

Most robots used in today's manufacturing systems are rigid-link manipulators. Making the robot links and drives extremely stiff to minimize vibrations allows rigid-link robots to track a desired trajectory with very high degree of accuracy, often using standard classical (PID) control schemes. However, the price paid for this includes heavy manipulators, a low payload-weight-to-arm-weight ratio, high power consumption, and slow response rates to motion control commands.

With the growing demand from industry automation for lower manufacturing costs, higher motion speeds, better performance, and easier transportation and setup, the rigid-link manipulators may, sooner or later, be replaced by some sort of lightweight mechanical structures, such as flexible-link robots. While lightweight flexible manipulators have certain inherent advantages over rigid-link robots, they impose more stringent requirements on system modeling and controller design because of the vibrations of the flexible modes.

Modeling of Flexible-Link Robots

One essential step toward successful control synthesis is to obtain an accurate dynamic model for flexible-link manipulators. The flexible manipulator dynamics can be derived on the basis of a recursive Lagrangian assumed-modes method (Book, 1984). The motion of robots with link flexibility is governed by partial differential equations that must be satisfied inside a given domain defining the flexible structure, and by boundary conditions to be satisfied at points bounding this domain. Therefore, the dynamic model of flexible-link manipulators consists of highly coupled nonlinear integro-partial differential equations. Control of a structure using a formulation based on partial differential equations is extremely difficult. To reduce the complexity of the model, the assumed-modes method is used to produce a set of nonlinear ordinary differential equations based on an orthonormal series expansion of the flexure variables.

A solution to the flexible motion of links is obtained through a truncated modal approximation, under the assumption of small deflections of the links. The dynamic equations of motion for an *n*-degree-of-freedom manipulator with up to *m* flexible links can be written as

$$\mathbf{M}(\mathbf{q},\delta)\begin{bmatrix}\ddot{\mathbf{q}}\\ \ddot{\delta}\end{bmatrix}+\mathbf{D}\left(\mathbf{q},\dot{\mathbf{q}},\delta,\dot{\delta}\right)\begin{bmatrix}\dot{\mathbf{q}}\\ \dot{\delta}\end{bmatrix}+\begin{bmatrix}0 & 0\\ 0 & \mathbf{K}_f\end{bmatrix}\begin{bmatrix}\mathbf{q}\\ \delta\end{bmatrix}+\begin{bmatrix}\mathbf{F}_r(\mathbf{q},\dot{\mathbf{q}})\\ 0\end{bmatrix}+\begin{bmatrix}\mathbf{G}_r(\mathbf{q})\\ 0\end{bmatrix}=\begin{bmatrix}I\\ \mathbf{B}_f\end{bmatrix}\tau$$

where $\mathbf{q} = [q_1\ q_2\ \ldots\ q_n]^T$ is the vector of rigid joint variables, $\delta = [\delta_1\ \delta_2\ \ldots\ \delta_m]^T$ is the vector of deflection variables, $\mathbf{M}(\mathbf{q}, \delta) \in R^{(n+m)\times(n+m)}$ is the inertia matrix, $\mathbf{D}(\mathbf{q},\dot{\mathbf{q}},\delta,\dot{\delta}) \in R^{(n+m)\times(n+m)}$ contains both rigid and flexible coriolis/centripetal terms and terms representing the interactions of the joint rigid variables with the deflections, $\mathbf{K}_f \in R^{m\times m}$ is the stiffness matrix, $\mathbf{F}_r(\mathbf{q},\dot{\mathbf{q}}) \in R^n$ is the friction, and $\mathbf{G}_r(\mathbf{q}) \in R^n$ is the gravity term. The control input is $\tau \in R^n$ and the input matrix $[\mathbf{I}\ \mathbf{B}_f]^T \in R^{(n+m)\times n}$ is generally a function of $(\mathbf{q}, \delta)$ depending on the boundary conditions (e.g., pinned-pinned, pinned-free, clamped-free) chosen by the designer. Note that the coriolis/centripetal matrix $\mathbf{D}(\mathbf{q},\dot{\mathbf{q}},\delta,\dot{\delta})$ can take several different definitions. However, among these definitions, there exists one such that the derivative of the inertia matrix $\mathbf{M}(\mathbf{q}, \delta)$ and the coriolis/centripetal matrix are related in a very particular way, that is, $\dot{\mathbf{M}}(\mathbf{q},\delta) - 2\,\mathbf{D}(\mathbf{q},\dot{\mathbf{q}},\delta,\delta)$ is *skew symmetric*, a property that is often very useful for controls design.

It is important to realize that the rank of the control effectiveness matrix rank ($[\mathbf{I}\ \mathbf{B}_f]^T$) *is* less than ($n + m$), that is, *rank* ($[\mathbf{I}\ \mathbf{B}_f]^T = n < (n + m)$. This means that the number of degrees of freedom is greater than the number of control inputs and is the major source of the problems in controlling flexible-link manipulators.

Control of Flexible-Link Robots

Control of mechanical manipulators to maintain accurate position and velocity is an important problem. Rigid-link manipulators are designed to be mechanically stiff precisely because of the difficulty of controlling flexible members. The major objectives in control of a robotic system with link flexibility are to command the tip of the flexible-link manipulator to move from one position to another as quickly as possible (point-to-point minimum-time control), or to follow preplanned desired trajectories (trajectory-following control) while keeping the oscillations of the flexible modes as small as possible. The inherent large nonlinearities of flexible-link manipulators make their control very difficult. The link flexibility makes the robot arm itself sensitive to external excitation; a small impulse signal may cause the flexible modes to oscillate wildly.

Several conventional control techniques have been studied by robotics researchers for the control of flexible-link manipulators. They fall into different categories. The first category includes some approximate techniques such as linear systems approaches, linear minimum-time control, decentralized approaches, and input-shaping techniques. Conventional control techniques cannot usually obtain very satisfactory results for fast desired motions.

The second category includes some new control approaches that take into account many of the nonlinearities. Among them are variable structure control, adaptive control, and the inverse dynamics approach (where the whole control signal is composed of a causal part and an anticausal part). To minimize residual vibrations, several constraints must be applied for the desired tip trajectories. As pointed out in Kwon and Book (1990), for a specified rigid mode trajectory, there is associated a unique flexible mode trajectory. The interactions between the desired rigid motion and the associated required flexible motion (e.g., the inverse dynamics) are very complicated and parametrically sensitive.

Since the number of independent control inputs is less than the number of the output variables in the case of flexible-link arms, the control problem is characterized as having *reduced control effectiveness.* The so-called "model matching conditions" do not hold, and the conventional control techniques usually used in the control of rigid-link robots (e.g., computed-torque control) cannot be directly applied to the control of flexible-link arm. This problem can be solved by a model-order reduction based on a singular perturbation strategy, in which the rigid modes are treated as slow-state variables, while the flexible modes and their time derivatives are treated as fast-state variables. Another approach is the "reduced-order computed torque scheme" that first removes the nonlinearities that are in the range of the control input matrix, then uses PD state-feedback loop to convert the flexible system to a set of uncoupled point-mass-like systems.

A third category of controllers includes various intelligent control schemes such as neural networks (NN) (Lewis et al., 1995) and fuzzy logic control (FLC). Many of the drawbacks mentioned above can be overcome by either FLC or NN control if these are used in conjunction with sound control engineering design practices (e.g., singular perturbation and/or feedback linearization techniques). The reason is obvious: FLC and NN are *model-free* control schemes applicable to a wide range of dynamical systems that are ill understood and ill defined. The primary reason for this model-free characteristic is the 'universal approximation property, shared by NN and FLC. Thus, by careful design, effective control actions can be generated without extended analyses based on a precise, explicit mathematical function.

Parallel-Link Robots

By far the most widely used commercial robots are the serial-link manipulators, whose links and joints alternate with one another in an open kinematic chain. This serially connected configuration is similar to that of the human arm, with each link connecting only to two neighboring links through either prismatic

or revolute joints, except for the last link which attaches to the end effector and the robot base which attaches to the floor. The advantage of the serial chain structural arrangement is that it provides a large work volume and dexterous manipulability; however, it suffers from a lack of rigidity and from accumulated actuator errors. Especially at high speed and high dynamic loading operating conditions, the serial-link manipulators show poor dynamic performance. To improve the dynamic performance and achieve high precision operations, the robot links must be made with high rigidity, which results in heavy robots with low force-output-to-manipulator-weight ratio. On the other hand, if the links can be arranged parallel to one another in a closed kinematic chain structure such that the major force components add together, then high precision operations and high force-output-to-manipulator-weight ratios can be achieved.

The Stewart Platform

The most popular and successful parallel mechanical structure is the so-called Stewart platform, which was first proposed by Stewart (1965) in 1965. As a manufacturing manipulator, the Stewart platform has two fundamental characteristics which set it apart from machine tools and industrial robots — it is a *closed kinematic system* with *parallel links.* The Stewart platform link ends are simply supported, making the manipulator system far more rigid in proportion to size and weight than any serial link robot. Furthermore, the links of the Stewart platform are arranged so that the major force components of the six actuators add together, yielding a force-output-to-manipulator-weight ratio more than one order of magnitude greater than most industrial robots.

The original Stewart platform was designed for an aircraft simulator and consisted of six linear hydraulic actuators acting in parallel between the base and the upper platform, as shown in Figure 14.12.1. All the links are connected both at the base and at the upper platform. Thus, by changing the length of each link, the position and orientation of the upper platform are able to be controlled.

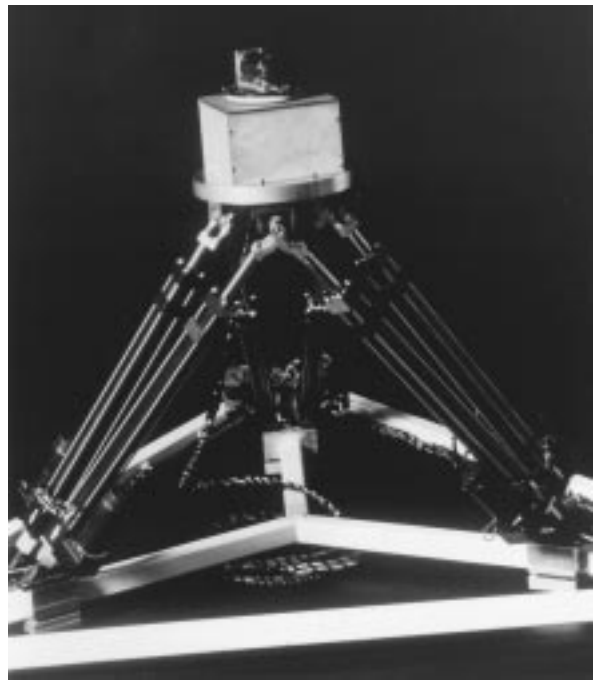

FIGURE 14.12.1 A six-degree-of-freedom *Stewart platform manipulator* developed at the Automation & Robotics Research Institute, The University of Texas at Arlington.

Some nice features of the original Stewart platform include:

- The manipulator design has six degrees of freedom, three for position and three for orientation.
- The six linear actuators are driven by six motors with each motor reacting on the base to avoid interaction between motors. Actually the manipulator can move when five of the jacks are locked merely by adjustment of the remaining jack.
- To achieve the maximum performance for a given power source, each motor operates directly on the same load (the upper platform). This makes a high payload-to-structure-weight ratio that at certain points of the workspace amounts to nearly six times the lifting capability of each individual actuator.
- Having low friction losses, with a powerful hydraulic system the manipulator can respond to commands very quickly.

It is interesting to note that the Stewart platform was not the first parallel link mechanical structure used in industry. As early as the 1950s, McGough devised a similar device for studying tire-to-ground forces and movements. The system had been in operation since 1955, but was never made known to the public until 1965 when Stewart published his journal article.

Advantages and Problems of the Stewart Platform

The Stewart platform appears simple and refined to the point of elegance. The performance mentioned above can be achieved using relatively inexpensive commercially available servo-actuator technology. The Stewart platform uses a closed kinematic chain which is structurally extremely strong and rigid, and is capable of distributing loads throughout the system. The actuator errors are not cumulative, allowing for high precision operations. However, the same closed kinematic structure that provides mechanical stiffness also complicates the forward kinematics analysis. This problem is an impediment to the derivation of dynamic equations and hence control schemes for real-time trajectory generation, which is necessary for industrial application of the manipulator (e.g., surface finishing applications).

It is known that in the case of fully parallel structures, the inverse kinematics (that is, solving for the corresponding lengths of the links given the position and orientation of the upper platform in Cartesian space) is relatively straightforward. However, the forward kinematics analysis for the fully parallel mechanism (e.g., given the length of each link, solve for the position and orientation of the upper platform in Cartesian space) is very challenging. The reason is that the kinematic equations are highly coupled and highly nonlinear.

Much effort has been devoted to finding an efficient algorithm for computing an accurate kinematic solution. To solve for the Cartesian position of the upper platform in terms of the given link lengths, thirty (30) nonlinear algebraic equations must be solved simultaneously, or polynomials of order 16 in a single variable must be solved. Due to the time-consuming nature of these procedures, it is difficult to compute the kinematic solutions on-line in real time. In Liu et al. (1993), a simplified algorithm was proposed which required to solve for only three (3) simultaneous nonlinear algebraic equations. Since the Stewart platform requires complex kinematics computations for trajectory following control, it is difficult to achieve real-time control capable of supporting high bandwidth motion.

The common feature of the forward kinematics analyses mentioned above is that there is no explicit analytical solution. Even for Liu et al.'s algorithm, it is still required to solve three nonlinear algebraic equations by numerical methods. Since there is no explicit expression available for the forward kinematics, deriving the Jacobian matrix and dynamic equations directly in link space and studying the singularity become impossible.

It is known that the Jacobian provides a transformation path which allows a two-way transformation between the link space and Cartesian space. If the Jacobian is not singular, then velocity in link space can be uniquely transformed to the corresponding velocity in Cartesian space. Particularly, if there is no movement in link space, then there is no movement in Cartesian space, so that the Stewart platform will remain rigidly fixed. However, at singular configurations, the transformation path from link space

to Cartesian space is blocked. In this case, even though there is no movement in link space, the upper platform can lose rigidity, still possibly moving along some directions. In other words, at singularities, the Stewart platform may gain extra degrees of freedom. The problem becomes even worse in that, in this situation, forces or torques in Cartesian space cannot be transformed to link space, that is, at singular positions the Stewart platform cannot be controlled to move in all directions and cannot exert force in all directions. From the applications viewpoint, investigating the conditions under which there will be singularities is important.

Thus, while the parallel link manipulators afford structural advantages, they also present severe difflculties for controller design. The control problems associated with such structures are not easy, as the systems do not satisfy most of the assumptions made in the controls literature (e.g., linearity in the parameters and feedback linearizability). Therefore, most existing control algorithms do not work well.

Manufacturing Applications of the Stewart Platform

Since proposed by Stewart (1965) in 1965, various applications of the Stewart platform have been investigated for use as aircraft simulators, as robot wrists, in mechanized assembly, and in active vibration control. As a manufacturing manipulator, the Stewart platform has great potential in automating many light machining applications such as surface finishing, edge finishing, routing, and profile milling. New manipulator applications to manufacturing processes requiring high force and power output such as combined assembly pressing are also possible. There are several light machining applications that a Stewart platform manipulator would perform with less set-up complexity and tooling cost than a serial link robot or a standard machine tool. In Figure 14.12.2 is shown a Stewart platform developed as a surface finishing milling machine.

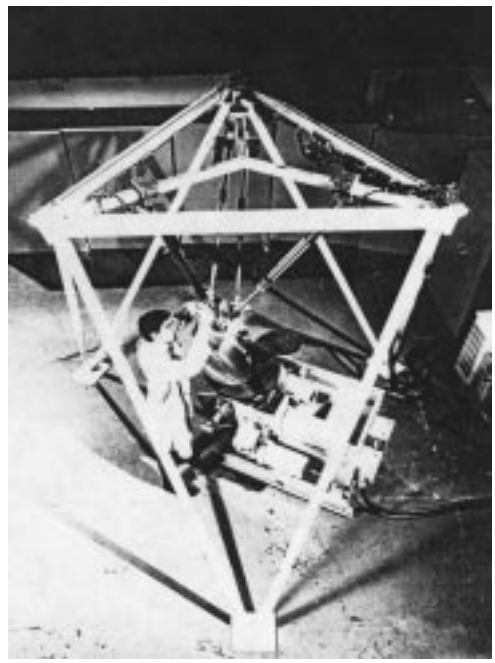

FIGURE 14.12.2 Stewart platform automated surface finishing cell.

Many applications of robotic manipulators to high precision routing can be found in the aerospace industry. A common application is trimming wing skin edges. The precision is usually achieved through the employment of expensive templates that provide a precise guide bearing for the tool to follow as it is held in the naturally compliant grip of a robotic manipulator. The major advantage for using a Stewart platform as a routing machine is that it can follow the contours of many aerospace parts without the

need for a tool guide; it is stiff enough to track the part precisely while withstanding the router cutting reactions. The cost of this contouring capability as compared to a standard five- or six-axis routing machine would be much lower.

The Stewart platform would be superior to any serial link robot as a drilling head manipulator. Virtually all applications of drilling robots in aerospace manufacturing require the use of expensive and complex end effectors of part jigs to compensate for the inaccuracy and lack of stiffness of the robots. Drilling jigs for some parts can cost as much as ten times more than the robot itself. Special end effectors are often used to apply preloads to prevent the drill from "walking" and chattering. The Stewart platform could perform many drilling tasks unaided by special tooling because of its stiffness and precision.

The industrial robot has generally not been considered to be a good milling manipulator. The Stewart platform could potentially perform contour milling of some materials with near-machine-tool accuracy. A Stewart platform milling machine with stiffness and dexterity characteristics intermediate between a large serial link robot and a five-axis mill could be built at or below the cost of a commercial serial link robot. A Stewart platform milling machine successfully used for industrial applications is shown in Figure 14.12.2.

When a direct contact tool like a grinder is used it is important to control both the tool position and the forces involved so that the substrate is not damaged. For example, when grinding mold scale a very aggressive tool may be needed, and the normal force applied can be as large as 40 to 50 lbs so long as the penetration into the surface is precisely controlled. The reactions in the surface tangent plane can be very large and could cause oscillations if not held rigidly. A Stewart platform with a constant force suspension for its tool could apply very large force with very high stiffness in one direction while being compliant and forceful in the normal direction.

Defining Terms

Accuracy. The degree to which the actual and commanded positions (of, e.g., a robot manipulator) correspond for computed as opposed to taught positions.

Adaptive Control. A large class of control algorithms where the controller has its own internal dynamics and so is capable of learning the unknown dynamics of the robot arm, thus improving performance over time.

AML. A Manufacturing Language — a robot programming language.

APT. Automatic Programming of Tools — a robot programming language.

Cell Decomposition. An approach to path planning where the obstacles are modeled as polygons and the free space is decomposed into cells such that a straight line path can be generated between any two points in a cell.

Compliance. The inverse of "stiffness" — useful in end effectors tooling whenever a robot must interact with rigid constraints in the environment.

Computed-Torque Control. An important and large class of robot arm controller algorithms that relies on subtracting out some or most of the dynamical nonlinearities using feedforward compensation terms including, e.g., gravity, friction, coriolis, and desired acceleration feedforward.

End Effector: Portion of robot (typically at end of chain of links) designed to contact world:

- **Compound.** A cluster of multiple end effectors and tooling mounted on the robot wrist.
- **Active.** An end effector with sensing and servo control of the grasp forces and/or finger motions.
- **Prehensile.** An end effector that holds parts between fingertips or encircled by fingers.
- **Vacuum.** A nonprehensile end effector that uses suction cups to hold parts.
- **Dextrous.** A hand with the ability to manipulate parts in the fingers and actively control grasp forces.

Feedback Linearization. A modern approach to robot arm control that formalizes computed-torque control mathematically, allowing formal proofs of stability and design of advanced algorithms using Lyapunov and other techniques.

Flexible-Link Robot. Lightweight mechanical structures where vibration and flexibility of the links must be taken into account in controller design. They possess favorable features including lower manufacturing costs, higher motion speeds, better performance, and easier transportation and setup.

Force Control. A class of algorithms allowing control over the force applied by a robot arm, often in a direction normal to a prescribed surface while the position trajectory is controlled in the plane of the surface.

Forward Kinematics. Identification of task coordinates given configuration.

Fuzzy Logic Control. A multilevel logic controller, which is different from the conventional dual (two-level) logic in which only two values (true and false) may be assigned to each state variable. Fuzzy logic controllers have advantages in being robust to disturbances and not requiring an explicit mathematical model for the design process. They consist of three parts: the fuzzifier, the rulebase, and the defuzzifier.

Grasp Isotropy. A measure of how uniformly forces and motions can be controlled in different directions.

IGES. International Graphics Exchange Specification — a data exchange standard.

Inverse Kinematics. Identification of possible configurations given task coordinates.

I/O Device. Input/output device — a port through which external information is connected to a computer. I/O devices may be A/D, which converts analog signals to digital, D/A, which converts digital signals to analog, or binary, which passes digital signals.

Joint Variables. Scalars specifying position of each joint — one for each degree of freedom.

Kitting. The process of taking parts from bulk and placing them on a *kit tray,* which is an organized group of all parts required to assemble a single product or subassembly.

Learning Control. A class of control algorithms for repetitive motion applications (e.g., spray painting) where information on the errors during one run is used to improve performance during the next run.

Linearity in the Parameters. A property of the robot arm dynamics, important in controller design, where the nonlinearities are linear in the unknown parameters such as unknown masses and friction coefficients.

Manipulator Jacobian. Matrix relating joint velocities to task coordinate velocities - configuration dependent.

Mechanical Part Feeders. Mechanical devices for feeding parts to a robot with a specified frequency and orientation. They are classified as vibratory bowl feeders, vibratory belt feeders, and programmable belt feeders.

Mobile Robot. A special type of manipulator which is not bolted to the floor but can move. Based on different driving mechanisms, mobile robots can be further classified as wheeled mobile robots, legged mobile robots, treaded mobile robots, underwater mobile robots, and aerial vehicles.

Path Planning. The process of finding a continuous path from an initial robot configuration to a goal configuration without collision.

PD-Gravity Control. A special case of computed-torque control where there is a PD outer control loop plus a gravity compensation inner control loop that makes the DC values of the tracking errors equal to zero.

Pinch Grasp. A grasp in which a part is clamped between fingertips.

Pixel. Picture element — one point of an image matrix in image processing terminology.

Prismatic Joint. Sliding robot joint which produces relative translation of the connected links.

Redundant Manipulator. Manipulator for which the number of joint variables is greater than the number of task coordinates.

Remote-Center Compliance (RCC). A compliant wrist or end effector designed so that task-related forces and moments produce deflections with a one-to-one correspondence (i.e., without side effects). This property simplifies programming of assembly and related tasks.

Revolute Joint. Rotary robot joint producing relative rotation of the connected links.

Robot Axis. A direction of travel or rotation usually associated with a degree of freedom of motion.

Robot Joint. A mechanism which connects the structural links of a robot manipulator together while allowing relative motion.

Robot Link. The rigid structural elements of a robot manipulator that are joined to form and arm.

Robust Control. A large class of control algorithms where the controller is generally nondynamic, but contains information on the maximum possible modeling uncertainties so that the tracking errors are kept small, often at the expense of large control effort. The tracking performance does not improve over time so the errors never go to zero.

SCARA. Selectively compliant assembly robot arm.

SET. (Specification for Exchange of Text) — a data exchange standard.

Singularity. Configuration for which the manipulator jacobian has less than full rank.

Skew Symmetry. A property of the dynamics of rigid-link robot arms, important in controller design, stating that $\dot{M} - {}^1/_2 V_m$ is skew symmetric, with M the inertia matrix and V_m the coriolis/centripetal matrix. This is equivalent to stating that the internal forces do no work.

Stewart Platform Manipulator. A special type of parallel-link robot consisting of six identical linear actuators in parallel, an upper platform, and a base. One end of each actuator connects to the base, and the other to the upper platform with two- or three-degrees-of-freedom joints. This manipulator has a greater force-to-weight ratio and finer positioning accuracy than any commercial serial-link robot.

Task Coordinates. Variables in a frame most suited to describing the task to be performed by manipulator.

VDAFS. (Virtual Data Acquisition and File Specification) — a data exchange standard.

Visibility Graph. A road map approach to path planning where the obstacles are modeled as polygons. The visibility graph has nodes given by the vertices of the polygons, the initial point, and the goal point. The links are straight line segments connecting the nodes without intersecting any obstacles.

Voronoi Diagram. A road map approach to path planning where the obstacles are modeled as polygons. The Voronoi diagram consists of line having an equal distance from adjacent obstacles; it is composed of straight lines and parabolas.

Wrap Grasp. A grasp in which fingers envelope a part, to sustain greater loads.

15.1 Introduction

The revolution in computer technology that has taken place over the last few decades has changed the face of all engineering disciplines. Fortunately, computers appropriate for solving complex mechanical engineering problems have evolved from complicated, rare, and expensive mainframes or supercomputers of yesterday to simple, common, and inexpensive desktop microcomputers widely available today. During this period, the application of improved computer technology has revolutionized the profession of mechanical engineering and enabled practicing engineers to solve problems routinely that a few decades ago would have resisted any available solution technique. However, many engineers possess only a limited grasp of important topics such as computational mechanics, computer science, and advanced computer-aided design principles. Thus, this chapter the present fundamentals of these computational

topics, in order to assist the practicing mechanical engineer in maintaining an appropriate high-level understanding of these emerging engineering tools.

Definition of Terms (CAD/CAM/CAE)

First, it is necessary to define a few terms related to the integration of the computer into various aspects of engineering practice:

- Computer-aided engineering (CAE) is a broadly inclusive term that includes application of the computer for general tasks encountered in mechanical engineering, including analysis, design, and production.
- Computer-aided manufacture (CAM) is the topic concerned with the integration of the computer into the manufacturing process, including such tasks as controlling real-time production devices on the factory floor. This subject is treated in Section 13.
- Computer-aided design (CAD) is a general term outlining areas where computer technology is used to speed up or eliminate efforts by engineers within the design/analysis cycle. This topic is also covered in Section 11.

The acronym CAD is also used as an abbreviation for computer-aided drafting. Since drafting is a key component of the mechanical engineering design process, this more narrow meaning will be integrated into the general notion of computer-aided design practice.

Overview of Computer-Aided Engineering

There are many important components of integrating the computer into mechanical engineering. In the past few decades, integrating the computer into mechanical engineering practice was largely a matter of generating input data for computational analyses and subsequent examination of the output in order to verify the results and to examine the response of the computer model. Today there are a wide variety of integration schemes used in engineering practice, ranging from artificial intelligence applications oriented toward removing the engineer from the design/analysis cycle, to “engineer in the loop” simulations intended to offload to the computer the quantitative tedium of design and analysis in order to permit the engineer to concentrate instead on qualitative issues of professional judgment. In the near future, these existing computer integration techniques will be combined with virtual reality technology and improved models for human/computer interaction. In order to use these new developments, engineers must be appropriately schooled in the fundamental tenets of modern computer-aided engineering.

Goals of Computer-Aided Engineering Chapter

This chapter is designed to aid practicing mechanical engineers in understanding the scope of applications of computer technology to their profession. To avoid premature obsolescence of the material presented here, a high-level orientation is utilized. Details of computational techniques are relegated to a catalog of appropriate references, and high-level “practical” concepts are emphasized. Low-level details (such as computer performance issues) change rapidly relative to high-level concerns (such as general classifications of computer function, or qualitative measures of computer solution quality). Thus, concentrating on a technical overview of computer-aided engineering will permit this chapter to stay up-to-date over the long term. In addition, this approach provides the practicing mechanical engineer with the fundamental principles required to accommodate the relentless pace of change that characterizes the world of modern computation.

In addition to providing engineers with basic principles of computer science, computational mechanics, computer intelligence, and examples of the application of CAD/CAM principles, this chapter also provides insight into such simple but commonly neglected issues as:

- What are the best ways to identify and judge computer applications for integration and use in a practical engineering setting?
- What common pitfalls can be encountered using general-purpose CAE software, and how can these problems be avoided?
- What are the most important characteristics of engineering computation, and how do engineering computer problems differ from computational methods used in other fields?

The development of material in this chapter is oriented toward presenting the practical *how* of effectively using engineering software as opposed to the mathematical *why* of identifying the cause of pathological computer results. This chapter therefore first provides the practicing mechanical engineer with an overview of the field of computer-aided engineering, and then presents that material in a manner less likely to become obsolete due to the rapid pace of change in this important engineering discipline. Finally, in order to avoid overlap with other chapters, many details (for example, mathematical definitions) are relegated to other chapters, or to appropriate references. Thus this chapter mainly provides an overview of the broad subject of computer-aided engineering, leaving the individual component subjects to other chapters or to outside references.

15.2 Computer Programming and Computer Architecture

Few other aspects of engineering practice change as rapidly as the use of the computer. Fifty years ago, mechanical engineers analyzed and designed automobiles that are not radically different from the automobiles of today, but practicing engineers of that era had no means of electronic calculation. Twenty-five years ago, mechanical engineers designed high-performance aircraft and space vehicles that are similar to those currently under development, but the computers of that more recent era had less power than a typical microprocessor available today in an automobile's braking system. Ten years ago, an advanced supercomputer appropriate for high-performance engineering computation cost several million dollars, required custom construction, installation, and support, and could perform between 10 million and 100 million floating-point operations per second. Today, one can buy such computational power for a few thousand dollars at a retail electronics store. Given this background of astonishing change in the performance, size, and cost of computers, it is clear that the applications of computers to the practice of mechanical engineering can be expected to advance at an equally breathtaking rate.

This section presents fundamental principles from the viewpoint of what can be expected between today and the beginning of the next century. The emphasis is on basic principles and fundamental definitions.

Software Engineering Overview

The modern field of software engineering is an outgrowth of what used to be called computer programming. Like many other engineering disciplines, software engineering gains much of its knowledge base from the study of failures in the specification, design, and implementation of computer programs. Unlike most engineering fields, however, the accepted codes of practice for software engineering are not yet universally adhered to and many preventable (and expensive) software failures still occur.

History of the Software Engineering Discipline

Software engineering is barely two decades old. Early efforts in this field are based on viewing the process of designing and implementing computer programs as analogous to designing and constructing physical objects. One of the most influential works demonstrating this "manufacturing tool" approach to the conceptualization of software is *Software Tools* (Kernighan and Plauger, 1976). In this view, large software projects are decomposed into reusable individual components in the same manner that complex machinery can be broken up into smaller reusable parts. The notion that computer programs could be constructed from components that can then be reused in new configurations is a theme that runs

throughout the history of the software engineering field. Modularity alone is not a panacea, however, in that programming effort contained within modules must be readable so as to facilitate verification, maintenance, and extension. One of the most influential references on creating readable and reliable code is *The Elements of Programming Style* (Kernighan and Plauger, 1978).

Emphasizing a modular and reusable approach to software components represents one of the primary threads of software engineering, and another important related thread arises in parallel to the idea of "manufacture" of software as an administrative process. After the failure of several large software projects in the 1960s and 1970s, early practitioners of software engineering observed that many of these software failures resulted from poor management of the software development process. Chronicles of typical failures and the lessons to be learned are detailed in Fred Brooks' *The Mythical Man-Month* (Brooks, 1975), and Philip Metzger's *Managing a Programming Project* (Metzger, 1983). Brooks' conclusions are generally considered among the most fundamental principles of the field. For example, his observation that adding manpower to a late software project makes it later is generally accorded the status of an axiom, and is widely termed "Brooks's law." More recent efforts in software management have concentrated on constructive solutions to past failures, as exemplified by Watts Humphrey's *Managing the Software Process* (Humphrey, 1989).

Understanding of the local (poor design) and global (poor management) causes of software failure has led to the modern study of software engineering. Obstacles to modularization and reuse of software tools were identified and proposed remedies suggested and tested. Administrative and large-scale architectural failures have been documented, digested, and their appropriate solutions published. The result is a substantial body of knowledge concerning such important topics as specification and design of computer programs, implementation details (such as choice of programming language), and usability of software (e.g., how the human user relates to the computer program). This collection of knowledge forms the basis for the modern practice of software engineering (see Yourdon, 1982).

Standard Models for Program Design and Implementation

A simple conceptual model of a program design and implementation methodology is presented by Yourdon (1993). This model is termed the "waterfall model" because its associated schematic overview bears a resemblance to a waterfall. The fundamental steps in the waterfall model (see Figure 15.2.1) proceed consecutively as follows:

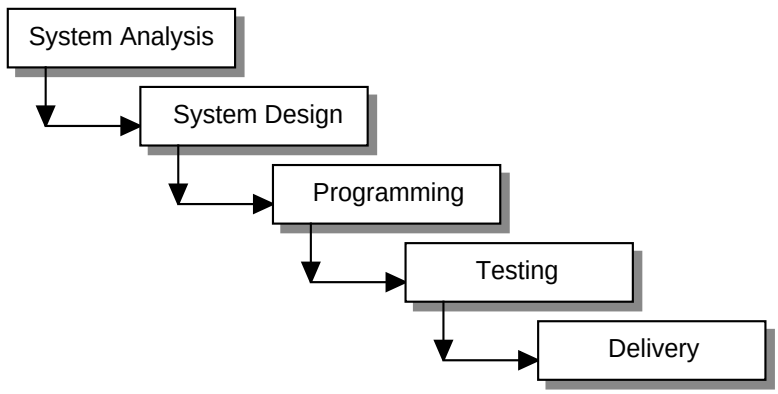

FIGURE 15.2.1 Waterfall model for software development.

- *System Analysis* — the requirements of the software system are analyzed and enumerated as a set of program specifications.
- *System Design* — the specifications are translated into precise details of implementation, including decomposition of the software system into relevant modules, and the implementation details required within this modular structure.

- *Programming* — the proposed design is implemented in a computer programming language (or collection of languages) according to the structure imposed in the system design phase.
- *Testing* — the resulting computer program is tested to insure that no errors ("bugs") are present, and that it is sufficiently efficient in terms of speed, required resources (e.g., physical memory), and usability.
- *Delivery* — the completed program is delivered to the customer.

This approach for software development works well for the small tasks, but for larger mechanical engineering projects there are many problems with this model. Probably the most important difficulty is that large projects may take years of development effort, and the customer is forced to wait nearly until the end of the project before any results are seen. If the project's needs change during the implementation period (or more commonly, if those needs were not specified with sufficient accuracy in the first place), then the final product will be inadequate, and required changes will have to be specified before those modifications can be "percolated" back through the waterfall life cycle again. Another important difficulty with this scheme occurs because quality-control issues (e.g., testing) are delayed until the project is nearly finished. In practice, preventative quality-assurance measures work better at reducing the likelihood that errors will occur in the program.

To avoid the inherent difficulties of the waterfall design, restructure this sequential design model into a spiral form that emphasizes more rapid incremental deliveries of programming function. These modified techniques are termed "incremental" or "spiral" development schemes (see Figure 15.2.2). The emphasis on quick delivery of incremental programming function permits seeing results sooner and, if necessary, making changes.

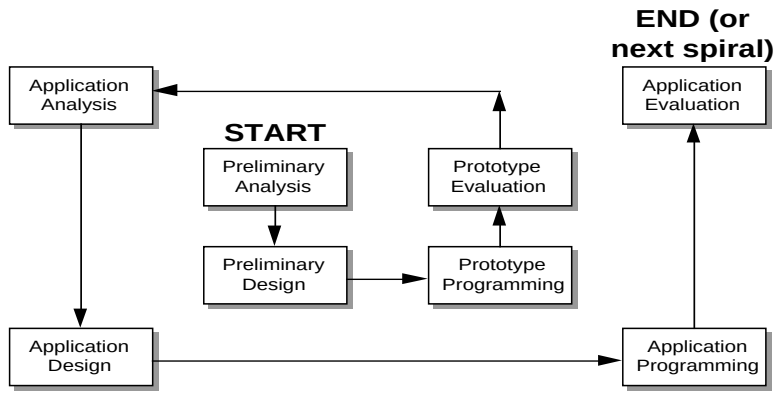

FIGURE 15.2.2 Spiral model for software development.

One important interpretation of the spiral development model is that the initial implementation of the program (i.e., the first pass through the spiral) can often be constructed as a simple prototype of the desired final application. This prototype is often implemented with limited function, in order to simplify the initial development process, so that little or no code developed in the prototypical implementation ends up being reused in the final commercial version. This approach has a rich history in practical software development, where it is termed "throwing the first one away" (after a similarly titled chapter in Brooks, [1975]). This widely used scheme uses the prototype only for purposes of demonstration, education (i.e., to learn the location of potential development pitfalls), and marketing. Once the prototype has been constructed and approved, design and implementation strategies more similar to the traditional waterfall approach are used for commercial implementation.

An obvious argument against spiral development models that incorporate a disposable prototype is that the cost of development is paid twice: once for the prototype and once again for the final implementation. Current remedies for this inherent problem include "rapid application development" (RAD)

methods, which emphasize the use of computer-assisted software engineering (CASE) tools to permit substantial reuse of the prototype in the final version. With this approach, the programmer uses specially designed computer applications that build the programs out of existing components from a software library. Program components that are especially mundane or difficult to implement (such as those commonly associated with managing a program's graphical user interface) often represent excellent candidates for automation using RAD or CASE tools. This area of software design and implementation will undoubtedly become even more important in the future, as the ability of computer programs to create other computer applications improves with time.

Computer Languages

Regardless of what future developments occur in the field of CASE tools, most current computer programming efforts are carried out by human programmers using high-level programming languages. These programming languages abstract low-level details of computer function (such as the processes of performing numerical operations or allocating computer resources), thus allowing the programmer to concentrate on high-level concepts appropriate for software design and implementation. Figure 15.2.3 diagrams the various interrelationships among abstractions of data, abstraction of instructions, and combinations of abstracted data and instructions. In general, more expressive languages are to be found along the diagonal line, but there are many instances in which increased abstraction is not necessarily a primary goal (for instance, performing fast matrix operations, which can often be done efficiently in a procedural language).

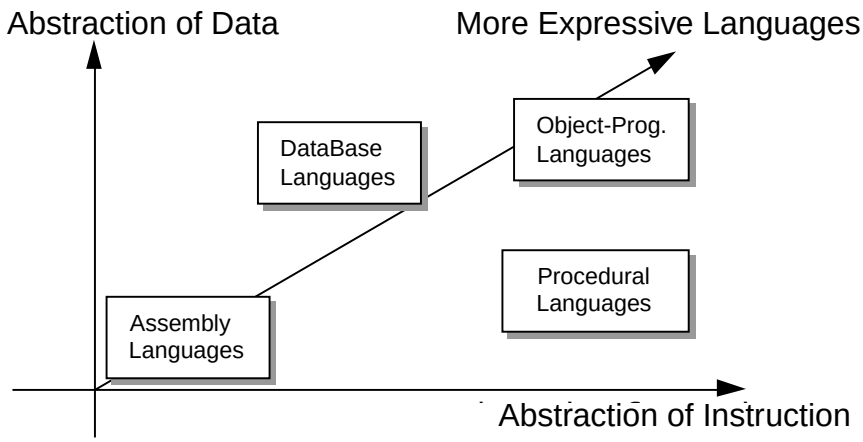

FIGURE 15.2.3 Language abstraction classification.

In addition, high-level programming languages provide a means for making computer programs *portable*, in that they may be moved from one type of computer to another with relative ease. The combination of portability of computer languages and adherence to standard principles of software design enables programmers to produce applications that run on a wide variety of computer hardware platforms. In addition, programs that are designed to be portable across different computers available today are generally easy to migrate to new computers of tomorrow, which insulates the longer-term software development process from short-term advances in computer architecture.

Perhaps the best example of how good program design and high-level language adherence work together to provide longevity for computer software is the UNIX operating system. This common operating system was designed and implemented in the 1970s using the C programming language, and runs with only minor modifications on virtually every computer available today. This operating system and its associated suite of software tools provide an excellent demonstration of how good software

design, when implemented in a portable programming language, can result in a software product that exhibits a lifespan much greater than that associated with particular hardware platform.

Computer Language Classification

Computer programs consist of two primary components: data and instructions. Instructions reflect actions taken by the computer program, and are comparable to verbs in natural human languages. In a similar manner, data reflect the objects acted on by computer instructions, in analogy with nouns in natural languages. Just as one would not attempt to construct sentences with only nouns or verbs, both data and instructions are necessary components of computer programs. However, programming languages are classified according to the relative importance of each of these components, and the resulting characterization of programming languages as "data-centered" (object-oriented) or "instruction-centered" (procedural) has major ramifications toward design, implementation, and maintenance of computer software.

Older programming languages (such as FORTRAN and COBOL) reflect a preeminent role for instructions. Languages that abstract the instruction component of programs permit the programmer to recursively decompose the overall computational task into logically separate subtasks. This successive decomposition of overall function into component subtasks highlights the role of the individual task as an encapsulated set of programming instructions. These encapsulated individual tasks are termed "procedures" (e.g., the SUBROUTINE structure in FORTRAN), and this "instruction first" approach to program design and construction is thus termed *procedural programming*. In procedural programming, the emphasis on decomposition of function obscures the important fact that the data component of the program is inherited from the procedural design, which places the data in a secondary role.

A more recent alternative model for programming involves elevating the data component of the program to a more preeminent position. This newer approach is collectively termed *object* programming, or *object-oriented* programming. Where procedural models abstract programming function via encapsulation of instructions into subroutines, object programming models bind the procedures to the data on which they operate. The design of the program is initially oriented toward modeling the natural data of the system in terms of its behaviors, and once this data component has been specified, the procedures that act upon the data are defined in terms of their functional operations on these preeminent data structures. Object programming models have been very successful in the important task of the creation of reusable code, and are thus valuable for settings (like implementation of a graphical user interface, where consistency among applications is desired) where there is a natural need for considerable code reuse.

The choice of language in computer programming is difficult because proponents of various languages and programming models favoring particular approaches often castigate those who advocate otherwise. Fortunately, there are few other branches of engineering that are so heavily politicized. It is important to look beyond the dogmatic issues surrounding language choice toward the important pragmatic goals of creating readable, verifiable, extensible, and reusable code.

Finally, it is important to recognize that the classification of programming languages into procedural and object-programming models is not precise. Regardless of whether data or instructions are given relative precedence, computer programs need both, and successful software design demands that the requirements of each component be investigated carefully. Although object-programming models relegate procedures to a secondary role to data structures, much of the final effort in writing an object-oriented program still involves design, creation, and testing of the procedures (which are termed "class methods" in object-programming models) that act upon the data. Similarly, it is possible to gain many object-programming advantages while using strictly procedural languages. In fact, some of the most successful languages utilized in current practice (e.g., the C++ programming language) are completely suitable for use as either procedural or object-oriented programming languages.

Procedural Programming Models

The most commonly used procedural programming languages in current use include Ada, C, FORTRAN, Basic, and Pascal. These procedural programming languages are characterized by a natural modular

structure based on programming function, which results in similar design methods being used for each. Since procedural languages are primarily oriented toward encapsulating programming function, each language has a rich set of control structures (e.g., looping, logical testing, etc.) that permits an appropriate level of control over the execution of the various procedural functions. Beyond this natural similarity, most procedural languages exhibit vast differences based on the expressiveness of the language, the range and extensibility of native data types, the facilities available for implementing modularity in the component procedures, and the run-time execution characteristics of the language.

Design Principles for Procedural Programming Models. The fundamental design principle for procedural programming is based on the concept of "divide and conquer," and is termed *functional decomposition* or *top-down design*. The overall effort of the program is successively decomposed into smaller logically separate subtasks, until each remaining subtask is sufficiently limited in scope so as to admit implementation within a procedure of appropriately small size. The overall process is diagrammed in Figure 15.2.4.

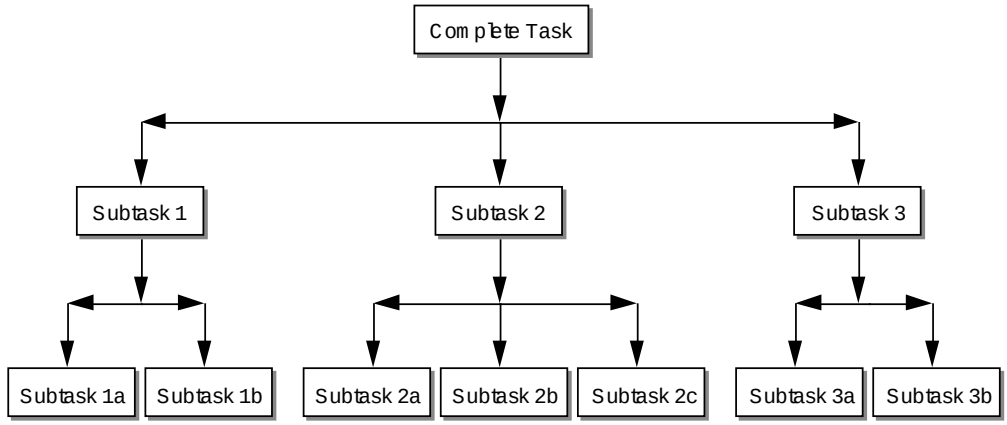

FIGURE 15.2.4 Sample functional decomposition.

The basic motivation behind functional decomposition is that the human mind is incapable of understanding an entire large computer program unless it is effectively abstracted into smaller "black boxes," each of which is simple enough so that its complete implementation can be grasped by the programmer. The issue of exactly how large an individual procedure can be before it becomes too large to understand is not an easy question to answer, but rules of thumb range from around ten up to a few hundred lines of executable statements. While it is generally accepted that extremely long procedures (more than a few hundred lines) have been empirically shown to be difficult to comprehend, there is still a lively debate in the software engineering community about how short procedures can become before an increased error rate (e.g., average number of errors per line of code) becomes apparent.

Although procedural programming languages possess the common characteristic of encapsulating programming function into separate granular modules, there are few similarities beyond this basic architectural resemblance. The various procedural languages often exhibit substantial differences in expressiveness, in the inhibition of practices associated with common language errors, and in the run-time characteristics of the resulting computer program.

Expressiveness represents the range of features permitted by the language that can be used by the programmer to implement the particular programming design. There is considerable evidence from the study of linguistics to support the notion that the more expressive the language, the wider the range of thoughts that can be entertained using this language. This important postulate is termed the "Sapir-Whorf hypothesis." While the Sapir-Whorf hypothesis is considered controversial in the setting of natural human languages, in the vastly simpler setting of programming languages, this phenomenon has been commonly

observed in practice, where use of more expressive high-level languages has been correlated with overall programmer productivity. Expressiveness in a computer language generally consists of permitting more natural control structures for guiding the execution of the program, as well as permitting a wide range of data representations appropriate for natural abstraction of data.

Sample Procedural Programming Languages. Some procedural languages (including FORTRAN and Basic) permit only a limited set of control structures for looping, branching, and logical testing. For instance, before the FORTRAN-77 standard was promulgated, FORTRAN had no way of expressing the standard logical "if-then-else" statement. The FORTRAN-77 specification still does not permit standard nondeterministic looping structures, such as "do while" and "repeat until". The standard Basic language suffers from similar limitations and is further impeded by the fact that most implementations of Basic are interpreted (each line of code is sequentially translated and then executed) instead of compiled (where the entire program's code is translated first and executed subsequently). Interpreted languages such as Basic are often incredibly inefficient, especially on problems that involve substantial looping, as the overhead of retranslating each line of code cannot be amortized in the same manner available to compiled languages. Finally, because Basic is limited in its expressiveness, many implementations of Basic extend the language to permit a greater range of statements or data types. While language extension facilitates programmer expression, it generally compromises portability, as different nonstandard dialects of the extended language generally develop on different computer platforms. The extreme case is illustrated by Microsoft's Visual Basic language, which is completely tied to Microsoft applications and operating systems software (and thus inherently nonportable), but so useful in its extensions to the original Basic language that it has become the de facto scripting language for Microsoft applications and operating systems.

Ada and Pascal are very expressive languages, permitting a rich set of control structures and a simple extension of the set of permitted data types. In addition, Ada and some Pascal dialects force the programmer to implement certain forms of data modularity that are specifically designed to aid in the implementation of procedural programs. In a similar vein, standard Pascal is so strongly typed that it forces the programmer to avoid certain common practices (such as misrepresenting the type of a data structure passed to a procedure, which is a widespread and useful practice in FORTRAN) that are associated with common errors in program implementation. In theory, Pascal's strict approach to representing data structures and its rich set of control structures ought to make it an attractive language for engineering programming. In practice, its lack of features for arithmetic calculation and its strict rules on data representation make it fairly difficult to use for numeric computation. Ada is a more recent language that is based on Pascal, but remedies many of Pascal's deficiencies. Ada is a popular language in mechanical engineering applications, as it is mandated for use on many Department of Defense programming projects.

C and FORTRAN are among the most common procedural languages used in large-scale mechanical engineering software applications. Both are weakly typed compiled languages with a rich set of available mathematical operations. C permits a considerable range of expressive control structures and extensible data structures. In addition, C is extremely portable and generally compiles and runs quickly, as the language's features are closely tuned to the instruction sets of modern microprocessors used in current generations of computers. The original C language specification was replaced in 1988 by a new ANSI standard, and this current language specification adds some features (such as type checking on arguments passed to procedures, a facility that aids greatly in preventing common programming errors) that resemble those found in Pascal, but do not seem to compromise the overall utility of the original C language standard.

FORTRAN's current implementation (FORTRAN-90) adds user-defined extensible data structures and a more expressive instruction set to the FORTRAN-77 standard, but the FORTRAN-90 standard has so far been slow to gain acceptance in the programming community. FORTRAN-77 compilers are still common, and the problems associated with this version of the language (e.g., minimal resources for abstracting data, limited control structures for expressing program flow) still compromise the archi-

tecture of FORTRAN programs. However, FORTRAN retains a rich set of intrinsic numeric operations, so it is still a good choice for its original goal of "Formula Translation" (where the language derives its name). In addition, FORTRAN programs often execute very rapidly relative to other procedural languages, so for programs that emphasize rapid mathematical performance, FORTRAN is still a good language choice. Finally, many FORTRAN-callable libraries of mathematical operations commonly encountered in engineering applications are available, and this ability to leverage existing procedural libraries makes FORTRAN an excellent choice for many mechanical engineering applications.

Advantages and Disadvantages of Procedural Programming. Procedural programming has inherent advantages and disadvantages. One of the most important advantages of some procedural languages (notably FORTRAN) is the existence of many complete libraries of procedures for solving complex tasks. For example, there are many standard libraries for linear algebra (e.g., LINPACK, EISPACK, LAPACK) or general scientific numerical computation (e.g., IMSL) available in FORTRAN-callable form. Reuse of modules from these existing libraries permits programmers to reduce development costs substantially for a wide variety of engineering applications. Under most current portable operating systems, multiple-language integration is relatively straightforward, so high-quality FORTRAN-callable libraries can be called from C programs, and vice-versa. The development of standard procedural libraries is largely responsible for the present proliferation of useful computer applications in mechanical engineering.

Another important advantage of procedural languages is that many important computational tasks (such as translating mathematical models into analogous computer codes) are naturally converted from the underlying mathematical algorithm (which is generally a sequence of instructions, and hence amenable to encapsulation within a procedure) into an associated modular procedure. As long as the data used within a program do not become unduly complex, procedural languages permit easy implementation of many of the standard methods used in engineering analysis and design.

Perhaps the biggest disadvantage of procedural models is that they are harder to reuse than competitive object-programming models. These obstacles to code reuse arise from the fact that data are modeled in procedural programming as an afterthought to the simulation of instructions. In order to reuse procedures between two different programs, the programmer must force the representation of data to be identical across the different computer applications. In procedural programming, the goal of code reuse requires standardization of data structures across different computer programs, regardless of whether or not such standardization is natural (or even desired) by those disparate computer programs. Object programming models are an attractive alternative to procedural programming schemes in large part because these newer programming methods successfully avoid such unwarranted data standardization.

Object Programming Models

Object-programming models place modeling of data structures in a more preeminent position, and then bind to the data structures the procedures that manipulate the data. This relegation of procedures (which are termed "methods" in object programming) to a more secondary role facilitates a degree of code reuse substantially better than is feasible with conventional procedural programming languages. Object programming languages employ aggregate data types (consisting of various data fields, as well as the associated methods that manipulate the data) that are termed *classes*, and these classes serve as templates for creation of *objects* that represent specific instances of the class type. Objects thus form the representative granularity found in object-oriented programming models, and interactions among objects during program execution are represented by messages that are passed among the various objects present. Each message sent by one object to another tells the receiving object what to do, and the details of exactly how the receiving object accomplishes the associated task are generally private to the class. This latter issue of privacy regarding implementation details of object methods leads to an independence among objects that is one of the main reasons that object-programming schemes facilitate the desired goal of code reuse.

One of the most important limitations of procedural languages is abstraction. High-level languages such as FORTRAN or C permit considerable abstraction of instructions, especially when compared to the machine and assembly languages they are designed to supplant. Unfortunately, these languages do not support similar levels of abstraction of data. For example, although FORTRAN-77 supports several different numeric types (e.g., INTEGER, REAL, DOUBLE PRECISION), the only derived types available for extending these simple numeric representations are given by vectors and multidimensional arrays. Unless the data of a problem are easily represented in one of these tabular forms, they cannot be easily abstracted in FORTRAN. To some extent, experienced programmers can create new user-defined data types in C using structures and typedefs, but effectively abstracting these derived data types requires considerable self-discipline on the part of the programmer.

Object-oriented programming languages avoid these pitfalls of procedural languages by using classes as templates for abstraction of both instructions and data. By binding the instructions and the data for classes together, the programmer can abstract both components of a programming model simultaneously, and this increased level of abstraction results in a radically new programming model. For instance, a natural class for finite-element modeling would be the class of finite-element mesh objects. A mesh object (which could easily be composed internally of node and element objects) makes it possible for the object programmer to hide all the details of mesh representation from the rest of the program. A procedural programming model would require standardization of the mesh to consist of (for example):

- A list of nodes, each associated with individual nodal coordinates given in 1D, 2D, or 3D (depending on the geometry of the model used)
- A list of elements, each with a given number of associated nodes
- A list of element characteristics, such as material properties or applied loads

In this representation, each procedure that manipulates any of the mesh data must know all of the details of how these data have been standardized. In particular, each routine must know whether a 1D, 2D, or 3D finite-element analysis is being performed, and pertinent details of the analysis (e.g., is the problem being modeled thermal conduction or mechanical deformation?) are also spread throughout the code by the standardization of data into predefined formats. The sum of these constraints is to require the programmer to recode substantial components of a procedural program every time a major modification is desired.

In the setting of objects, the finite-element mesh object would store its particular geometric implementation internally, so that the rest of the program would be insulated from the effects of changes in that representation. Rather than calling a procedure to generate a mesh by passing predefined lists of nodes, elements, and element characteristics, an object-oriented approach to mesh generation would employ sending a message such as “discretize yourself” to the mesh object. This object would then create its internal representation of the mesh (perhaps using default values created by earlier messages) and store this information privately. Alternatively, the object-oriented program might later send a “solve yourself” message to the mesh object and then a “report your results in tabular form” message for generating output. In each case, the rest of the program has no need to know the particular details of how the mesh object is generating, storing, or calculating results. Only the internal procedures local to the class (i.e., the class methods) generally need to know this private data, which are used locally to implement the functions that act on the class.

This hiding of internal function within an object is termed *encapsulation*, and object programming models permit simultaneous encapsulation of both data and instructions via appropriate abstraction. In this setting, encapsulation permits the programmer to concentrate on creating data and procedures naturally, instead of forcing either component into predefined formats such as floating-point arrays (for data) or predefined subroutine libraries (for instructions). Data and instruction abstraction of this form are thus useful additions to the similar (but less flexible) features available in procedural languages. If these new features constituted the only improvements available from object-programming models, then

they would offer only slight advantages over traditional procedural programming. There are many other advantages present in object-programming models.

The most important advantages of object programming occur because of the existence of *class hierarchies*. These hierarchies permit new objects to be created from others by concentrating only on the differences between the object's behaviors. For instance, a finite-element mesh for a rod lying in three dimensions can be derived from a one-dimensional mesh by adding two additional coordinates at each node. An object programmer could take an existing one-dimensional mesh class and derive a three-dimensional version using only very simple steps:

- Adding internal (private) representation for the additional coordinate data
- Overriding the existing discretization method to generate the remaining coordinates when the "discretize yourself" message is sent
- Overriding some low-level calculations in class methods pertinent to performing local element calculations using the new coordinate representation

Note that all of these steps are private to the mesh object, so that no other part of the program needs to be changed to implement this major modification to the problem statement. In practice, the added details are implemented via the creation of a derived class, where the additional coordinates and the modified methods are created. When messages appropriate to the new class are sent, the derived object created from the new class will handle only the modified data and instructions, and the parent object (the original mesh object) will take care of the rest of the processing. This characteristic of object-programming models is termed *inheritance*, as the individual derived ("child") objects inherit their behavior from the parent class. When the changes required by the modification to the program's specifications are small, the resulting programming effort is generally simple. When the changes are large (such as generalizing a one-dimensional problem to a fully three-dimensional one), it is still often feasible to make only minor modifications to the program to implement the new features.

One of the most important rationales for using object-programming methods arises from the desire to provide a consistent user-interface across diverse programs. Existing standardized graphical interface models (such as the Motif interface available on OSF/UNIX, or the Microsoft Windows interface used on Windows and Windows NT) place a premium on a consistent "look and feel" across different applications. Since managing the user-interface commonly constitutes much of the programming effort required to implement interactive engineering applications, it is advantageous to consolidate all of the code required to implement the standard graphical user-interface into a class library and allow the programmer to derive new objects pertinent to the application at hand.

One such class library is the Microsoft Foundation Classes, which implement the Windows interface via a class hierarchy requiring around a hundred thousand lines of existing C++ source code. Programmers using class libraries such as these can often generate full-featured graphics applications by writing only a few hundred or a few thousand lines of code (notably, for reading and storing data in files, for drawing content into windows, and for relevant calculations). In fact, it is relatively easy to graft graphical user interfaces onto existing procedural programs (such as old FORTRAN applications) by wrapping a C++ user-interface layer from an existing class library around the existing procedural code, and by recycling relevant procedures as class methods in the new object-oriented setting. This "interface wrapper" approach to recycling old procedural programs is one of many standard techniques used in *reengineering* of existing legacy applications (Barton and Nackman, 1994).

One other important characteristic of many object-programming languages is *polymorphism*. Polymorphism (Latin for "many forms") refers to the ability of a single message to spawn different behaviors in various objects. The precise meaning of polymorphism depends upon the run-time characteristics of the particular object-programming language used, but it is an important practical feature in any object-programming language.

Object-Oriented Design Principles. Because object-oriented programming is a relatively new discipline of software engineering (when compared to procedural programming), one cannot yet identify the best

design schemes among the various competing object-oriented design principles. For this reason (and to avoid prejudging the future), this section treats the subject of object-oriented design in less detail than procedural design methods.

The fundamental tenet of object-oriented program design is that the programming objects should be chosen to model any real-world objects present in the system to be analyzed and simulated. For example, in a thermal analysis of a microprocessor, one might identify such natural physical objects as "heat sink," "thermocouple," and "fan." In general, the nature of the physical objects in a mechanical system is stable over long periods of time, so they make natural candidates for programming objects, as their specifications are least likely to vary, and thus they will require minimal modifications to the basic program design.

The next step in performing an object-oriented design is to model the behaviors of the various objects identified within the system. For example, a fan object can "turn on" and "turn off", or might vary in intensity over a normalized range of values (e.g., 0.0 = off, 1.0 = high speed), and this behavior will form the basis for the messaging protocols used to inform objects which behaviors they should exhibit. At the same time, any relevant data appropriate to the object (in this case, fan speed, power consumption, requisite operating voltage) should be identified and catalogued. Here, these individual items of data will represent the private data of the fan class, and the behaviors of this class will be used to design class methods.

The final step in specifying an object-oriented design is to examine the various objects for interrelationships that can be exploited in a class hierarchy. In this setting, "heat sink" and "fan" could be considered to be derived from a larger class of "cooling devices" (although in this trivial example, this aggregation is probably unnecessary). Careful identification of hierarchical relationships among the candidate objects will generally result in an arrangement of classes that will permit considerable code reuse through inheritance, and this is one of the primary goals of object-programming design practice.

In practice, there is no "final" step in designing object-oriented programs, as the design process is necessarily more complex and iterative than procedural programming models. In addition, the object-oriented designer must take more care than given here in differentiating the role of classes (which are the static templates for construction of objects) from objects themselves, which are the dynamic realization of specific members of a class created when an object-oriented program executes. Objects are thus specific instances of generic classes, and the process of creating objects at run time (including setting all appropriate default values etc.) is termed *instantiation.*

Sample Object-Oriented Languages. There are not as many successful object-oriented languages as there are procedural languages, because some languages (such as Ada and FORTRAN-90) that possess limited object-oriented features are more properly classified as procedural languages. However, ADA 95 does include excellent facilities for object-oriented programming.

C++ is the most commonly used object-oriented language and was primarily developed at Bell Labs in the same pragmatic vein as its close procedural relative, C. In theory, the C++ language includes both procedural and object-programming models, and thus C++ can be used for either type of programming. In practice, the procedural features on C++ are nearly indistinguishable from those of ANSI C, and hence the phrase "programming in C++" is generally taken to mean "object-programming in C++". C++ is well known as an object-programming language that is not particularly elegant, but that is very popular because of its intimate relation with the C procedural programming language (C++ is a superset of ANSI C) and because of its extensive features. The design goal of maintaining back-compatibility with ANSI C has led to shortcomings in the C++ language implementation, but none of these shortcomings has seriously compromised its popularity. C++ is an efficient compiled language, providing the features of object-programming models without undue loss of performance relative to straight procedural C, and C++ is relatively easy to learn, especially for knowledgeable C programmers. It supports extensive inheritance, polymorphism, and a variety of pragmatic features (such as templates and structured exception handling) that are very useful in the implementation of production-quality code.

An important recent development in object-oriented design is the Java programming language: the popularity of this new language is closely tied to the explosion of interest in the Internet. Java is widely used to provide interactive content on the World-Wide-Web, and it has a syntax very similar to C++, a pervasive object-orientation, and provides portable elements for constructing graphical user interfaces. Java programs can be deployed using interpreted forms over the web (utilizing a "Java Virtual Machine" on the client platform), or by a more conventional (though less portable) compilation on the target computer.

SmallTalk is one of the oldest and most successful object-programming languages available, and was designed at the Xerox Corporation's Palo Alto Research Center (also responsible for the design of modern graphical user interfaces). SmallTalk supports both inheritance (in a more limited form than C++) and polymorphism, and is noted as a highly productive programming environment that is particularly amenable to rapid application development and construction of prototypes. SmallTalk is *not* a compiled language, and while this characteristic aids during the program implementation process, it generally leads to computer programs that are substantially less efficient than those implemented in C++. SmallTalk is generally used in highly portable programming environments that possess a rich library of classes, so that it is very easy to use SmallTalk to assemble portable graphical interactive programs from existing object components.

Eiffel is a newer object-oriented language with similar structure to object-oriented variants of the Pascal procedural programming language. Eiffel is similar in overall function to C++ but is considerably more elegant, as Eiffel does not carry the baggage of backward compatibility with ANSI C. Eiffel has many important features that are commonly implemented in commercial-quality C++ class libraries, including run-time checking for corruption of objects, which is a tremendous aid during the program debugging process. Even with its elegant features, however, Eiffel has not gained the level of acceptance of C++.

There are other object-oriented programming languages that are worth mentioning. The procedural language Ada provides some support for objects, but neither inheritance or polymorphism. FORTRAN-90 is similarly limited in its support for object-programming practices. Object Pascal is a variant of Pascal that grafts SmallTalk-like object orientation onto the Pascal procedural language, and several successful implementations of Object Pascal exist (in particular, the Apple Macintosh microcomputer used Object Pascal calling conventions, and this language was used for most commercial Macintosh application development for many years). For now, none of these languages provides sufficient support for object-oriented programming features (or a large-enough user community) to provide serious competition for C++, SmallTalk, Eiffel, or Java.

Data Base Systems

In procedural programming practice, modeling data are relegated to an inferior role relative to modeling instructions. Before the advent of object-oriented programming languages, which permit a greater degree of data abstraction, problems defined by large or complex data sets required more flexibility for modeling data than traditional procedural programming techniques allowed. To fill this void, specialized data base management systems were developed, and a separate discipline of computer programming (data base management) arose around the practical issues of "data-centered" programming practice. The study of data base management evolved its own terminology and code of application design, and suffered through many of the same problems (such as language standardization to provide cross-platform portability) that had plagued early efforts in procedural programming. The data base management subdiscipline of software engineering is still fundamentally important, but the widespread adoption of object-oriented languages (which permit flexible modeling of data in a more portable manner than that provided by proprietary data base management systems) has led to many of the concepts of data base management becoming incorporated into the framework of object-oriented programming practice.

Technical Overview of Data base Management

Many important engineering software applications are naturally represented as data base applications. Data base applications are generally developed within specialized custom programming environments specific to a particular commercial data base manager, and are usually programmed in a proprietary (and often nonportable) data base language. Regardless of these issues, data base programming is a particular form of computer programming, and so the relevant topics of software engineering, including procedural and object models, portability, reliability, etc., apply equally well to data base programming. Because many of these principles have already been presented in considerable detail, the following sections on design and programming issues for data base systems are kept relatively concise.

Data base applications are very similar to conventional programming applications, but one of the most important differences is in the terminology used. Data base applications have developed a nomenclature specifically defined to dealing with structured and unstructured data, and this terminology must be addressed. Some of the most appropriate terms are enumerated below.

- Table: a logical organized collection of related data
- Record: a collection of data that is associated with a single item (records are generally represented as rows in tabular data base applications)
- Field: an individual item of data in a record (fields are generally represented as columns in a tabular data base)
- Schema: the structure of the data base (schema generally is taken to mean the structure and organization of the tables in a tabular data base)
- Query: a structured question regarding the data stored in the data base (queries are the mechanism for retrieving desired data from the data base system)

There are many other relevant terms for data base management, but these are sufficient for this brief introduction. One important high-level definition used in data base management is *Structured Query Language*, or SQL. SQL is a standard language for creating and modifying data bases, retrieving information from data bases, and adding information to data bases. In theory, SQL provides an ANSI standard relational data base language specification that permits a degree of portability for data base applications. In practice, standard SQL is sufficiently limited in function so that it is commonly extended via proprietary addition of language features (this situation is similar to that of the Basic procedural language, which suffers from many incompatible dialects). The practical effect of these nonstandard extensions is to compromise the portability of some SQL-based data base systems, and additional standardization schemes are presently under development in the data base management industry. One such scheme is Microsoft's *Open data base Connectivity* (ODBC) programming interface, which provides portable data base services for relational and non-relational data base applications.

Classification of Data Base Systems

There are many different types of data base systems in common use. One of the most important initial steps in designing and implementing a data base application is to identify the relevant characteristics of the data in order to choose the most appropriate type of data base for development. Depending upon the structure of the data to be modeled, the data base application developer can select the simplest scheme that provides sufficient capabilities for the problem. Three sample data base structures are presented below: flat-file data bases, relational data bases, and object-oriented data bases.

Flat-File Data Bases. Flat-file data bases represent the simplest conceptual model for data base structure. A flat data base can be idealized as a table with a two-dimensional matrix or grid structure. The individual data base records are represented by the rows of the matrix, and each record's component fields are represented by the columns of the matrix structure, as shown in Figure 15.2.5. Flat-file data bases are thus confined to applications where all records are structurally identical (i.e., have the same configuration of fields) and where the underlying matrix structure naturally represents the data component of the application.

	Field 1: Name	Field 2: Yield Strength	Field 3: Young's Modulus	Field 4: Shear Modulus
Record 1: Material 1	Aluminum	250 MPa	70 GPa	25 GPa
Record 2: Material 2	Magnesium	150 MPa	45 GPa	18 GPa
Record 3: Material 3	Steel	400 MPa	200 GPa	85 GPa

FIGURE 15.2.5 Flat data base example.

The simplicity of a flat-file data base is simultaneously its greatest advantage and worst disadvantage. The main advantage of using a flat-file data base structure is that querying the data base is extremely simple and fast, and the resulting data base is easy to design, implement, and port between particular data base applications. In practice, spreadsheet applications are often used for constructing flat-file data bases, because these packages already implement the requisite tabular structure and include a rich variety of control structures for manipulating the data.

The biggest disadvantage of flat-file data bases is that the extreme simplicity of the flat structure simply does not reflect many important characteristics of representative data base applications. For programs requiring flexibility in data base schema, or complex relationships among individual data fields, flat-file data bases are simply a poor choice, and more complex data base models should be used.

Relational Data Bases. In practice, data base applications often require modeling relationships among various fields that may be contained in separate data files. Applications with these "relational" features are term relational data bases. Relational data base technology is a rapidly evolving field, and this family of data bases is very common in practical data base applications.

Relations provide a way to generalize flat-file data base tables to include additional features, such as variation in the numbers of fields among different records. A schematic of a simple relational data base schema is shown in Figure 15.2.6. Here a data base of material properties is represented by related tables. Note that because of the disparity in number of material constants (i.e., differing numbers of fields for each material record), a flat-file data base would not be suitable for this data base storage scheme.

The material properties tables (containing the lists of material properties) are related to their parent table, which contains overall identification information. These parent-child relationships give relational data bases considerable flexibility in modeling diverse aggregates of data, but also add complexity to the task of storing and retrieving data in the data base. In a flat-file data base system, a simple lookup (similar to indexing into a two-dimensional array) is required to find a particular field. In a complex relational data base, which may exhibit many nested layers of parent-child relations, the task of querying may become very complex and potentially time-consuming. Because of this inherent complexity in storing and retrieving data, the topics of efficient data base organization and of query optimization are essential for careful study before any large-scale relational data base application is undertaken.

Object-Oriented Data Bases. Many of the data base schemes found in relational and flat-file data base systems arose because of the inability to model data effectively in older procedural programming languages like FORTRAN. Commercial relational data base managers combined powerful data-modeling capabilities with new procedural languages (such as SQL or XBase) specifically designed to manipulate data base constructs. Recently, the current proliferation of object-oriented programming languages, with their innate ability to abstract data as effectively as possible with dedicated data base management systems, has led to the development of object-oriented data base systems. These object-oriented data base packages provide extremely powerful features that may ultimately make traditional SQL-based relational data base applications obsolete.

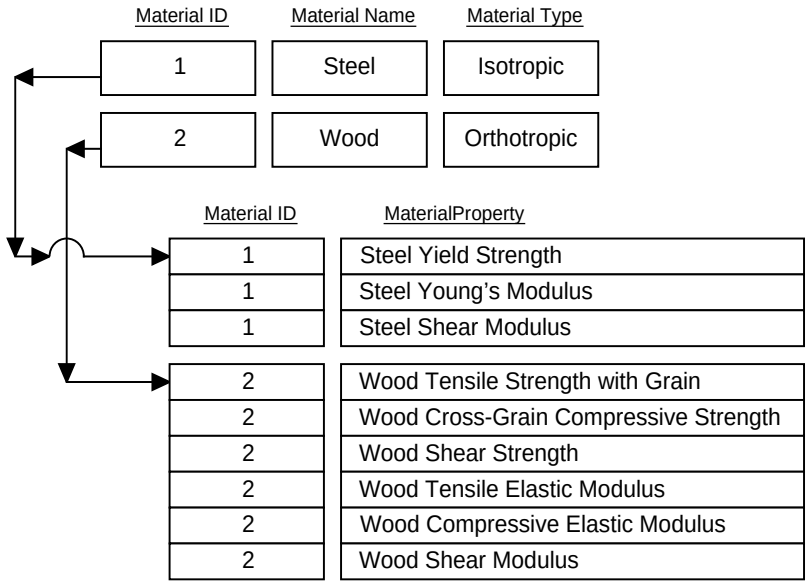

FIGURE 15.2.6 Example relational data base structure.

One interesting example of object-oriented data base technology is the integration of data base technology into a C++ framework. The Microsoft Foundation Class library for C++ provides numerous features formerly requiring custom data base programming that are implemented as C++ class library members. For example, there are extensible data base classes that provide direct support for common data base functions, and there are ODBC (Open Data Base Connectivity, the extension of SQL to generic data base environments) classes allowing the C++ program to access existing relational data bases developed with specialized data base management systems. Given the extensibility of C++ class libraries, this object-oriented approach makes it feasible to gain all of the advantages of proprietary relational data base applications, while preserving the numerous features of working in a standard portable programming language.

Operating System Characteristics

Computer programs depend on low-level resources for execution support, including file services for input/output, graphical display routines, scheduling, and memory management. The software layers that provide these low-level services are collectively termed the computer's *operating system*. Operating systems thus insulate individual programs from the details of the hardware platform where they are executed, and choosing the right operating system can be a critical decision in engineering practice.

Engineering computation is generally identified by three fundamental characteristics:

- Large demand for memory, where extremely large data sets (generally on the order of megabytes or gigabytes) are used, and where all components of these demanded memory resources must be accessible simultaneously (This demand for memory can be contrasted with standard on-line-transaction-processing schemes used in finance and commerce, where there is a similar characteristic of large data sets, but these large financial data models are seldom required to have all components available in memory at the same time.)
- Dependence on floating-point computation, where there are high-precision floating-point representations of numbers (i.e., numbers stored in the binary equivalent of "scientific notation", where storage is divided among sign, mantissa, and exponent, requiring more extensive storage than that required for characters or integer data types)

- Extensive use of graphics in input and display, as graphics is generally characterized as an engineer's "second language," because only the human visual sense has sufficient bandwidth to process the vast amounts of data generally present in engineering computation

While many of these characteristics may be found in other computational settings, the simultaneous presence of all three is a hallmark of computation in science and engineering. Identifying and selecting an operating system that provides appropriate support for these characteristics is thus a fundamentally important problem in the effective development and use of engineering software.

Technical Overview of Operating Systems

A simple and effective way to gain an overview of operating systems theory is to review the classification scheme used to identify various operating systems in terms of the services that they provide. The most common characteristics used for these classifications are enumerated below.

Multitasking. Humans are capable of performing multiple tasks simultaneously, and this characteristic is desirable in a computer operating system as well. Although an individual computer CPU can only process the instructions of one application at a time, it is possible with high-performance CPUs to manage the execution of separate programs concurrently by allocating processing time to each application in sequence. This sequential processing of different applications makes the computer appear to be executing more than one software application at a time. When an operating system is capable of managing the performance of concurrent tasks, it is termed a *multitasking* operating system. Many early operating systems (such as MS/DOS) could only execute a single task at a time and were hence termed *single-tasking* systems. While it is possible to load and store several programs in memory at one time and let the user switch between these programs (a technique sometimes termed *context switching* that is commonly used in MS/DOS applications), the lack of any coherent strategy for allocating resources among the competing programs limits the practical utility of this simple tasking scheme.

A simple generalization of context switching is known as *cooperative multitasking*, and this simple tasking scheme works remarkably well in some settings (in fact, this method is the basis for the popular Microsoft Windows 3.x and Apple Macintosh 7.x operating systems). In a cooperative multitasking setting, the allocation of computer resources is distributed among the competing programs: the individual programs are responsible for giving up resources when they are no longer needed. A comparison to human experience is a meeting attended by well-behaved individuals who readily yield the floor whenever another speaker desires to contribute. Just as this scheme for managing human interaction depends on the number of individuals present (obviously, the more people in the meeting, the more difficult the task of distributed management of interaction) as well as on the level of courtesy demonstrated by the individual speakers (e.g., there is no simple means for making a discourteous speaker yield the floor when someone else wants to speak), the successful use of cooperative multitasking schemes is completely dependent on the number and behavior of the individual software applications that are being managed. Ill-behaved programs (such as a communications application that allocates communications hardware when executed, but refuses to release it when not needed) compromise the effectiveness of cooperative multitasking schemes and may render this simple resource-sharing model completely unusable in many cases.

The obvious solution to managing a meeting of humans is to appoint a chair who is responsible for allocating the prioritized resources of the meeting: the chair decides who will speak and for how long, depending upon scheduling information such as the meeting's agenda. The computer equivalent of this approach is termed *preemptive multitasking* and is a very successful model for managing the allocation of computer resources. Operating systems that use a preemptive multitasking model make use of a *scheduler* subsystem that allocates computer resources (such as CPU time) according to a priority system. Low-priority applications (such as a clock accessory, which can update its display every minute or so without causing serious problems) are generally given appropriately rare access to system resources, while high-priority tasks (such as real-time data acquisition applications used in manufacturing, which cannot tolerate long intervals without access to the operating system's services) are given higher priority.

Of course, the scheduler itself is a software system and generally runs at the highest level of priority available.

Preemptive multitasking operating systems are natural candidates for engineering software, as the intense memory and hardware resources associated with engineering computation require appropriately high-powered operating system support. Virtually all large engineering computers of the present era (e.g., workstations, mainframes, and supercomputers) run operating systems that provide preemptive multitasking, and many microcomputers are now available with similar operating system support.

Multithreading. In the setting of multitasking, the term "task" has some inherent imprecision, and this ambiguity leads to various models for allocation of computer resources among and within applications. In the simplest setting, a task can be identified as an individual software application, so that a multitasking operating system allocates resources sequentially among individual applications. In a more general context, however, individual programs may possess internal granularity in the form of subprocesses that may execute in parallel within an application. These subprocesses are termed "threads," and operating systems that support multiple threads of internal program execution are termed *multithreaded* operating systems.

Examples of multiple threads of execution include programs that support internally concurrent operations such as printing documents while other work is in progress (where a separate thread is spawned to handle the printing process), displaying graphical results while performing other calculations (where a separate thread can be used to paint the screen as data are read or calculated), or generating reports from within a data base application while other queries are performed. In general, multithreading of individual subtasks within an application will be advantageous whenever spawned threads represent components of the application that are complicated enough so that waiting for them to finish (which would be required in a single-threaded environment) will adversely affect the response of the program.

Multiprocessing. One of the most important advantages of separating a program into multiple threads is that this decomposition of programming function permits individual threads to be shared among different processors. Computers with multiple CPUs have been common platforms for performing high-end engineering computation for over a decade (e.g., multiprocessor supercomputer architectures, such as the Cray X/MP and Cray Y/MP models introduced in the 1980s), but the availability of multiple processing units within a single computer has finally gravitated to the realm of low-end microcomputers. The ability of an operating system to support concurrent execution of different program threads on different processors is termed *multiprocessing*. Multiprocessing occurs in two fundamental flavors:

- Symmetric multiprocessing (SMP), where each individual CPU is capable of executing any process, including threads originating within applications or within operating system services
- Asymmetric multiprocessing (ASMP), where different processors are relegated to different tasks, such as running applications or running operating systems services

Asymmetrical processing is commonly implemented using a dual-CPU architecture involving a master/slave relation between the processing units. The master CPU performs the application and some system services, while the slave CPU is relegated to pure system tasks (such as printing, waiting for slow input/output devices, etc.). Asymmetric multiprocessing architectures provide some speed-up of individual programs, but this increased performance is often limited to reducing the wait time required for some system services. Symmetric multiprocessing can produce substantial gains in program execution speed, as long as individual threads do not contend for resources. The ability of a program (or an operating system) to take advantage of multiple CPU resources is termed *scalability*, and scalable operating systems are well positioned to take advantage of current improvements in available multiprocessing hardware platforms.

Virtual Memory. Providing the extensive memory resources required for most engineering software can be an expensive undertaking. Dynamic Random-Access Memory (DRAM) is too expensive to maintain an appropriate supply for every program used in a multitasking environment. In practice, much of the

memory demand in a multitasking setting can be satisfied by caching some of the blocks of data ostensibly stored in main memory to a fast disk storage subsystem. These blocks of data can be reloaded to main memory only when they are absolutely required, and this practice of *paging* memory to and from the disk is termed *virtual memory management.* In most common implementations of virtual memory, the paging scheme provides a level of independence of memory addressing between processes that is carefully implemented so that one process cannot corrupt the memory of another. Such schemes that implement memory protection to prevent interapplication memory corruption are termed *protected virtual memory management.*

Depending on demand for physical memory, virtual memory schemes may be a great help or a hindrance. While there are sophisticated paging algorithms available that are designed to prevent writing needed to memory to disk, in practice, if there are enough different applications competing for memory, the relative disparity in speed of memory vs. disk subsystems may lead to very sluggish performance for applications whose memory resources have been written to the disk subsystem. In addition, multiprocessing architectures place further constraints on virtual memory performance in order to avoid corruption of memory by different threads running on different CPUs. Modern virtual memory management is an active area of research in computer science, but one empirical rule is still true: perhaps the best way to improve the performance of any virtual memory operating system is to add physical ("real") memory!

Networking and Security. One of the most fundamental shifts in computing over the last decade has been the transition from disconnected individual computers to a distributed computing model characterized by networked workstations that support various remote processing models. Most modern operating systems support standard networking protocols that allow easy integration of different computers into local- and wide-area networks, and also permit sharing of resources among computers. Traditional networking functions (such as sharing files between different computers on the same network) have been augmented to encompass remote computing services, including sharing applications between networked computers (which represents a generalization of symmetric multiprocessing architectures from a single computer to a disparate network of connected computers).

Because of the tremendous pace of changes in the field of computer networking, one of the most important features of any network operating system involves adherence to standard networking protocols. Networking standards provide a portable implementation of networking function that effectively abstracts network operations, allowing existing networking applications to survive current and future changes in networking hardware and software. The most common current networking model is one promulgated by the International Standards Organization and termed the *Open Systems Interconnect* (OSI) reference model. The OSI model uses layers (ranging from low-level hardware to high-level application connections) to idealize networking function. Adherence to the OSI model permits operating systems to become insulated from improvements in networking hardware and software, and thus preserves operating system investment in the face of rapid technological improvements in the field of computer networking.

Once an individual computer is connected to a network, a whole host of security issues arise pertaining to accessibility of data across the network. Secure operating systems must satisfy both internal (local to an individual computer) and global (remote access across a network) constraints to ensure that sensitive data can be protected from users who have no right to access it. Since many mechanical engineering applications involve the use of military secrets, adherence to appropriate security models is an essential component of choosing an operating system for individual and networked computers.

There are many aspects to securing computer resources, including some (such as protected virtual memory schemes) that satisfy other relevant computer needs. In the setting of computer security, operating systems are classified according to criteria developed by the Department of Defense (DOD 5200.28-STD, December 1985). These DOD criteria provide for such features as secure logons (i.e., logging into a computer requires a unique user identifier and password), access control structures (which restrict access to computer resources such as files or volumes), and auditing information (which provides

automated record keeping of security resources so as to help prevent and detect unauthorized attempts at gaining access to secure computer resources).

Portability. Some operating systems (for example, MS/DOS, written in Intel 8080 assembly language) are inextricably tied to the characteristics of a particular hardware platform. Given the rapid pace of development in CPU hardware, tying an operating system to a particular family of processors potentially limits the long-term utility of that operating system. Since operating systems are computer software systems, there is no real obstacle to designing and implementing them in accordance with standard practice in software engineering, and in particular, they can be made portable by writing them in high-level languages whenever possible.

A portable operating system generally abstracts the particular characteristics of the underlying hardware platform by relegating all knowledge of these characteristics to a carefully defined module responsible for managing all of the interaction between the low-level (hardware) layer of the operating system and the overlying systems services that do not need to know precise details of low-level function. The module that abstracts the low-level hardware layer is generally termed a *hardware abstraction layer* (HAL), and the presence of a HAL permits an operating system to be ported to various processors with relative ease. Perhaps the most common portable operating systems are UNIX and Windows NT. Both of these operating systems are commonly used in engineering applications, operate on a wide variety of different CPUs, and are almost entirely written in the procedural C language.

Classification of Representative Operating Systems

Several operating systems commonly encountered in engineering practice are classified below in accordance with the definitions presented above. Note that some of these operating systems are presently disappearing from use, some are new systems incorporating the latest advances in operating system design, and some are in the middle of a potentially long life span.

MS/DOS and Windows 3.x. The MS/DOS (Microsoft Disk Operating System) operating system was introduced in the 1980s as a low-level controlling system for the IBM PC and compatibles. Its architecture is closely tailored to that of the Intel 8080 microprocessor, which has been both an advantage (leading to widespread use) and disadvantage (relying on the 8080's arcane memory addressing scheme has prevented MS/DOS from realizing effective virtual memory schemes appropriate for engineering computation). MS/DOS is a single-processor, single-tasking, single-threaded operating system with no native support for virtual memory, networking, or security. Despite these serious shortcomings, MS/DOS has found wide acceptance, primarily because the operating system is so simple that it can be circumvented to provide new and desirable functions. In particular, the simplicity of MS/DOS provides an operating system with little overhead relative to more complex multitasking environments: such low-overhead operating systems are commonly used in realtime applications in mechanical engineering for such tasks as process control, data acquisition, and manufacturing. In these performance-critical environments, the increased overhead of more complex operating systems is often unwarranted, unnecessary, or counterproductive.

Microsoft Windows is an excellent example of how MS/DOS can be patched and extended to provide useful features that were not originally provided. Windows 3.0 and 3.1 provided the first widely used graphical user-interface for computers using the Intel 80 $\times$ 86 processor family, and the Windows subsystem layers, which run on top of MS/DOS, also provided for some limited forms of cooperative multitasking and virtual memory for MS/DOS users. The combination of MS/DOS and Windows 3.1 was an outstanding marketing success. An estimated 40 million computers eventually ran this combination worldwide. Although this operating system had some serious limitations for many engineering applications, it is widely used in the mechanical engineering community.

VAX/VMS. Another successful nonportable operating system that has found wide use in engineering is VAX/VMS, developed by Dave Cutler at Digital Equipment Corporation (DEC) for the VAX family of minicomputers. VMS (Virtual Memory System) was one of the first commercial 32-bit operating systems

that provided a modern interactive computing environment with features such as multitasking, multithreading, multiprocessing, protected virtual memory management, built-in high-speed networking, and robust security. VMS is closely tied to the characteristics of the DEC VAX microprocessor, which has limited its use beyond that platform (in fact, DEC has created a software emulator for its current family of 64-bit workstations that allows them to run VMS without the actual VAX microprocessor hardware). But the VMS architecture and feature set is widely imitated in many popular newer operating systems, and the flexibility of this operating system was one of the main reasons that DEC VAXs became very popular platforms for midrange engineering computation during the 1980s.

Windows NT. Windows NT is a scalable, portable, multitasking, multithreaded operating system that supports OSI network models, high-level DOD security, and protected virtual memory. The primary architect of Windows NT is Dave Cutler (the architect of VAX/VMS), and there are many architectural similarities between these two systems. Windows NT is an object-oriented operating system that supports the client-server operating system topology, and is presently supported on a wide range of high-performance microprocessors commonly used in engineering applications. Windows NT provides a Windows 3.1 subsystem that runs existing Windows 3.1 applications within a more robust and crash-proof computational environment, but NT also provides other user interfaces, including a console interface for textual applications ported from mainframes and MS/DOS, a UNIX-like graphical user interface (provided by implementing common UNIX window management functions on top of NT), and the Macintosh-like interface similar to that introduced in Windows 95 as a replacement for Windows 3.1 in mid-1995.

UNIX. The UNIX operating system was developed during the 1970s at Bell Laboratories to satisfy the need for a flexible and inexpensive operating system that would provide high-end system services (e.g., multitasking, virtual memory) on low-cost computers. Since its initial inception, the UNIX operating system has evolved to become one of the most successful operating environments in history. UNIX provides preemptive multitasking, multithreading (threads are termed “lightweight processes” in most implementations of UNIX), multiprocessing, scalability, protected virtual memory management, and built-in networking. Although there are a variety of competing UNIX implementations, substantial standardization of the UNIX operating system has occurred under the auspices of the Open Software Foundation (OSF), a consortium of computer companies that includes IBM, DEC, and Hewlett-Packard. OSF UNIX is based on IBM’s AIX UNIX implementation and represents one of the most advanced operating systems available today. Another important emerging standard for UNIX is the public-domain version termed Linux: this UNIX variation runs on a wide range of computers, is freely distributed, and has an incredibly diverse feature set, thanks to the legions of programmers around the world who have dedicated their skills to its development, extension, and support. Various versions of UNIX run on virtually every type of computer available, ranging from inexpensive microcomputers through engineering workstations to expensive supercomputers. The ability of the UNIX system to evolve and retain a dominant market position over two decades is a concrete testimonial to the advantages of strict adherence to the principles of software engineering, because nearly all aspects of the UNIX operating system have been designed and implemented according to these principles. In fact, much of the history of software engineering is inextricably bound up with the history of the UNIX operating system.

Parallel Computation

The use of multiple processors and specialized hardware to speed up large-scale calculations has a rich history in engineering computation. Many early mainframe computers of the 1970s and most supercomputers of the 1980s used specialized hardware whose design was influenced by the nature of engineering computation. Vector processors, gather/scatter hardware, and coarse-grain parallel CPU architectures have been used successfully over the past few decades to increase the performance of large-scale computers used in engineering computation. Currently, most of the hardware advances of these past large computers have migrated to the desktop, where they are readily available on microcomputers and

workstations. Understanding the basic principles of these advanced computer architectures is essential to gain efficient utilization of their advantages, and so the following sections present an overview of the fundamentals of this important field.

Technical Overview of Parallel and Vectorized Computation

Parallelism in computer hardware can occur on many levels. The most obvious example was addressed in the setting of operating system services, where scalability over multiple CPUs was presented as a means for a computer's operating system to utilize additional CPU resources. Parallelism achieved by adding additional CPUs to a computer commonly occurs in two variations: a coarse-grained parallelism characterized by a relatively small number of independent CPUs (e.g., typically from 2 to 16 CPUs), and a fine-grained parallelism commonly implemented with substantial numbers of CPUs (typically, from a minimum of around 64 up to many thousands). The former is termed *symmetric multiprocessing*, or SMP, and the latter is referred to as *massively parallel* (MP) computing. Each is frequently encountered in practical engineering computation, although SMP is much more common due to its lower cost and relative simplicity.

It is also possible for parallelization to occur within an individual CPU. On specialized mainframes with attached vector processors (and within the CPUs of most supercomputers), various different machine instructions can be pipelined so that more than one instruction occurs in parallel in a particular arithmetic unit. The practical effect of this internal parallelization in instruction execution is that many common arithmetic operations (such as the multiplication of a vector by a scalar) can be performed by carefully arranging the pipelined calculations to permit impressive performance relative to the computational effort required on a nonpipelined CPU. One of these forms of internal parallelism within the CPU (or attached processor) is termed *vectorization*, as it permits vector operations (i.e., those associated with a list, or vector, of floating-point numbers that are stored contiguously in memory) to be processed at very fast rates.

Such pipelined execution characteristics have now become commonplace even on low-cost microcomputers. In fact, current high-performance microprocessors used in engineering workstations and high-performance microcomputers generally have multiple independent arithmetic units that can operate in parallel. Such internally redundant designs are called *superscalar* architectures and allow the CPU to execute more than one instruction per clock cycle. The cumulative effect of such multiple independent pipelined arithmetic units operating in parallel within an individual CPU is that current microprocessors exhibit astonishing performance on typical engineering problems when compared to large (and expensive) central computers of the 1980s. Engineering problems that required dedicated vector processors in the 1980s are commonly executed faster on low-priced microcomputers today. In addition to current hardware eclipsing older vector processors in performance levels, modern computer language compilers are now commonly tuned to particular microprocessor characteristics in order to provide the same sort of computational performance formerly associated with specialized vectorizing compilers (i.e., compilers that could recognize common vector operations and generate appropriately efficient machine instructions).

Finally, another important form of parallelism has developed in conjunction with high-performance networking schemes. Distributed computing applications are commonly designed to parallelize calculations by dividing up individual threads of execution among disparate computers connected via a high-speed network. While this sort of distributed computing was sometime encountered in the 1980s on high-priced computers (such as DEC VAX clusters, which transparently balanced computational loads over a collection of networked minicomputers), similar distributed computing schemes are now becoming commonplace on microcomputers and workstations connected over local-area networks.

Classification of Parallel Architectures

There are many schemes to characterize parallel computer architectures, including the SMP/MP classification given above. Since computer programs consist of instructions and data, it is possible to further classify parallelization schemes by considering the redundancy (or lack thereof) in these components.

The four possible classifications are single instruction/single data (SISD); single instruction/multiple data (SIMD); multiple instruction/single data (MISD); and multiple instruction/multiple data (MIMD). Of these four, the first pertains to nonparallel computation (such as a standard computer with a single processor). The others include representations of practical schemes for MP (massively parallel) computing, SMP (symmetric multiprocessing) computation, and networked distributed computing.

SIMD computers are particularly simple representatives of massively parallel systems. In order to run at maximum speed, each CPU in a SIMD architecture has to execute the same instructions as its neighbors (here "neighbors" is a flexible term that represents various topological arrangements among small groups of processors). The result is a massively parallel computer where individual processors act in unison: every instruction is executed by many processors, each with its own local data. If the underlying algorithm used can be constrained to fit into this SIMD architecture, the performance obtained can be phenomenal. Many standard numerical schemes were already well organized for SIMD calculations: for example, simple two-dimensional finite-difference calculations for heat conduction involve replacing the value at a node with the average of the node's four neighbors in a north/west/south/east pattern. This simple calculation is relatively easy to implement on a SIMD computer, and so calculations such as these finite-difference molecules result in highly scalable performance. More complex calculations, such as those found in modeling nonlinear problems, are generally much more difficult to implement on SIMD computers and often result in poor performance on these simplified computer architectures.

MISD computers are commonplace today, both in the form of supercomputers and in SMP desktop workstations. In each case, a small set of individual processors shares memory (single data), and each processor operates more or less independently of the others (multiple instructions). This form of parallelism has been aided by operating systems (such as current flavors of UNIX and Windows NT) that support multithreading, allowing the programmer (or the operating system) to distribute threads among the various processors in a typical SMP environment. Given appropriate programmer and operating system support, MISD computers can be highly scalable, so that adding additional processors results in associated decreases in execution time. There are substantial obstacles of increased performance in a MISD environment, including the important issue of contention by different threads for common resources. An example of resource contention occurs when two different processors attempt to access a shared memory address simultaneously: some form of signaling and locking mechanism must be provided to insure that more than one processor cannot simultaneously modify memory. Currently, many vendors offer hardware-based support for resolving contention (and related bottlenecks) in symmetric multiprocessing, and standards are currently evolving in this important area of support.

Probably the most common MIMD example of current interest is in distributed computing performed on networked computers. Since each computer has its own local data and instruction stream (MIMD), this approach combines many of the best features of single-computer implementations of both symmetric multiprocessing and massively parallel architectures. While networks of computers have been used for over a decade in solving many easily parallelized applications (such as classical mathematical problems arising in number theory), using such distributed computer networks to perform general-purpose engineering computations is a more recent development. MIMD networked computation requires a host of instruction synchronization and data replication issues to be resolved (these are the network equivalent of the resource contention problems of SMP architectures), but substantial progress is underway in addressing these bottlenecks to distributed computing. The use of object-oriented models for distributed computing, which permit hiding many of the details of the distribution process via appropriate process abstraction, appears to be an especially important avenue toward the efficient use of distributed networked computing.

Computer Graphics and Visualization

Mechanical engineering is one of the most important sources of applications in computer graphics, and mechanical engineers form a significant market for computer-graphics software. Many of the most important developments in the history of computer graphics, such as the development of spline models

for realistic surface representations, were originally motivated by the particular needs of the mechanical engineering profession. Current topics of importance to researchers in computer graphics, such as the applications of scientific visualization or the use of rational physical-based models in computer animation, are also motivated in large part by the diverse needs or the knowledge base of the mechanical engineering field.

Technical Overview of Computer Graphics

The fundamental motivation for computer graphics and visualization arises from the adage that "a picture is worth a thousand words." The human visual sense is the only sensory apparatus with sufficient bandwidth (i.e., information-carrying capacity) to permit rapid evaluation of the large data sets characteristically associated with problems in science and engineering. Mechanical engineers have historically been aware of the importance of using graphics, and college students in this field have traditionally been required to study engineering graphics as a required course during their first-year programs of study. The commonly cited observation that "graphics is an engineer's second language" is pertinent today, especially in light of the importance of television and other visual arts during the formative years of younger engineers.

There is a rich nomenclature associated with the field of computer graphics (see Foley and VanDam, 1982, for a detailed overview). Some high-level terms commonly used in the field should be defined before more detailed exposition of this important field is attempted; the definitions given below are not intended to be all-inclusive, but instead to be concise enough to permit further review of this topic.

- Visualization: the study of applying computer graphics toward the goal of displaying collections of data in a relevant and informative manner
- Rendering: converting a mathematical model of a scene geometry (or a collection of data values) into a visually meaningful image on the computer
- Virtual reality: technology permitting simultaneous display and control of graphical simulations so that the user interprets the display as the existence of an alternative reality
- Multimedia: the integration of senses besides the visual sense into a computer application or simulation
- Graphical user-interface: a metaphor for human-computer interaction using standardized graphical mechanisms for control, input, and output

One of the main reasons that rapid progress has occurred in computer graphics is that practitioners in the field have learned to leverage the efforts of others by adhering to industry-wide standards. The code of standardization and practice in computer graphics exists on many levels, ranging from low-level coordinate choices developed as a foundation toward abstracting the rendering and display process to high-level format standardizations required for the portable use of multimedia content. The breadth of standardization in computer graphics is beyond the scope of this handbook, but relevant information can be found in the publications of the ACM/SIGGRAPH. This organization is the primary instrument of dissemination and standardization efforts in the computer graphics industry.

Visualization Methods in Mechanical Engineering

The fundamental problem of visualization in science and engineering is the conversion of raw data into an informative visual display. The data may arise from a closed-form mathematical representation, or it may be obtained as an organized collection of data presented in tabular or related formats. The most important initial step in engineering visualization is the recognition of the domain (i.e., the set of input values) and range (i.e., the set of output values) of the data to be represented, so that an appropriate visual display can be synthesized. For example, if the range of the data includes a temporal component, then a time-dependent display scheme such as an animation is often warranted. If the domain is a physical region in space (such as a mechanical object being analyzed), then a common visualization scheme consists of mapping that region onto the display surface as a background for visual results. The details of the particular display choice depend upon the range of the output data: for display of scalars (such

as temperature, or specific components of stress), appropriate visualization schemes include contour maps using lines or color-filled contours, as shown in Figure 15.2.7 (in two dimensions) and in Figure 15.2.8 (in three dimensions, for the same general stress analysis problem). When rendering three-dimensional results as in Figure 15.2.8, it is necessary to provide for removal of hidden surfaces from the display.

For display of vectors, the use of arrows aligned with the local vector field is a common means for displaying this more complex type of range: an example is shown in Figure 15.2.9.

In order to aid in the understanding of complicated visualizations, it is often useful to provide visual cues to aid the viewer in understanding the display presented. In Figure 15.2.10, a contour plot of pressure within a heater fan is shown (at high Reynolds' number), with an inset picture showing the geometry of the fan used in the computational simulation. The combination of virtual display (the pressure contours) and physical display (the fan assembly) aids the viewer in understanding the model geometry and solution response. (Figures 15.2.9 and 15.2.10 are included courtesy of Advanced Scientific Computing Corporation of El Dorado Hills, CA.)

Another useful approach to provide contextual cues to aid in understanding a complex visualization is to overlay the graphical image on top of a physical setting associated with the simulation. For example, geographical simulations (such as models of contaminant transport used for air pollution modeling) can be overlayed on a map of the geographical area under study: viewers will instantly grasp the problem domain in terms of landmarks such as rivers, roads, mountains, and other obvious visual cues. An alternative approach is shown in Figure 15.2.11, where a visualization of a complex reactor simulation is overlayed on a picture of the reactor itself. In this figure, the color contours plot gas temperatures in a model of a chemically reacting Navier-Stokes simulation used for modeling vapor deposition processes occurring in semiconductor manufacture. (The simulation and visualization were both performed at Sandia National Laboratories in Livermore, CA.)

When time-dependent results are to be visualized, there are two standard schemes commonly used. The first approach involves treating the time-dependent behavior of the data as another spatial dimension. This approach is commonly used to graph scalar-valued functions of time t as $y = y(t)$, with the function's variation plotted on the vertical axis and the time on the horizontal axis. It can also be used to draw more complex functions such as the one shown in Figure 15.2.12, where a scalar-valued function of two variables $z = z(x, t)$ is plotted as a three-dimensional surface (in this example, the axial displacement of a bar as a wave moves along its length). Note that the surface is drawn in perspective to aid in the perception of three-dimensional behavior even though it is plotted on a two-dimensional page. Using such depth cues as perspective (as well as others, including hidden-surface removal and shading and realistic illumination models) to aid in realistic display of computer images is the essence of the rendering process.

The other standard approach for visualizing time-dependent data is to treat the temporal variation of the data in a natural form by animating the history of the display. Standard animation techniques were formerly beyond the range of cost and effort for most engineering purposes, as computer-generated animation workstations of the 1980s typically cost over $100,000 and required considerable dedicated expertise for operation. Currently, microcomputers have become excellent platforms for animation and visualization, and appropriate computer programs (known as nonlinear digital video editing software) for generating and composing animations from engineering simulations have become popular on inexpensive microcomputers and low-end engineering workstations.

Multimedia in Mechanical Engineering Practice

Multimedia is an imprecise term whose definition has evolved over the recent past as the performance of computers has improved substantially. Formerly, multimedia was taken to mean integration of different types of display (such as a textual computer used to control a graphical device for display of archived images). The current context of the term includes multiple senses, such as the integration of video and sound, or the control of a visual display by a tactile three-dimensional graphical input device. The former flavor of multimedia naturally draws the analogy with silent movies being replaced by those with a

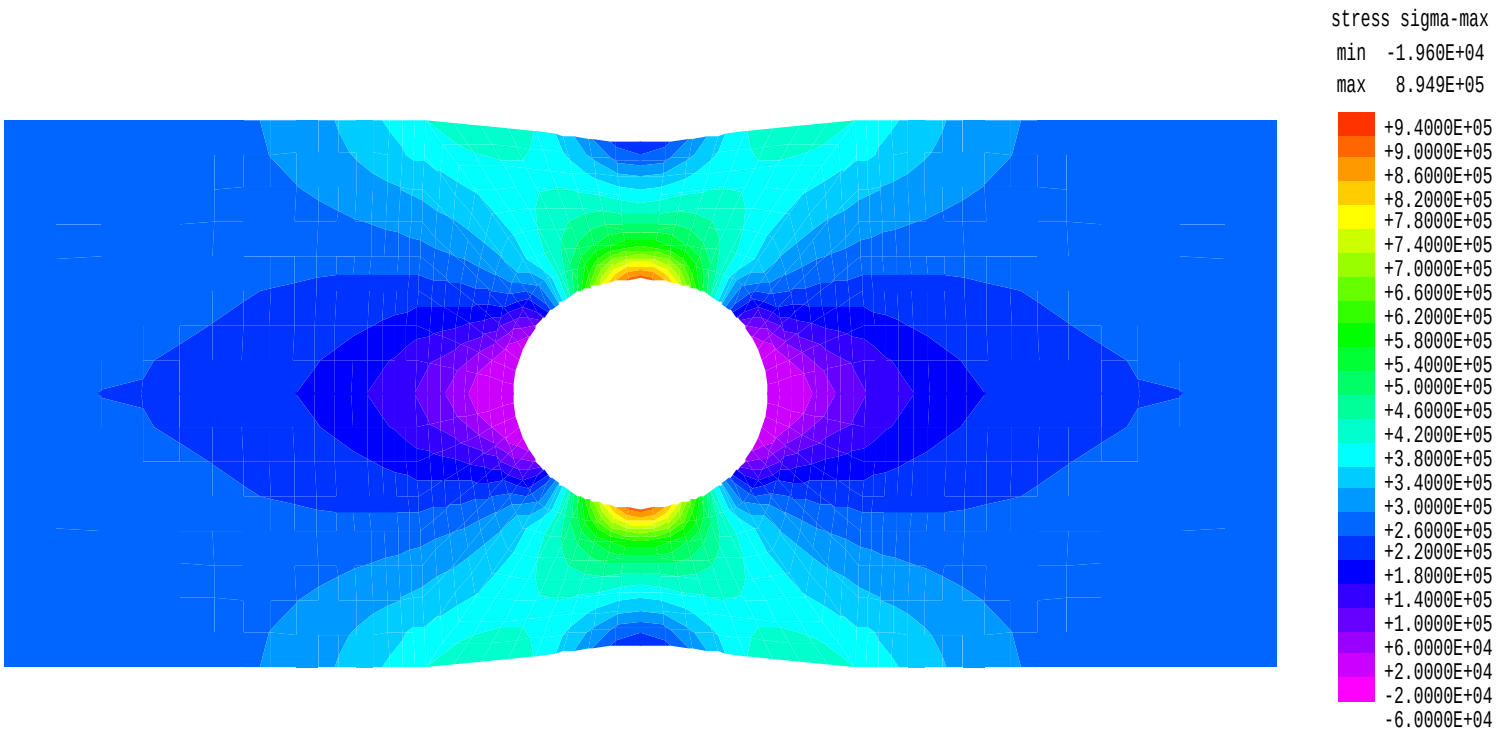

FIGURE 15.2.7 Two-dimensional contour plot for stress analysis.

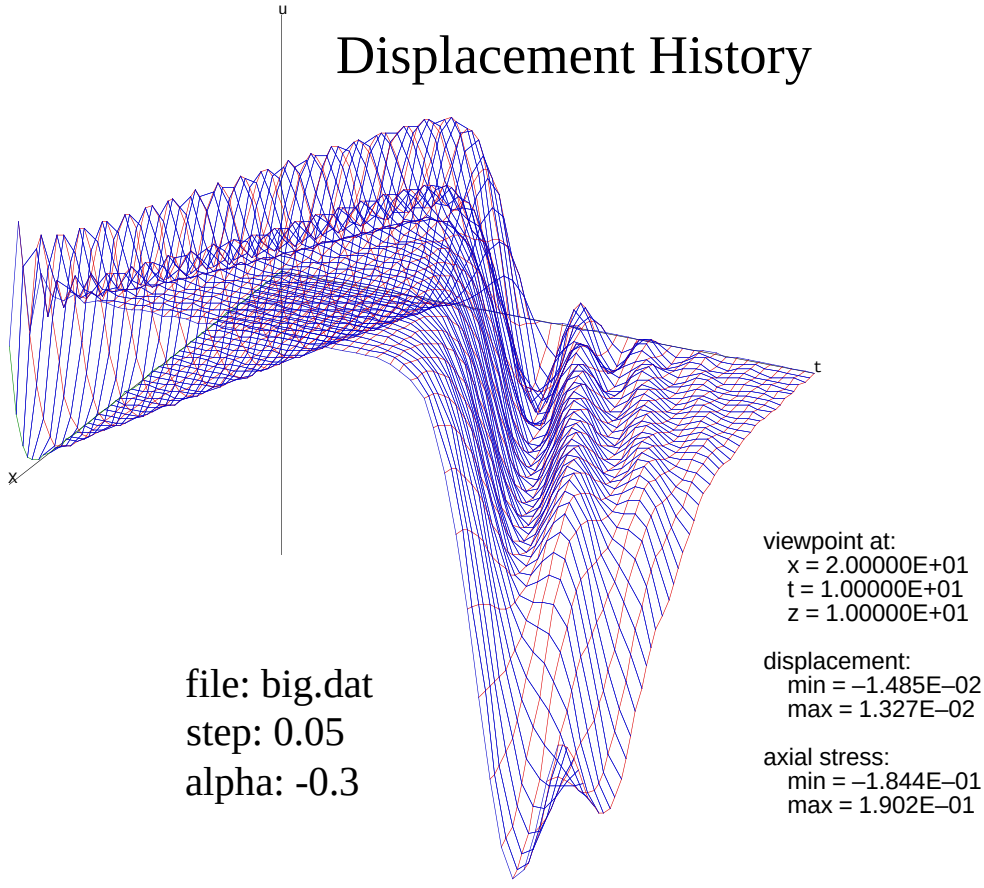

FIGURE 15.2.12 Time-dependent data viewed as space-time surface plot.

sound track: that technological development revolutionized the movie industry in a manner similar to the predicted impact of multimedia on computing practice. The latter example is widely used in virtual reality applications.

Multimedia is presently used in education, training, marketing, and dissemination efforts in the engineering profession (see Keyes [1994] for a detailed exposition of the application of multimedia to all of these fields). Each of these uses is based on two empirical observations: (1) people generally find multimedia presentation of data more interesting, and this increased interest level translates into better retention of data presented; and (2) good use of visualization principles in multimedia presentation provides a better audience understanding of the material presented. The promise of simultaneous increased understanding and improved retention is a strong motivation for using multimedia in the presentation of information.

There are considerable technical issues to address in efficient use of multimedia technology. The most important technical problem is the sheer volume of stored data required to make animations, which are a mainstay of multimedia presentations. A single high-quality color computer workstation image (e.g., one frame of an animation that would typically be displayed at 24 to 30 frames per second to convey the sense of continuous motion) requires from approximately 1 to 4 million bytes of storage. Generating full-screen animations therefore requires anywhere from a few dozen to over a hundred megabytes of data to be processed and displayed every second. Such video bandwidths are rare on computers, and even if they were available, the demand for storage would soon outstrip available supply, as each 10 sec of video potentially requires up to a gigabyte of high-speed storage. Storing sound requires less dramatic capacities, but even low-quality (e.g., AM-radio quality) audio storage requires substantial storage for long durations of audio.

The practical way to overcome these technical limitations to storage and display bandwidth is to develop efficient ways to compress visual and aural redundancies out of the data stream on storage, and then decompress the archived data for editing or display. Such COmpression/DECompression schemes (termed CODECs) are generally used to support multimedia applications ranging from digital animation preparation on microcomputers to video teleconferencing applications. Common CODECs are tailored for individual applications and auxiliary technology (for example, playing video from a CD/ROM device generally requires high compression ratios in order to accommodate the relatively poor data transfer rates obtained with CD/ROM technology), and their performance is measured in terms of compression ratio, which is the ratio of uncompressed image size to compressed image size.

Various CODECs in common use include:

- JPEG (Joint Photographic Experts Group) CODEC. JPEG is a CODEC originally developed for efficient storage of individual images, such as photographic libraries. JPEG is a lossy algorithm (i.e., some information may be lost during compression), but JPEG is so carefully tuned to human perceptual characteristics that it is feasible to achieve compression ratios on the order of 10:1 or more without being able to detect any losses, even after repeated recompressions. Higher compression ratios (on the order of 100:1) can be achieved, but these more efficient rates may introduce visible artifacts of the compression process. JPEG is generally only feasible for animation applications through the use of specialized hardware, but the same hardware can be used for both compression and decompression tasks. JPEG is a very commonly used CODEC in animation applications, as the required hardware is relatively inexpensive, the performance (e.g., speed, image quality) is acceptable, and the algorithm is easy to implement within animation applications (e.g., digital video editing software).

- MPEG (Motion Pictures Experts Group) CODEC. MPEG is a family of CODECs that is becoming popular for display-only animation applications. The various MPEG implementations (MPEG and MPEG-2) require prodigious amounts of computational effort for the compression step, so they are not presently feasible for inexpensive video capture applications. MPEG CODECs routinely provide compression ratios approaching 100:1 with relatively little degradation of image quality. This compression efficiency permits very large and complex animations to be stored and played back using low-technology devices such as CD/ROMs. The fundamental difference between MPEG and JPEG schemes is that with JPEG,each video frame is compressed independently of all the other frames, where MPEG uses adjoining frame information by concentrating on the *differences* between frames to compress the overall animation more efficiently (most animations have only small temporal differences among adjacent frames, and this time-dependent redundancy is ignored by the JPEG algorithm and carefully exploited by the MPEG family). It is expected that the near-term will see many inexpensive implementations of MPEG CODECs for microcomputers, and many proposed video storage standards (e.g., new videodisc technology designed to replace existing VHS video playback devices) rely on MPEG compression schemes for efficient storage of movies on CD/ROMs.

Another important technical issue arising in multimedia applications is the synchronization of time-dependent data streams. For example, multimedia applications using both video and sound must guarantee synchronization of these two data streams in order to maintain audience interest. Probably the most important synchronization method is that provided by the Society of Motion Picture and Television Engineers (SMPTE). SMPTE synchronization depends on a time-code that numbers every frame of video. This time-code information can be used to synchronize audio information to the video source; in fact, this is exactly how commercial movie soundtracks are synchronized with the motion picture. Other time-code mechanisms include RC time-code, which is a frame-indexing scheme that is available on many consumer-grade video products, including camcorders, video recorders, and video editing equipment. RC provides the same sort of synchronization as SMPTE, but with fewer features and at a reduced cost.

Standard microcomputer multimedia programming interfaces generally provide synchronization mechanisms for simultaneous audio and video display. Both Microsoft's Video for Windows system software (used under Windows and Windows NT operating systems) and Apple's QuickTime software (available for Macintoshes, Windows, Windows NT, and UNIX workstations) provide time-code information pertinent for simple synchronization of multimedia. In addition, current versions of QuickTime also provide SMPTE time-code support, in order to simplify the task of high-performance digital video editing on the Macintosh platform.

Graphical User-Interface Design and Implementation

The marriage of human perceptual principles from applied psychology with the technology of interactive computer graphics resulted in the development of graphical user-interfaces (GUIs). GUIs have since evolved into one of the most revolutionary ideas in the history of computing. The basic idea behind a GUI is that visualization can be used to provide a powerful abstraction for the interaction between human and computer, and that basing that graphical abstraction on principles of human perception and ergonomics will result in increased user productivity. Most of the early work on development of GUIs occurred at the Xerox Palo Alto Research Center in California, and the fundamental ideas developed there were first implemented in a consumer setting when Apple Computer released the Macintosh in 1984. Since then, virtually every major vendor of computer has adopted a GUI similar in appearance to that of the Macintosh, and it is clear that using a well-designed GUI yields substantial gains in productivity for most computer-assisted tasks.

The fundamental rules for implementing a GUI within a computer program are simple: the program's interface must be intuitive, consistent, permissive, and responsive (see Apple [1985] for a well-written introduction relating to the widely imitated Macintosh user-interface guidelines). An intuitive program

interface is easy to understand and responds naturally to a user's actions. Implementing an intuitive interface is a similar task to good industrial design, where principles of cognitive ergonomics are used to insure that controls of manufactured products (such as household appliances) are appropriately easy to use. The classic example of an appliance with an intuitive user interface is a toaster (in fact, one of the design goals of the Macintosh development process was to design a computer that would be as easy to use as a toaster), as the controls are naturally placed and behave intuitively. Intuition in computer applications thus implies natural composition, arrangement, and performance of graphical controls, such as buttons to be pressed for execution of commands.

The role of consistency is essential to the goal of improving the productivity of computer users. Until the widespread use of GUIs, most application programs used individual and unique schemes for such mundane tasks as saving files, printing documents, or quitting the program. Unfortunately, there was little standardization of commands for performing these common functions, so the user was faced with a substantial learning curve for each program encountered. With the advent of consistent graphical user-interfaces, the effort of learning most standard commands needs to be learned only once; all other applications will use the same mechanism for performing these common functions. The cost of training is thus primarily amortized over the first program learned, and the resulting productivity gains are often substantial. While the goal of complete consistency between applications (and especially between different types of GUI) has not yet been realized, there has been considerable progress toward this ultimate goal.

Permissiveness places the user in control of the computer, instead of the opposite situation, which was routinely encountered in older textual interfaces. The user should decide what actions to do and when to do them, subject only to the feasibility of those actions. Permissiveness allows users to structure their workflow in a personalized manner, which allows them to seek and find the best individualized way to accomplish computer-assisted tasks. Permissiveness is one of the most difficult attributes for a computer programmer to implement, as it requires enabling and testing a myriad of different execution pathways in order to guarantee that all feasible approaches to using the computer program have been insured to work reliably. The quality control processes of permissive GUI-based programs are often automated (using software that generates random input processes to simulate a variety of user actions) in order to test unexpected command sequences.

Responsiveness is another essential element of ensuring that the user feels in control of the software. In this sense, a responsive GUI-based program provides some appropriate feedback (generally graphical) for every legitimate user-initiated action. This feedback may be as simple as a "beep" when an improper command is issued, or as complicated as rendering a complex picture in response to user-supplied input data. Responsiveness and intuition work together in the control of the program's actions; for example, the pull-down menu command procedures of most current GUI programs permits the user to see clearly (typically, via highlighting of the currently selected menu item) which of a series of intuitive commands are about to be initiated.

Writing good GUI-based software is a difficult process and is especially cumbersome when procedural languages are used. Modern event-driven interactive software is naturally suited to the more asynchronous message-driven architecture available with object-oriented programming models, and it is in the area of GUI-based applications that object-oriented languages have begun to corner the development market. Since managing the GUI requires so much programmer effort (and because the goal of consistency requires that all such code behave in a similar manner), there is a considerable incentive to reuse code as much as possible in this task. The use of class libraries designed for implementing a standard GUI model is a highly effective way to develop and maintain graphical interactive computer programs, and this use is one of the most common applications of class libraries in software engineering.

There are many standard GUI elements, including:

- Menus for permitting the user to initiate commands and exert program control
- Dialogs for field-based input of data by the user

- Windows for graphical display (output) of program data
- Controls (such as buttons or scroll bars) for auxiliary control of the program

Virtual Reality Applications in Engineering

Virtual reality is one of fastest-growing aspects of computer graphics. Efficient and realistic virtual reality applications require incredible amounts of computational effort, so advances in this area have been limited in the past, but the increased computational performance available with current CPUs (and with better support for multiprocessing and parallelization of effort) has made virtual reality solutions feasible for many engineering problems. The primary motivation for virtual reality is the same one as for computer graphics: using the body's senses (and especially the sense of sight) is a very productive way to gain insight into large amounts of data or for simulating difficult (e.g., life-threatening) situations.

There are two common technological approaches to virtual reality: *windowed* virtual reality applications, in which the view into the virtual world is represented by a conventional planar graphical computer display, and *immersive* virtual reality which requires specialized hardware (such as display headsets) to convey a sense of being immersed in the artificial virtual world. While windowed virtual reality applications are common (running on platforms ranging from high-performance computers with color displays to mass-market dedicated computer game machines designed for use with television sets), immersive virtual reality applications are still fairly expensive and rare. In addition, there is considerable anecdotal evidence that attempting to perform immersive virtual reality with equipment insufficiently powerful to update the display instantaneously (i.e., within the interval of around 1/30 sec associated with the persistence of vision) may induce nausea and disorientation in many users.

There are many important types of virtual reality applications in use in engineering and related fields. *Walkthrough* (or perambulatory) virtual reality programs permit the user to move around in the virtual world, where either easily recognizable images (such as architectural renderings of virtual construction) or completely virtual images (such as visualization displays involving surface plots, color contours, streamline realizations, and other standard visualization schemes updated in realtime) are encountered and manipulated. Walkthrough virtual reality applications are typically used to gain new perspective on simulations or proposed constructions. The primary control ceded to the user is the power to move through the virtual world, and perhaps to modify the type of display encountered.

Synthetic experience is another important component of the application of virtual reality. The classic example of this form of virtual reality application is a flight simulator, where an integrated display and a movable cockpit are used to simulate the "look and feel" of flight. Synthetic experience applications permit the user to manipulate the virtual world in exactly the same manner as the real world, and these programs are used for education, training, and professional practice. The basic motivation for this class of virtual reality applications is to permit the user to practice and learn techniques that would be otherwise too expensive or too dangerous to perform by "real" methods as opposed to virtual practice. This approach has been used extensively in military applications (e.g., battle simulators) and is gaining wide use in medicine and other professional fields (e.g., virtual surgery, where surgeons can practice surgical techniques on the computer or even perform real surgery from a remote "virtual" location).

15.3 Computational Mechanics

Computational mechanics is the art and science of simulating mechanics problems on the computer. The rapid development of computational mechanics is an important component of the foundation of the today's high-technology world. Current developments in aerospace, automotive, thermal, biomedical, and electromagnetic engineering applications are in large part due to the success of computational mechanics researchers in finding efficient schemes to simulate physical processes on the computer. Understanding the strengths and weaknesses of the current computational mechanics field is an important task for the practicing mechanical engineer interested in using computer-aided engineering methods.

Computational approximations for mechanics problems are generally constructed by discretizing the domain of the problem (i.e., the underlying mechanical system) into smaller components. Ideally, in the limit as the size of each of these individual discretized components becomes negligibly small, the computational approximation obtained becomes exact. In practice, there is a lower limit on how small a discretization can be used, as round-off error (caused by truncation of numerical representations used on computers) and requisite computational effort eventually conspire to produce inaccurate or excessively expensive results. Other alternative approximation schemes, including semi-analytical methods such as truncated Fourier series representations, are also commonly used to provide numerical solutions for engineering problems. These nondiscretized methods require letting the number of solution functions (such as the trigonometric functions used in Fourier series) approach infinity to gain convergent results and are thus superficially similar to discretization schemes such as finite-element and finite-difference methods, where the number of grid points tends to infinity as the size of the grid spacing decreases.

Computational Solid, Fluid, and Thermal Problems

Before specific computational approximation schemes are presented, it is enlightening to enumerate the wide variety of problems encountered in mechanical engineering practice. In many cases, each individual subdiscipline of mechanics (e.g., solid mechanics) uses different modeling techniques to obtain computational approximations, so that reviewing the various branches of mechanics also serves to foreshadow the spectrum of numerical schemes used in the different branches of computational mechanics.

Solid Mechanics

Solid mechanics is one of oldest and most well-understood branches of mechanics, and its associated computational schemes are similarly well established. The most common application of solid mechanics is *stress analysis*, where the mechanical deformation of a body is studied to determine its induced state of stress and strain. The study of stress analysis formerly included considerable emphasis on construction and instrumentation of physical models using strain gauges and photoelastic coatings, but modern computational schemes for modeling deformation of solids have rendered these traditional laboratory techniques nearly extinct. The most currently popular stress analysis methods are those based on computational approximations using *finite-element* models. This family of computer simulation techniques is one of the most successful branches of modern computational mechanics, and practical implementations of finite-element methods represent a unified computational model for nearly the entire range of solid mechanical response.

Solids are modeled by appealing to three classes of mathematical relationships: equilibrium, compatibility, and stress-strain laws. Equilibrium statements represent mathematical expressions of conservation laws and are generally expressed in terms of the conservation of linear and angular momentum. Compatibility conditions include the kinematical strain-displacement relations of mechanics, where strains are expressed as spatial derivatives of the displacement field. Stress-strain laws are also termed constitutive relations, because they idealize the constitution of the material in order to relate the interplay of stresses and strains in a deformed body. The fundamental mathematical relations for the dynamic response of a three-dimensional isotropic linear-elastic solid body are given below — note that these equations are linear, in that they involve no products of the solutions components of displacement, stress, or strain.

This linearity arises from the assumptions of small deformations, a linear stress-strain law, and the fact that the reference frame for these equations is attached to the solid body. The linear nature of these relations makes them relatively easy to solve for a wide range of problems, and this simplicity of analysis is an important reason why stress analyses based on these relations is such an important part of computational mechanics.

Definitions for Solid Mechanics Equations

$u, v, w = x, y, z$ components of displacement

$\ddot{u}, \ddot{v}, \ddot{w} = x, y, z$ components of acceleration

$\sigma_x, \sigma_y, \sigma_z, \tau_{xy}, \tau_{yz}, \tau_{zx}$ = stress components

$\varepsilon_x, \varepsilon_y, \varepsilon_z, \gamma_{xy}, \gamma_{yz}, \gamma_{zx}$ = engineering strains

g_x, g_y, g_z = gravity body force components

E = Young's Modulus

ν = Poisson's Ratio

ρ = Density (15.3.1)

"Dynamic" Equilibrium Equations for a Solid

$$\rho\ddot{u} = \frac{\partial\sigma_x}{\partial x} + \frac{\partial\tau_{xy}}{\partial y} + \frac{\partial\tau_{zx}}{\partial z} + \rho g_x$$

$$\rho\ddot{v} = \frac{\partial\tau_{xy}}{\partial x} + \frac{\partial\sigma_y}{\partial y} + \frac{\partial\tau_{yz}}{\partial z} + \rho g_y \qquad (15.3.2)$$

$$\rho\ddot{w} = \frac{\partial\tau_{zx}}{\partial x} + \frac{\partial\tau_{yz}}{\partial y} + \frac{\partial\sigma_z}{\partial z} + \rho g_x$$

Compatibility Equations for a Solid

$$\varepsilon_x = \frac{\partial u}{\partial x} \qquad \gamma_{xy} = \frac{1}{2}\left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right)$$

$$\varepsilon_y = \frac{\partial v}{\partial x} \qquad \gamma_{yz} = \frac{1}{2}\left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}\right) \qquad (15.3.3)$$

$$\varepsilon_z = \frac{\partial w}{\partial z} \qquad \gamma_{zx} = \frac{1}{2}\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right)$$

Isotropic Linear-Elastic Stress-Strain Relations

$$\varepsilon_x = \frac{1}{E}\left[\sigma_x - \nu\left(\sigma_y + \sigma_z\right)\right] \qquad \gamma_{xy} = \frac{2(1+\nu)}{E}\tau_{xy}$$

$$\varepsilon_y = \frac{1}{E}\left[\sigma_y - \nu\left(\sigma_z + \sigma_x\right)\right] \qquad \gamma_{yz} = \frac{2(1+\nu)}{E}\tau_{yz} \tag{15.3.4}$$

$$\varepsilon_z = \frac{1}{E}\left[\sigma_z - \nu\left(\sigma_x + \sigma_y\right)\right] \qquad \gamma_{zx} = \frac{2(1+\nu)}{E}\tau_{zx}$$

Solids are commonly distinguished from liquids by the ability of solids to maintain their shape without restraint due to enclosing containers. Because of this particular form of mechanical strength, solids provide many simple structural approximations that naturally arise as degenerations of full three-dimensional solid mechanical response. These idealizations of solid mechanical behavior are diagrammed in Figure 15.3.1 and include:

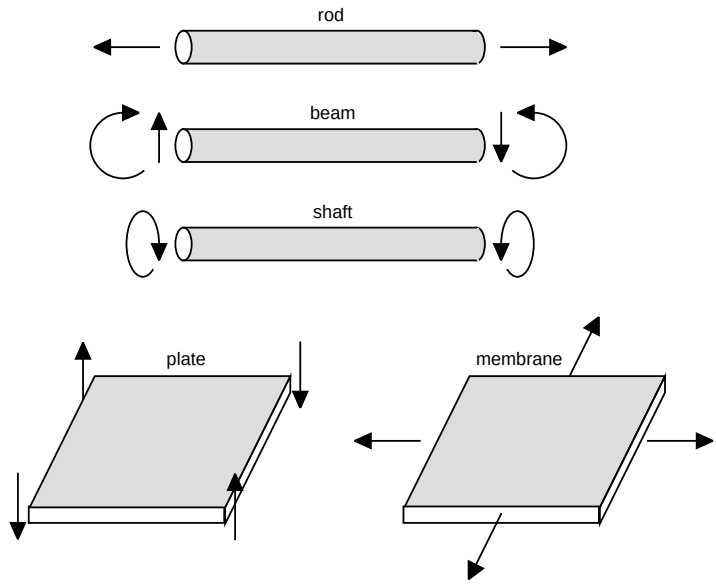

FIGURE 15.3.1 Common idealizations of solid mechanical behavior.

- Rods, with a local one-dimensional geometry and applied loads directed along the natural axis of the rod (rods are also termed spars or struts)
- Beams, which are similar to rods except that beams permit loads to be applied in directions perpendicular to the natural axis
- Shafts, which are also similar to rods, except that they are loaded by torques directed along their natural axis in addition to forces applied in that axial direction
- Membranes, which are locally two-dimensional structures loaded in the plane defined by their geometry
- Plates, which are two-dimensional flat structures loaded by arbitrary forces and couples, including those that excite membrane response and those that bend or twist the natural two-dimensional reference surface of the plate
- Shells, which are generalizations of plates to include curvature of the reference surface in three dimensions

Theories of computational solid mechanics are often categorized by reference to the particular structural idealization being studied. In particular, computational theories for beams, plates, and shells are similar because each is characterized by bending deformation, in which the primary mechanical response may occur at right angles to the natural geometric reference frame for the structure. Problems that include substantial bending deformation often require considerable care in computational modeling in order to avoid inaccurate results.

Another very important aspect of solid mechanics involves nonlinear material and geometric response. Nonlinear material behavior is commonly encountered in computational *inelasticity*, where the plastic, viscous, or nonlinear elastic response of a solid material must be modeled. In many materials (such as most metals) this inelastic behavior in realized after considerable elastic response, and hence it may often be neglected. In other materials (such as rubber or its relatives commonly used in aerospace applications), the nonlinear material properties must be addressed throughout the range of computational simulation. Furthermore, many of the idealizations presented earlier (such as rods and membranes) possess nonlinear geometric behavior that may dominate the mechanical response. One important example of this form of geometric nonlinearity is the buckling of a rod subjected to axial compressive stresses.

Fluid Mechanics

The basic principles of fluid mechanics are exactly the same as those for solid mechanics: the mechanical system under consideration is analyzed using appropriate equilibrium, compatibility, and stress-strain relations. In practice, because of the inability of a fluid to resist shear, fluids are considerably more difficult to characterize than solids, and the effective computational mechanics of fluids is therefore a more difficult and diverse topic. Perhaps the most important difference between common models for solid and fluid mechanics is that the base reference frame for the solution process is generally different. For solids, most analyses proceed by modeling the deformation relative to a reference frame attached to the material body being deformed. Fluids are generally modeled instead by attaching the problem's reference frame to a region in space and analyzing the flow of the fluid as it is transported through this geometric reference frame. The latter scheme is termed an *Eulerian* formulation of the reference frame, and the former is called a *Lagrangian* reference configuration. While the Eulerian world view is more common for analyzing fluids (primarily because tracking the individual motion of all particles of the fluid material is generally intractable in practice), this conceptually simpler approach gives rise to many practical computational difficulties because the underlying conservation principles are most readily posed in a reference frame attached to the material.

One of the most important mathematical models of fluid response are the Navier-Stokes equations. These equations are presented below for a three-dimensional flow field involving a Newtonian fluid (i.e., one readily characterized by the material parameter *viscosity*, which is assumed not to depend upon fluid stress) and an incompressible formulation (see Panton, 1984 or White, 1979). It is worth noting that even in the case of these simplifying assumptions, which correspond to those given above for the mathematical formulation of solid mechanics, the Navier-Stokes equations are nonlinear, in that products of solution quantities occur in the convective terms on the left-hand side of the momentum conservation equations. These nonlinearities arise because of the Eulerian reference frame used to model fluid flow, and cause fluid mechanics problems to be generally much more difficult to solve than analogous solid mechanics problems.

Definitions for Fluid Conservation Equations

u, v, $w = x, y, z$ components of velocity

p = pressure field

g_x, g_y, g_z = gravity body force components (15.3.5)

ρ = density

μ = viscosity

Fluid Momentum Conservation Equations

$$\rho\left(\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}\right)=\rho g_x-\frac{\partial p}{\partial x}+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}+\frac{\partial^2 u}{\partial z^2}\right)$$

$$\rho\left(\frac{\partial v}{\partial t}+u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+w\frac{\partial v}{\partial z}\right)=\rho g_y-\frac{\partial p}{\partial y}+\mu\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}+\frac{\partial^2 v}{\partial z^2}\right) \quad (15.3.6)$$

$$\rho\left(\frac{\partial w}{\partial t}+u\frac{\partial w}{\partial x}+v\frac{\partial w}{\partial y}+w\frac{\partial w}{\partial z}\right)=\rho g_z-\frac{\partial p}{\partial z}+\mu\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}+\frac{\partial^2 w}{\partial z^2}\right)$$

Fluid Mass Conservation Equation

$$\frac{\partial}{\partial x}(\rho u)+\frac{\partial}{\partial y}(\rho v)+\frac{\partial}{\partial z}(\rho w)=0 \quad (15.3.7)$$

Fluid mechanical response is generally classified according to a variety of schemes, including whether the flow is internal (confined, as in flow-through ducts) or external (confining, as in the case of modeling flow around an airfoil in aerospace applications), and whether the internal or external flow field contains a fluid-free surface. Free-surface flows are considerably more complex to model using computational methods because the physical extent of the fluid material (and hence of the problem's geometric domain) is unknown *a priori*, and therefore determining the geometry of the mechanical problem must be considered as an essential part of the problem solution process.

One important facet of mechanical engineering practice involves diffusion phenomena, such as the flow of heat through a conductor. Such problems in heat conduction, porous media flow, and other diffusive systems can be readily modeled using standard fluid mechanical models appropriate for diffusion and dispersion. In addition, problems involving combined advection and diffusion (such as mass transport problems encountered in environmental engineering or in manufacturing) are readily modeled using techniques similar to related fluid mechanics models.

One of the most common ways to categorize fluid mechanical behavior arises from consideration of various dimensionless parameters defined by the constitution of the fluid and its flow regime. Representative dimensionless parameters relevant to fluid mechanics include:

- The Reynolds number, which relates the effects of fluid inertia to those of fluid viscosity forces and which naturally arises in a broad range of fluid problems
- The Mach number, which measures the ratio of fluid speed to the speed of sound in the fluid: this parameter is important in compressible flow problems
- The Peclet number, which quantifies the relative effects of fluid transport due to advection and dispersion and is used in fluid mass transport modeling

- The Taylor number, which is used to predict instabilities present in various fluid flow regimes and may be encountered when dealing with the computational ramifications of fluid instability

Unlike solid mechanics, there is no body of computational expertise that provides a generic model for computational approximation of the full range of fluid response. In practice, computational schemes are chosen according to particular aspects of fluid behavior (such as the various classifications and dimensionless parameters given), which substantially limits the range of applicability of any particular computational solution scheme. Many fluid models are solved using finite-element models, as in solid mechanics, but others have largely resisted characterization by such general computational schemes.

Fluid material models are generally more complex than those found in solid mechanics, as fluids exhibit a bewildering array of diversified material responses. Because of the difficulty in modeling many fluid constitutive parameters, many fluid models are analyzed using gross constitutive models that often neglect complicating material behavior (one common example of this case is the case of inviscid flow models, where neglecting the presence of fluid viscosity results in tremendous simplification of the resulting computational approximation). When fluid material response is important, as in the example of modeling transition from laminar to turbulent fluid behavior, the requisite constitutive equations for the fluid become appropriately more complex. While there is not yet a completely unified model for fluid constitutive behavior, each individual subdiscipline of computational fluid mechanics utilizes fluid material models that provide reasonable accuracy for fluid response within the range of the particular problems studied.

Electromagnetics problems are commonly solved by practicing mechanical engineers using techniques originally utilized for computational fluid dynamics. It is feasible to recast much of the computational technology developed for fluids into the setting of electromagnetics problems, because many electromagnetic simulations are qualititatively similar to fluid response. For example, potential flow simulation techniques are readily adapted to the potential formulations of electrostatics and magnetostatics. Alternatively, the full range of fluid response exhibited by the Navier-Stokes equations, which includes transient inertial and dissipative effects, is qualitatively similar to large-scale transient problems involving coupled magnetic and electrical fields. Mechanical engineers interested in performing electromagnetic simulations will commonly find that expertise in fluid computer modeling provides an excellent understanding of methods appropriate for solving electromagnetic problems.

Thermal Analysis

The determination of the static or transient temperature distribution in a physical medium is one of the best-known cases of the mathematical setting known as “scalar potential field” theory. In this case, the scalar potential is the temperature field, and the heat flow in the physical domain occurs in a direction governed by the product of a constitutive tensor known as the *thermal conductivity* and the gradient of the temperature distribution. In simple terms, heat flows downhill, or opposite the direction of the temperature gradient. The governing mathematical relations for transient conductive heat transfer in a three-dimensional solid are given below (see Kreith and Bohn, 1993). Note that this form of the energy conservation law will not apply if the conductivity varies with position, as is common in many mechanical engineering applications: in this case, the second derivatives on the right-hand side of this relation must be generalized to include spatial derivatives of the conductivity term.

Definitions for Thermal Equation

T = temperature field

k = thermal conductivity

s = distributed heat sources (15.3.8)

ρ = density

c = specific heat

Heat Energy Conservation Equation

$$\rho c \frac{\partial T}{\partial t} = -k\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) + s \tag{15.3.9}$$

Conductive thermal problems are relatively straightforward to solve, which leads to the incorporation of thermal effects in many commercial solid and fluid mechanics analysis programs. The mathematical quality of these thermal analyses is that they are diffusive phenomena, in that they exhibit smooth solution behavior and that there are few localization effects either in space or time that cause serious computational problems such as those commonly found in transient analyses in solid, fluid, and electromagnetic systems. Convective thermal problems are considerably more difficult to model by computer because they involve transport of heat by a moving fluid, and thus may suffer from the same difficulties inherent in modeling transient fluid response.

Biomechanics

Biomechanics is an increasingly important component of mechanics (see Section 20.3) Computational simulation of biomechanical systems is difficult because many biomechanical problems straddle the boundary between solid and fluid mechanics and the mechanical properties of many organic components are diverse. For example, the computational modeling of head trauma, which is of considerable interest in automotive engineering applications, is complicated by the fact that the brain is a semisolid porous mechanical system, and its motion and deformation are further constrained by the solid enclosure of the skull. While rational finite-element mechanical modeling of head trauma has been underway for over two decades (Shugar, 1994), the problem still resists accurate computational simulation.

Even though biomechanical problems are inherently difficult, they are often encountered in professional practice. The practicing engineer interested in performing accurate computational modeling of complex biomechanical systems should insure that appropriate verification measures (such as computer visualization of model geometry and results) are undertaken in order to minimize the potential for errors caused by the overwhelming difficulties in modeling these important but often intractable mechanical systems.

Coupled Solid/Fluid/Thermal Field Analyses

Many “real-world” problems encountered in mechanical engineering practice defy simple categorization into solid, fluid, or otherwise. These practical problems often include combinations of classes of response, and the efficient solution of such coupled problems requires careful investigation of the individual components of the combined problem. There are several important questions that must be addressed when solving a coupled mechanical problem:

- Is it necessary to solve for all components of the solution response simultaneously (i.e., can the problem components be decoupled)?
- If the solution processes can be decoupled, which aspects of the solution must be found first, and which components can be considered of secondary relevance during the decoupled solution process?

- Are there any mathematical pathologies present in the coupled problem that may compromise the accuracy of the computed solution?

In general, fully coupled solution schemes (in which all components of the solution are found at the same time) will be more accurate over the entire range of solution response and will also require more computational effort. Under some circumstances, one or more components of the solution can be identified as of relatively minor importance (either because of their relative magnitude or their insignificant rate of change with time), and then the solution process can be decoupled in order to simplify the resulting calculations. For example, in many problems involving the coupled mechanical/thermal response of a material, it is common practice to assume that the temperature field can be calculated independently of the state of stress. Furthermore, an additional simplification can be obtained by assuming that the mechanical deformation of the system does not affect the temperature distribution substantially. The analysis of a mechanical system during relatively slow changes in ambient temperature (such as the diurnal variations of temperature encountered outdoors between night and daytime direct sunlight) could be modeled with reasonable accuracy using these assumptions, and the net result of this simplification is that the coupled problem could be solved as a series of uncoupled transient problems. At each time in the solution history, the temperature field would be computed, and this temperature distribution would then be used to compute the mechanical deformation at the same time. As long as the underlying assumptions leading to these simplified decoupled problems are satisfied, this uncoupled approach works well in practice.

In many problems, it is not possible to decouple the component problems, and all aspects of the solution must be determined simultaneously. Some important examples occur in aerospace applications, including the modeling of flutter instabilities in aircraft structures (where the coupled external flow and solid mechanics problems are considered concurrently) and the ablation of rocket engine components (where the modeling of combustion, heat transfer, thermal pyrolysis, mechanical deformation, and porous media flow effects all must be considered simultaneously).

In many coupled problems, there are mathematical solution pathologies present that may corrupt the accuracy of the computer solution. In particular, whenever the solution process involves determination of coupled kinematical solution components (i.e., geometric unknowns such as velocities and displacements) and statical solution parameters (i.e., force-like quantities such as pressure), then the mathematical setting for guaranteeing accuracy of the computer approximation may become considerably more complex. Coupled problems involving both statical and kinematical solution components are termed *mixed* problems, and practicing engineers who must model mixed problems ought to familiarize themselves with an outline of the potential pathologies that can be exhibited by naive application of mixed computational technologies. While a complete characterization of these problems is far beyond the scope of this brief introduction to coupled problems, some hint of the underlying theory and practice is presented in the following sections.

Mathematical Characteristics of Field Problems

Effective computational solution of the problems encountered in mechanical engineering requires at least an introductory knowledge of the underlying mathematics. Without a fundamental understanding of such relevant issues as solvability (the study of the conditions required for a solution to exist), convergence (measuring whether the computed solution is accurate), and complexity (quantifying the effort required to construct a computational solution), the practicing engineer may spend considerable time and resources constructing computational approximations that bear little or no resemblance to the desired “exact” answers. The material presented below is intended to provide an overview of the relevant mathematical content required to evaluate the quality of a computer approximation.

Solvability Conditions for Computational Approximations

Before any physical problem is modeled using a computational approximation, it is essential to ensure that the underlying mathematical model is *well posed*. Well-posed problems can be characterized as

those where a solution exists and where that solution is unique. While solvability concerns (i.e., those relating to whether a mathematical problem can be solved) such as mathematical existence and uniqueness are often considered as mere niceties by practicing engineers, in fact these properties are important aspects of constructing a numerical solution. It is imperative for engineers using numerical approximation schemes to understand that the computer programs generally used are deterministic: they will construct a numerical solution to the problem and will generate results, *regardless of whether the physical solution actually exists.* One of the most important components of the practical use of computational approximations such as finite-element models is the verification that the solution obtained actually provides a reasonable representation of the physical reality. There are a number of important problems that arise in mechanical engineering practice that are *not* well posed, and it is important for the engineer to recognize symptoms of this sort of mathematical pathology.

Existence of a solution is often guaranteed by the underlying physics of the problem. Most practical stress analyses model well-posed physical problems whose analogous mathematical existence is established by appropriate mechanics theorems. For example, any linear-elastic stress analysis of a compressible solid body can be shown to possess at least one solution. Furthermore, if the elastic body is constrained to prevent rigid-body translations and rotations, those same theorems insure that the solution is unique. As long as the engineer uses appropriately convergent computational models (i.e., ones that can be shown to be capable of getting arbitrarily close to exact results in the limit as the discretization is refined), then the unique solution constructed on the computer will represent an appropriate approximation to the unique physical problem being modeled. Analogous existence and uniqueness theorems can be found for a wide variety of problems commonly encountered in mechanical engineering practice.

There are many instances in which the physical problem is not well posed. One important example is when a stress analysis is performed on a problem that is not constrained to prevent rigid-body translations and/or rotations. In this case (which commonly arises during the modeling of vehicles and aircraft) the computational solution obtained will generally represent the "exact" static solution superimposed onto a large rigid body displacement. Depending upon the precision of the computer used (among other details), the computed stresses and strains may be accurate, or they may be contaminated due to truncation errors resulting from the static displacements being overwhelmed by the computed rigid-body motion that is superimposed upon the desired static solution. Proper attention to detail during the modeling process, such as constraining the solution to prevent unwanted rigid body displacement, will generally prevent this class of solvability pathologies from occurring.

Other more complex solvability concerns commonly arise in mechanical engineering problems where there is an underlying constraint applied to components of the solution field. Problems such as incompressible elasticity (where the volume of the mechanical body is invariant under deformation), incompressible flow (where the conservation of mass implies a "continuity" constraint on the velocity field), or electromagnetic field applications (where the magnetic field must be divergence-free) all possess constraints that can lead to serious solvability difficulties during the computational approximation process. In incompressible elasticity (the other mentioned cases admit similar resolutions), two particular pathologies present themselves: if there are no prescribed displacement constraints on the problem, then a solution will exist, but it will not be unique. In this case, the resulting computational approximation will exhibit rigid body motion, and the underlying stress analysis may or may not be accurate, depending upon the precision of the computer and the magnitude of the computed rigid-body motion. On the other hand, if the entire boundary of the incompressible body is subject to a constrained displacement field, then either the overall prescribed displacement of the boundary will satisfy a global incompressibility condition (in which case the solution will exist, the computed displacements will be unique, but the associated stresses may be suspect), or the global incompressibility condition is not satisfied (in which case there is no feasible solution to the underlying physical problem, so the computed solution will be completely spurious and should be ignored).

Because of the difficulty in ascertaining *a priori* whether solvability considerations are germane to the physical problem being modeled, alternative schemes are often desirable for verifying that the computed solution actually represents a reasonable approximation to the physical problem being mod-

eled. One particularly useful computational scheme for verifying solution quality involves the application of computer graphics and visualization to display solution behavior (e.g., stresses and strains) for interactive interpretation of the results by the engineer. Verification of input and output via graphical means involves the development and use of graphical pre- and postprocessors (respectively) designed to permit interactive review of the solution behavior. High-quality interactive pre- and postprocessors for use with a particular computational mechanics application are very desirable characteristics and should be given due consideration during the selection of CAE software for use in mechanical engineering practice. When nonlinear problems (with their accompanying solvability pathologies) are encountered, use of interactive graphics for solution verification is often required to insure the reliability of the computed nonlinear solution.

Convergence, Stability, and Consistency

In any numerical method, the primary issue that must be addressed is that of *convergence*. A convergent method is one that guarantees that a refinement of the discretization will produce generally more accurate results. Ultimately, as the discretization mesh size decreases, the exact solution can be approximated to an arbitrarily small tolerance; as the size of the discretization measure decreases, the answers should converge to the correct solution. A second criterion is that of *accuracy*, which is related to that of convergence. Where convergence addresses the question "does the error go to zero as the discretization step size decreases?," accuracy is concerned with "at any particular size step, how close is the approximation to the solution?," and with "at what *rate* does the error go to zero with step size?." A convergent method in which the error tends to zero as the square of the step size (a *quadratic* convergence rate) will eventually become more accurate than another scheme in which the error and step size decrease at the same rate (a *linear* convergence rate).

Concern especially relevant to time-dependent simulations is that of *stability*: a stable method is one that guarantees that errors introduced at one step cannot grow with successive steps. If a method is unstable, even when the errors introduced at each step are small, they can increase exponentially with time, thus overwhelming the solution. In a stable method this cannot occur, although stability alone does not imply anything about the size of solution errors that may be introduced at each step, or whether errors from different times can grow by accumulation. Many numerical methods for time-dependent approximation are only *conditionally stable*, implying that stability is guaranteed only when the step size is smaller than some critical time scale dictated by the data of the physical problem and by the discretization (in mechanics problems, this time scale is often related to the shortest period of vibration for the structure). Some idea of this critical time scale must be known *a priori* for a conditionally stable method to behave in a robust manner. For this reason, the use of *unconditionally stable* methods is often preferred, since these methods are stable regardless of the step size (although the actual size of the errors introduced at each step may still be large).

Another important issue in numerical approximations for differential equations is *consistency*. A consistent discrete approximation is one that approaches the underlying continuous operator as the size of the discretization tends to zero. All standard finite-difference operators (and their finite-element relatives used for time-dependent approximations) are consistent, because as the size h of the discretization parameter tends to zero, the appropriate derivative is recovered. Inconsistent discretization schemes are rarely (if ever) encountered in practice.

The convergence and stability characteristics of a numerical method are not independent: they are related by the *Lax Equivalence Theorem*, which is alternatively termed "The Fundamental Theorem of Numerical Analysis." In simple terms, the Lax Equivalence Theorem states that *convergence* (which is the desired property, but one which is often difficult to demonstrate directly) is equivalent to the combination of *consistency* and *stability*. Because consistency and stability are relatively easy to determine, the task of finding convergent approximations is often replaced by that of searching for schemes that are simultaneously consistent and stable.

Computational Complexity

Computational complexity is another important characteristic of a numerical scheme. The complexity of an algorithm is measured in terms of the asymptotic rate of growth of computational effort required to perform the algorithm. For example, standard schemes (such as factorization or Gauss Elimination) for solving a full linear system of equations with N rows and columns require computational effort that grows as the cube of N; these algorithms thus possess a *cubic* rate of growth of effort. (Note that standard schemes such as Gauss Elimination also involve terms that grow as the square of N, or linearly with N: as N becomes asymptotically large, these latter terms diminish in size relative to the cube of N, so the algorithm is characterized by the cubic term which ultimately dominates the growth of effort.) Many (or most) standard numerical schemes exhibit some form of polynomial computational complexity, and for large problems, selecting the algorithm with the lowest polynomial exponent (i.e., the slowest asymptotic rate of growth) is generally a good idea.

Many common algorithms encountered in engineering handbooks are not suitable for large-scale engineering computation because their computational realizations exhibit prohibitively large growth rates. For example, many recursive schemes, such as Cramer's rule for finding the solution of a linear system of equations via recursive evaluation of various matrix determinants, exhibit rates of growth that are larger than *any* polynomial measure. Cramer's rule possesses a *factorial* rate of growth of computational effort (i.e., the effort grows as N!), and thus should be avoided completely for N larger than ten. When faced with implementing or using a computational scheme such as this, the practical engineer should consult appropriate references in order to determine whether alternative simpler algorithms are available — in the case of Cramer's rule, it is easy to solve a linear system (or evaluate a determinant) using algorithms that grow cubically, and for large N, there is a vast difference in effort between these latter schemes and a naive implementation of Cramer's rule, as shown in the Table 15.3.1 (note that the values of N presented in the table are extremely small by the standards of typical computational approximations, and hence the relative gain in using lower-order complexity schemes is even more important than the results in the table might indicate).

TABLE 15.3.1 Polynomial and Factorial Growth Rates

N	N^2	N^3	N!
2	4	8	2
5	25	125	120
10	100	1,000	3,628,800
20	400	8,000	2.433×10^{18}
50	2,500	125,000	3.041×10^{64}

In general, the choice of algorithms for computational simulation of mechanics problems should be restricted to methods that are both convergent and at least conditionally stable. In addition, it should be clear that an unconditionally stable method, especially if it has a higher-order convergence rate, is to be desired. Finally, one normally prefers those methods that exhibit the slowest asymptotic rate of growth of computational effort, especially when large problems are to be solved.

Finite-Element Approximations in Mechanical Engineering

Finite-element models are among the most efficient, general, and accurate computational approximation methods available in engineering. Many of the attractive characteristics of finite-element computational models arise from a seemingly unlikely source: instead of representing the mathematical statement of the underlying mechanics as systems of *differential* equations, finite-element models are motivated by considering instead equivalent *integral* formulations, e.g., the basic equations of equilibrium, compatibility, and stress-strain can be replaced by equivalent integral energy formulations such as the Principle

of Virtual Work or the Theorem of Minimum Potential Energy. These latter integral principles form the basis for finite-element computational approximations.

For example, the differential equations for equilibrium of a solid body can be replaced by an integral formulation: the principle of virtual work of elementary mechanics is one particular well-known example of this equivalence. Once identified, the equivalent integral formulation is considerably simpler than the differential form, and this simplicity is even more apparent when mechanics problems are generalized to include such practical effects as point loads, arbitrary geometric constraints, and heterogeneous or anisotropic material properties. Under these more interesting conditions (i.e., in situations that are likely to arise in mechanical engineering practice), the differential equations of mechanics become nearly impossible to write, as the standard calculus symbolism is barely sufficient to express the range of intractable differential behavior. However, the integral formulation requires only marginal modifications under these more general conditions, and this simpler integral approach also leads to appropriate elegant and general computational approximation schemes.

In addition to providing a simpler means to express the fundamental mathematical relations of mechanics, the integral foundation of finite-element models also provides other important features. One important aspect of finite-element models is their computational efficiency; another is that strong and general convergence proofs can be cited for large classes of finite-element models, obviating the need for application of the more complicated Lax Equivalence Theorem to prove convergence and estimate accuracy. Perhaps the most important theoretical characteristic of these integral calculus models is that their general formulation provides a unified computational framework that includes many other practical schemes (such as finite-difference models) as special cases of a general integral theory of computational mechanics. Therefore, careful study of the mathematical underpinnings of finite-element modeling also provides considerable insight into such diverse alternative computational schemes as finite-difference models and boundary-element methods.

Overview of Finite-Element Models

Finite-element models are most commonly utilized in computational solid mechanics, where they have been used successfully on a very general range of practical problems. Integral formulations for solid mechanics (such as the Principle of Virtual Work) are well-established general results, and it is straightforward to develop generic finite-element computer models from these fundamental integral mechanics formulations. Since many problems in other branches of mechanics (such as Stokes Flow in fluid mechanics, which is a direct mathematical analog of the solid mechanical problem of deformation of an incompressible elastic medium) are closely related to standard problems of solid mechanics, finite-element models are rapidly gaining favor in many other branches of mechanics as well. In general, any physical problem that can be expressed in terms of integral energy formulations is a natural candidate for finite-element approximation.

The most common application of finite-element models is in computational solid mechanics. In this area, finite-element models can be made arbitrarily accurate for a wide range of practical problems. Standard stress analysis problems involving moderate deformations of well-characterized materials (such as metals) are generally easy to solve using finite-element technology, and static or time-dependent simulations of these mechanical systems are routinely performed in everyday mechanical engineering practice. More complex problems (such as computational fluid mechanics, coupled problems, or electromagnetic simulations) can readily be solved using finite-element techniques, though the accuracy of the solution in these areas is often limited, not by the finite-element technology available, but by difficulties in determining accurate characterizations for the materials used. For example, in many biomechanical problems, the model for simulating the stress-strain response of the biological material may contain uncertainties on the order of many percent; in cases such as these, it is not the quality of the finite-element application that limits the accuracy of the solution, but instead the inherent uncertainty in dealing with realistic biological materials.

There are still many practical limitations to finite-element modeling in engineering practice. Some of these problems arise from inherent difficulties in developing generic finite-element computer programs,

while others arise from the same generality that makes finite-element models so attractive as computational approximations. Examples of the former include computer programs that do not contain completely robust modern finite-element models for plates and shells, while examples of the latter include finite-element applications that incorporate the latest computational technology but are so difficult to use that inaccuracies result from gross errors in preparing input data. Finally, many practical limitations of finite-element modeling are due to theoretical difficulties inherent in the mathematical formulations of mechanics, and these last pathologies are the most difficult to remove (as well as being problematic for *any* computational scheme and not therefore particular to finite-element techniques).

Classification of Finite-Element Models

There are many classifications possible in computational mechanics, and so choosing an appropriate classification scheme for any general method such as finite-element modeling is necessarily an ambiguous task. The most common classification scheme for categorizing finite-element models is based on consideration of the physical meaning of the finite-element solution, and a simplified version of this scheme can be described by the following list:

- If kinematical solution unknowns (such as displacement or velocity) are determined first, then the model is termed a displacement-based finite-element model.
- If statical finite-element solution parameters are the primary unknowns determined during the computational solution process, then the model is termed a stress-based finite-element model.
- If a combination of kinematical and statical solution unknowns are determined simultaneously, then the computational scheme is called a mixed finite-element model.

Displacement-based finite-element models are the most common schemes used at present, and most commercial-quality finite-element applications contain extensive element libraries consisting primarily of displacement-based families. In a displacement-based model, the analyst creates a finite-element mesh by subdividing the region of interest into nodes and elements, and the program calculates the solution in terms of nodal displacements (or velocities, in the case of flow problems). Once the displacements have been determined, the unknowns in the secondary solution (such as stress and strain) are derived from the finite-element displacement field by using appropriate compatibility and stress-strain relations. Some common two-dimensional finite elements used for displacement-based formulations are catalogued in Figure 15.3.2. The elements shown are successfully used for common problems in stress analysis, simple fluid flow, and thermal analyses, and their generalization to three-dimensional problems is straightforward and computationally efficient.

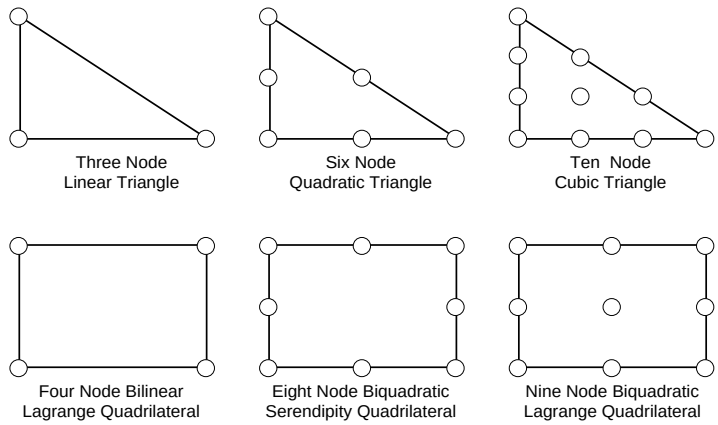

FIGURE 15.3.2 Common two-dimensional finite elements.

Stress-based finite-element schemes are much more rare than displacement models, although stress-based finite elements have some attractive theoretical qualities (such as more direct calculation of stresses and strains, which are the most important currency in practical stress analysis). Many practical stress-based finite-element methods are recast into a form involving determination of nodal approximations for displacement, so that these alternative formulations can be easily integrated into existing displacement-based finite-element programs.

Mixed finite-element schemes commonly arise in problems involving constraints, such as electromagnetics, incompressible deformation or flow, and (in some cases) solid mechanics problems characterized by substantial bending deformation. When using a mixed computational scheme, considerable care must be taken to insure that the resulting approximation is convergent: these subtle mathematical solvability conditions are best approached by a practicing engineer by insuring that the program used automatically applies appropriate consistency conditions (which are commonly presented in the literature for each given field of practice). In short, the best ways to insure that reasonable results are obtained from mixed models are to:

- Know which problems commonly result in mixed formulations.
- Use finite-element computer programs that have already been tested and verified for use on the class of problems of interest.
- Take advantage of auxiliary software (such as graphical visualization applications) to verify the input and output data for all problems.

Note that the potential convergence problems that haunt some mixed formulations in finite-element modeling are generally caused by the underlying mathematical model used to represent the engineering system. In these cases, *any* computational method used may exhibit solution pathologies, and, in fact, the finite-element model (while still containing the pathology) is often the best approach for identifying and rectifying the underlying mathematical problem (this result follows from the fact that the integral framework underlying finite-element approximation permits a more general study of convergence than do competing differential frameworks utilized in finite-difference and finite-volume models).

Finite-element formulations can also be classified into two particular flavors of development: Rayleigh-Ritz and Galerkin. Rayleigh-Ritz finite-element models are developed by applying theorems of minimum potential energy (or some similar integral extremization measure). Galerkin models arise from so-called weak statements of boundary-value problems and are simultaneously more complicated to derive and substantially more general in scope. For problems (such as standard linear stress-analysis problems) where both minimum and equivalent weak statements of the problem exist, the resulting Rayleigh-Ritz and Galerkin finite-element models will yield identical results. For problems where no extremization principle exists (such as high-Reynolds number fluid flow), Galerkin finite-element models (and their relatives) can still be used in practice.

Computational Characteristics of Finite-Element Models

Finite-element models are widely used in mechanical engineering precisely because of their computational efficiency. A brief enumeration of the computational characteristics of finite-element models highlights many reasons why they form such an effective family of computational approximation techniques.

- Finite-element models tend to result in computational algorithms that are readily understood, easily implemented, and exhibit well-known computational advantages. For example, finite-element equation sets tend to be sparse (i.e., to have a relatively small percentage of nonzero terms in the coefficient matrix, with these nonzero entries in a well-defined pattern that can be utilized to achieve efficient computational implementation of required matrix operations) and preserve physical characteristics (such as symmetry and structural stability) that are readily exploited by common matrix algebra schemes.

- Finite-element models are readily shown to possess optimal accuracy characteristics for a substantial portion of problems commonly encountered in engineering practice. For example, for most classes of practical stress analysis, finite-element solution schemes can be shown to yield the most accurate results (measured in terms of minimizing the energy of the error) of any standard numerical approximation scheme, including competing finite-difference and finite-volume methods. In contrast to these latter discretization schemes, finite-element optimal convergence rates are preserved even in the important case of irregular or unstructured meshes. The practical effect of this optimality is that there is often little or no incentive to use any other technique for solution of many computational mechanics problems encountered in the mechanical engineering profession.
- Many finite-element calculations are inherently scalable, in that they can be readily implemented in a manner amenable to parallel computer architectures. The practical result of this scalability property is that current advances in multiprocessor computer architectures are easily leveraged to gain substantial improvements in finite-element program performance with little additional effort required by either users or programmers.
- Finite-element results are defined everywhere in the problem domain, and these results include derived parameters such as stress and strain. Because these solution components are defined everywhere, it is very easy to apply additional computer technology (such as integrated graphical postprocessors) to verify and interpret the results of the finite-element analysis. It is commonly (and incorrectly!) believed that *all* numerical methods provide computational solutions only at a finite number of points in the domain, but this observation is erroneous in the case of finite-element models. The global definition of the finite-element solution is of considerable utility toward the important goal of evaluating the convergence of finite-element models. In addition, the derived secondary solution parameters are also convergent, so that the optimal accuracy characteristics of finite-element models generally apply to both primary (e.g., displacement) and secondary (e.g., stress) solution unknowns. This latter advantage is much harder to prove for many competing numerical methods such as finite-difference and finite-volume schemes.
- It is relatively easy to guarantee the convergence of common finite-element solution schemes, and this characteristic, when combined with the mathematical optimality of the finite-element solution, facilitates trust in the computed finite-element results. The convergence properties of finite-element models are cast in an integral (as opposed to a differential) form, which results in their applicability toward a wide spectrum of engineering problems that contain mathematical pathologies (such as heterogeneous materials, point loads, and complex boundary conditions) that compromise the convergence statements for models (such as finite-difference schemes) that would otherwise be competitive with finite-element models in terms of computational effort.
- For some problems, including those involving substantial convective nonlinearities due to high-speed fluid flow, the optimality characteristics of standard finite-element models can no longer be guaranteed, and an alternative integral convergence formulation must be sought. In the setting of finite-element models for flow, this convergence framework is termed *weak convergence*. It is important to understand that "weak" in this sense is not a pejorative term, but instead refers to the topological structure of the solution space for these flow problems. In fact, weak formulations for problems in science and engineering are useful representations for many practical cases; for example, in the study of statics, the principle of virtual work is a weak formulation of the equations of equilibrium of a rigid body. The weak integral convergence framework for Galerkin finite-element models is an attractive alternative to analogous (but generally more complex) convergence results used in finite-difference modeling for fluid problems.

In simple terms, finite-element models are very attractive candidates for computational approximation efforts. Under very general conditions, they can be demonstrated to be extremely accurate, computationally efficient, and amenable to improvements in computer hardware and software technology. Because

of these computational advantages, finite-element models have become popular in virtually all branches of computational mechanics.

Advantages and Disadvantages of Finite-Element Models

Like all computer approximation schemes, finite-element modeling has characteristic advantages and disadvantages, and the effective use of finite-element technology requires at least an introductory understanding of each. Besides the computational advantages of efficiency and optimality presented above, most finite-element schemes include other practical advantages. Foremost among the advantages are the characteristics of generality of function and flexibility of modeling. The primary disadvantages occur when naive finite-element implementations are applied to mathematically ill-behaved problems.

Finite-element models can be cast into general computer applications that permit a tremendous variety of problems to be solved within the scope of a single program. Some commercial-quality finite-element programs permit the analysis of static and time-dependent problems in solid mechanics, fluid mechanics, and heat conduction within one monolithic computer application. In contrast, alternative computer analysis techniques often place substantial constraints on the range of problems that can be solved, and these limitations require the practicing engineer to be familiar with a variety of different software packages instead of an inclusive general analysis application.

Most finite-element packages are very permissive in the modeling of complexities that regularly occur in engineering practice. These complicating factors include material discontinuities (which are common in composite applications), material anisotropies (implementing more general material response within typical finite-element applications is generally a simple programming task) and complex boundary conditions (such as combinations of traction and displacement on boundaries not readily aligned with the coordinate directions). Because most commercial finite-element applications have very general features, a common source of analysis errors arises from gross mistakes in creating input data (such as specifying a different material model or an incorrect boundary condition). One of the easiest ways to identify gross modeling errors is to make use of solution verification tools (such as integrated graphical pre- and postprocessors) whenever possible. Virtually all high-quality commercial finite-element packages incorporate integrated visualization tools, and utilizing these tools to verify input data and output results is always a good idea.

There are also more complicated problems that can arise in the course of finite-element modeling: the most common pathologies arise from analyses incorporating mixed finite-element models. Guaranteeing the convergence of mixed finite-element models is a much more difficult mathematical problem than the analogous proof of convergence for displacement-based models, and it is possible to get unreliable results from naive use of mixed finite-element models. While most modern commercial finite-element programs will largely guard against the possibility of constructing inherently poor finite-element approximations, there are older or less robust finite-element applications available that do not incorporate completely dependable finite-element technologies. Therefore, it is important to identify potential problem areas for finite-element modeling. The most common sources of difficulty are presented below.

Incompressible Problems. Problems where volume is preserved commonly occur in mechanical engineering practice, but errors arising from inaccurate finite-element modeling techniques are often readily identified and corrected. Incompressible solid elastic materials include rubber and solid propellants, and models for inelastic response of metals also require incompressible or near-incompressible plastic behavior. The most common artifact of poor modeling of incompressibility is known as mesh locking, and this aptly named phenomenon is characterized by grossly underestimated displacements. The easiest way to test for potential incompressibility problems is to solve a suite of simple case studies using small numbers of elements, as shown in Figure 15.3.3. If the finite-element mesh locks in these test examples, then either different elements or a different finite-element application should be considered, as adding more elements to the mesh does not generally improve the results in this case. It is easy to accommodate incompressibility in the setting of standard finite-element libraries. Figure 15.3.4 shows several two-dimensional elements that are accurate when used in an incompressible elasticity setting. Modern

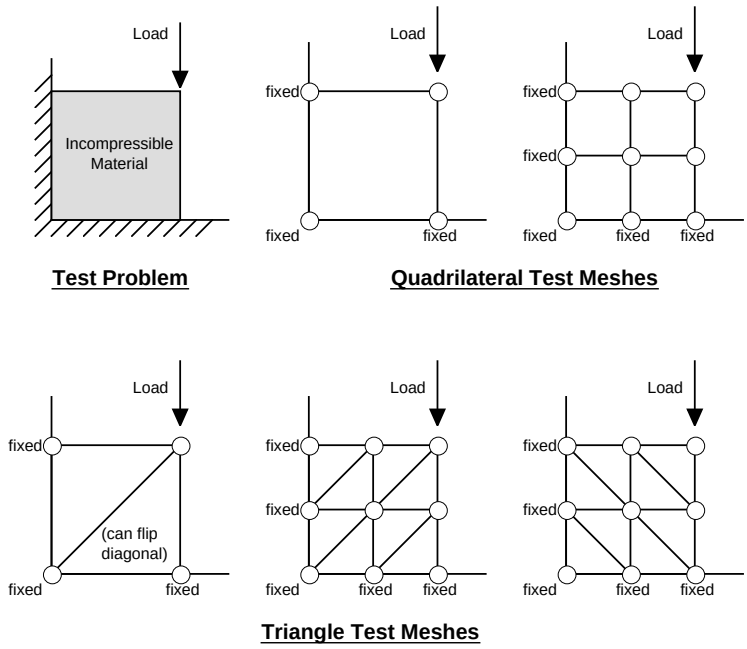

FIGURE 15.3.3 Test problem suite for incompressibility.

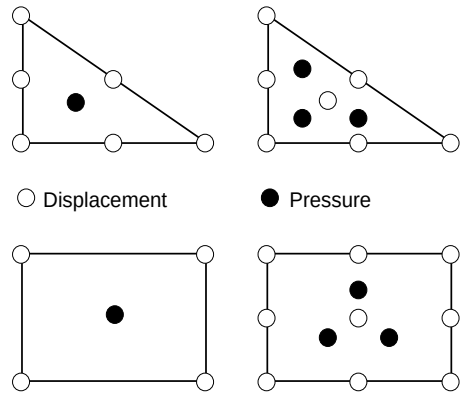

FIGURE 15.3.4 Incompressible elasticity finite elements.

textbooks on finite-element theory (e.g., Hughes, 1987 or Zienkiewicz, 1991) generally provide guidelines on choice of element for incompressible problems, and the user's manuals for many commercial finite-element packages offer similar preventative advice.

Bending Deformation. Problems involving beams, plates, and shells may exhibit solution pathologies similar to those found in incompressible elasticity. In these problems, one-dimensional beam elements or two-dimensional plate elements are loaded in directions normal to the element's reference surface, and naive coding practices for these cases may result in locking of the finite-element mesh, with attendant underprediction of the displacement field. Depending upon the characteristics of the particular element and the stability of the geometric boundary constraints, mesh locking errors may instead be replaced by wildly unstable solution response, with the displacement field oscillating uncontrollably over adjacent elements. In practice, it is very easy to avoid both of these pathologies by incorporating simple additional programming effort, so this problem is rarely encountered when commercial finite-element packages are used. It may be important when the finite-element application is a local or unsupported product, and

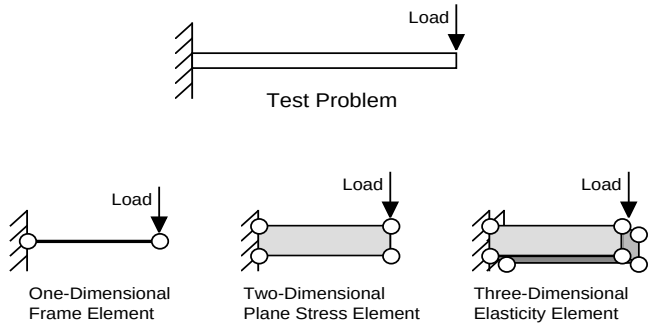

FIGURE 15.3.5 Single-element flexure test problems.

in these cases, appropriate care should be taken to verify the solution. If graphical solution visualization tools are available, they should be used in these cases. If such tools are not available, then the computed results should be compared to simplified problems that can be solved analytically using engineering beam theory analogies or closed-form plate models. One simple test case for naive finite-element coding practices is shown below (see Hughes, 1987); if this simple (but marginally stable) structure is analyzed and gives excessively large or oscillating displacements, then a better finite-element model (or application) should be sought.

Lack of Curvature Deformation in Low-Order Elements. Low-order linear, bilinear, and trilinear elements (such as four-node bilinear quadrilaterals used in plane stress and plane strain applications) are commonly utilized in finite-element packages because they are easy to implement and because many software tools exist for creating two- and three-dimensional meshes for such low-order elements. Unfortunately, there are common circumstances when these low-order elements give inaccurate and unconservative results. One such example is shown in Figure 15.3.5. Many simple finite-element packages will provide accurate answers for the one-dimensional problem, but will substantially underpredict the two- and three-dimensional displacements. Unlike the mesh-locking pathology encountered in incompressible cases, the underprediction of displacements from low-order elasticity elements eventually disappears as more elements are used when the mesh is refined. It is easy to remedy this problem in general by choosing appropriate continuum elements, and many commercial codes provide appropriate low-order elements automatically. Problems due to poorly implemented low-order elements are best avoided by solving simple one-element models first to determine whether the particular element to be used exhibits these errors, and if this is found to be the case, the analyst can either choose a different type of element (or a better finite-element package!) or take pains to insure that the mesh is appropriately refined.

It is important to recognize that many of the problems that arise when using finite-element models for these more difficult cases are not completely due to the particular finite-element model used, but may arise from pathologies in the underlying mathematical problem statement. In these cases, any computational approximation scheme may be susceptible to errors, and so care should be used in evaluating any computational results.

Test Problem Suites for Finite-Element Software

It is easy to avoid most errors in finite-element analysis, by first insuring that no mathematical pathologies are present in the problem or in the elements to be utilized and then by guarding against gross modeling errors in preparation of the input data. The best way to guard against both forms of errors is to use a suite of simpler problems as a “warm-up” to the more complex problems that must be solved. The general idea here is to solve a series of problems of increasing complexity until the final member of the series (namely, the complex problem to be modeled accurately) is obtained. The simpler members of the suite of problems generally involve simplifications in geometry, in material response, and in scale of deformation. For example, if a complicated problem involving large-deformation behavior of an inelastic material is to be analyzed, simpler problems using small-deformation theories, elastic material

models, and simplified problem geometry should be solved and carefully verified. These simpler problems can then be used to verify the response of the complex problem, and this approach is of considerable help in avoiding spectacular engineering blunders.

Another role of a problem suite arises when different competing commercial finite-element packages are to be evaluated. Most commercial finite-element packages are specifically oriented toward different engineering markets, and their respective feature sets depend upon the needs of those particular engineering disciplines. When evaluating commercial finite-element software for potential purchase, a wide selection of representative problems should be analyzed and verified, and two excellent sources of test problems are the pathological examples of the last section (which will provide insight into the overall quality of the commercial finite-element application) and any suite of test cases used to verify more complex problems with a competitive program (which will provide information on how well the proposed application provides support for the particular class of problem encountered in local practice). Problems encountered with either type of test problems should be appropriately investigated before purchase of new finite-element software.

Finite-Difference Approximations in Mechanics

Finite-difference models include many of the first successful examples of large-scale computer simulation for mechanical engineering systems. Finite-difference modeling techniques were originally developed for human calculation efforts, and the history of finite-difference calculations is considerably longer than the history of finite-element modeling. Once automatic computation devices replaced humans for low-level computing tasks, many of the existing finite-difference schemes were automated, and these simple numerical techniques opened up much of engineering analysis to computer simulation methods. Over time, improved finite-difference approximations (including ones that would be prohibitively difficult for human calculation) resulted, and the range of problems solvable by finite-difference models became more diverse.

Throughout the 1970s and 1980s, a natural division developed between finite-difference and finite-element models in computational mechanics. Finite-difference models were utilized primarily for a wide variety of flow problems, and finite-element approximations were used for modeling the mechanical response of solids. While many finite-element approximations were proposed for fluid problems such as the Navier-Stokes equations, in practice these first-generation finite-element models generally performed poorly relative to more advanced finite-difference schemes. The poor performance of naive finite-element models relative to carefully optimized finite-difference approximations was widely (but incorrectly) accepted in the mechanical engineering profession as evidence that fluid problems were best solved by finite-difference methods, even as finite-element technology gained near-exclusive use in such fields as stress analysis.

In fact, the problems associated with early-generation finite-element models in fluids were due primarily to rampant overgeneralization of insight gained in solid mechanics instead of any inherent limitations of finite-element technology applied to fluid mechanics problems. Similar problems developed in the early stages of finite-difference modeling; for example, one of the first finite-difference references published by Richardson used theoretically attractive but practically worthless difference schemes and resulted in a completely unusable algorithm (see Richardson, 1910 or Ames, 1977 for details of this interesting historical development). During the 1980s and 1990s, a better understanding emerged of how to utilize finite-element technology on the relatively more complicated models for fluid behavior, and there has been an explosion of interest in using finite-element approximations to replace finite-difference schemes in a variety of fluid mechanics settings. While finite-difference methods (and especially carefully optimized applications found in certain difficult and narrow specialties in fluid modeling) continue to be widely used in fluid mechanics and electromagnetic simulations, the range of mechanics problems thought to be resistant to finite-element solution approaches is rapidly diminishing.

Finally, a word regarding nomenclature is warranted. Originally, finite-difference models were developed using regular grids of equally spaced points, with the solution approximation computed at the

vertices of this structured lattice. As increasingly complicated problems were solved with finite-difference technology, it became desirable to be able to model more complex problems involving variable material properties, singular data (such as point sources), and irregular geometries. In order to permit these more general problems to be solved, finite-difference modeling was generalized to include various averaged (i.e., integrated) schemes that augmented classical vertex-oriented finite-difference methods to include cell-centered schemes where appropriate integral averaging of the underlying differential equation is utilized to permit modeling discontinuous or singular data. Ultimately, these various improvements led to the development of *finite-volume* schemes, which are a general family of integrated finite-difference approximations that preserve the relative simplicity of finite-difference equations, while casting the underlying theory in a form more amenable to modeling complicated problems. Finite-volume methods are discussed in a later section of this chapter, but the general characteristics given below apply to the entire finite-difference/finite volume family of approximate solution techniques. Because of the widespread application of these integral generalizations of classical vertex-based finite-difference schemes, it has become commonplace to use the term "finite-difference methods" collectively to include all the members of this computational family, including vertex-centered schemes, cell-averaged methods, and finite-volume approximations.

Overview of Finite-Difference Models

Finite-difference methods arise from the combination of two components:

- Differential equations of mathematical physics
- Replacement of differential operators with discrete difference approximations

Differential statements of the equations of mathematical physics are well known, as most of engineering and physics instruction is provided in this form. For example, the familiar relation "$\underline{f} = m\,\underline{a}$" is a vector differential equation relating the components of the applied force to the differential temporal rate of change of momentum. The analogous integral statement of this fundamental relation (which is used to motivate finite-element modeling instead of finite-difference approximation) is probably more useful in computational practice, but it is definitely less well known than its differential brethren. Similar instances occur in every branch of mechanics, as the differential equations for engineering analysis are generally introduced first, with their equivalent integral statement presented later, or not at all. Because of this widespread knowledge of the differential form of standard equations for modeling physical systems, the supply of differential equations that can be converted to analogous finite-difference schemes is essentially inexhaustible.

The computational component of finite-difference modeling arises from the replacement of the continuous differential operators with approximations based on discrete difference relations. The gridwork of points where the discrete difference approximation is calculated is termed the finite-difference *grid*, and the collection of individual grid points used to approximate the differential operator is called (among other terms) the finite-difference *molecule*. Sample finite-difference molecules for common differential operators are diagrammed in Figure 15.3.6. One of the most obvious characteristics of the molecules represented in Figure 15.3.6 is that the discrete set of points where the finite-difference approximation is computed is very structured, with each grid point occurring in a regularly spaced rectangular lattice of solution values.

The fundamental reason for this regular spacing has to do with necessary conditions for optimal convergence rates for the finite-difference solution. This regular spacing of points provides simultaneously the greatest incentive and the biggest constraint toward practical use of finite-difference methods. Performing finite-difference calculations on a regular grid provides desirable fast convergence rates on one hand, but the regularity in the placement of solution sampling points often forces the analyst into a fixed grid structure that is difficult to adapt to nonregular domains without sacrificing optimal rates of convergence. For some problems, it is possible to perform coordinate transformations of the entire physical (i.e., problem) domain onto a regularized computational domain in order to gain simultaneous high convergence rate and geometric modeling flexibility. Unfortunately, these requisite coordinate

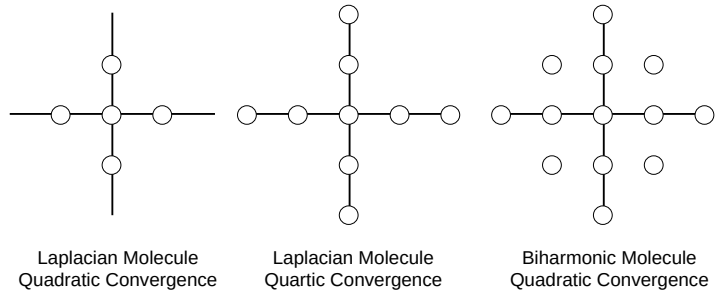

FIGURE 15.3.6 Sample finite-difference molecules.

transformations may be difficult to determine for sufficiently complicated problem geometries. This limitation should be contrasted with the geometric flexibility inherent in analogous finite-element models, where optimal rates of convergence are readily realized even in the presence of irregular or unstructured finite-element meshes.

A geometric motivation for the improved performance of regularly spaced finite-difference molecules can be seen in Figure 15.3.7. Here a representative function has been drawn, along with its tangent derivative and two estimates of the derivative's slope given by standard secant formulas from elementary calculus. In particular, the forward and centered-difference approximations for the slope of the tangent line can be visualized by passing lines through the points $[x, f(x)]$ and $[x + h, f(x + h)]$ for the forward-difference approximation, and $[x - h, f(x - h)]$ and $[x + h, f(x + h)]$ for the centered-difference estimate. (Note that it is also possible to define a backward-difference slope estimate by considering the secant line passing through the function at the points x and $(x - h)$. In problems involving spatial derivatives, this backward-difference estimate has numerical properties that are generally indistinguishable from the forward-difference approximation, but in the setting of time-dependent derivatives, there are considerable differences between forward- and backward-difference schemes.)

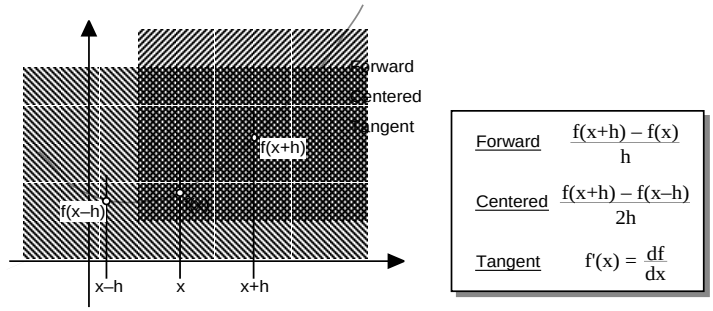

FIGURE 15.3.7 Finite-difference formulas and geometry.

It is apparent from the figure that the centered-difference approximation for the slope is substantially better than that obtained from the forward difference. While it may appear from this particular example that the improved quality of the centered-difference estimate is due to the particular shape of the function used in this case, in fact these results are very general and represent a common observation encountered in finite-difference practice: centered-difference formula are generally optimal in providing the highest rate of convergence relative to the number of points required to evaluate the difference approximation. While this observation can be motivated from a variety of viewpoints (the most common example for purpose of development of finite-difference methods is the use of Taylor Series expansions), it is particularly instructive to perform some computational experimentation regarding this optimality of centered-difference models.

Consider the following simple FORTRAN program:

```
      REAL X, H, FXH, FX, FPRIME, ERR
      INTEGER I
*
*     calculate estimates of the slope of the curve f(x) = exp(x)
*     at the point x = 0
*
      X = 0.0
      FX = EXP(X)
      DO 100 I = 0, 20
         H = (0.1)**I
         FXH = EXP(X + H)
         FPRIME = (FXH - FX)/H
         ERR = 1.0 - FPRIME
         WRITE(*, '(2E20.10)') H, ERR
  100 CONTINUE
*
      STOP
      END
```

This program evaluates forward difference estimates for the derivative of the exponential function at the point $x = 0$. The program is easily modified to provide a centered-difference approximation by adding an evaluation of $exp(x - h)$. The results of running these two computational experiments are diagrammed in Figure 15.3.8, where forward- and centered-difference results are graphed for two different precisions of FORTRAN REAL declarations (32-bit, which represents a lower limit of quality on floating-point numeric representation, and 80-bit, which represents a high-quality floating-point format). Important features presented in these two graphs are

- In each graph there is a region at the right where the error in replacing the differential operator with a difference approximation decreases with a characteristic linear behavior on the log-log plots. In this region, the difference estimates are *converging* to the exact value of tangent slope, as might be expected given the definition of the derivative as the limit of a secant.
- In these linear regions, the centered-difference error decreases with a slope of two, while the forward-difference error decreases with unit slope. This implies that the forward-difference approximation has a *linear* rate of convergence, while the centered-difference estimate is converging *quadratically.*
- The size of these convergent regions depends upon the precision used for floating-point calculations. Extended-precision formats (such as 80-bit reals) provide both a larger region of convergence and improved accuracy (obtained by being able to use smaller values of the step size h).
- To the left (smaller values of the step size h) of these linear regions, the convergent behavior of each estimate breaks down: upon passing through the minimum of each curve (which represents the most accurate estimate that can be obtained for a given precision by using these difference molecules), the effect of decreasing step size is *not* to decrease the error, but instead to ultimately *degrade* the approximation quality.
- Eventually, the denominator of each difference formula underflows (vanishes due to truncation error) as the values of $f(x)$, $f(x + h)$, and $f(x - h)$ become indistinguishable in terms of their respective floating-point representations. This implies that the estimate of the slope is computed as zero, and thus the error eventually tends to unity, which each curve approaches at the left edge [recall that $exp(0) = 1$].

This numerical experiment clearly shows the interplay of convergence rate, numerical precision, and truncation error. The centered-difference formula converges much more rapidly than the forward-differ-

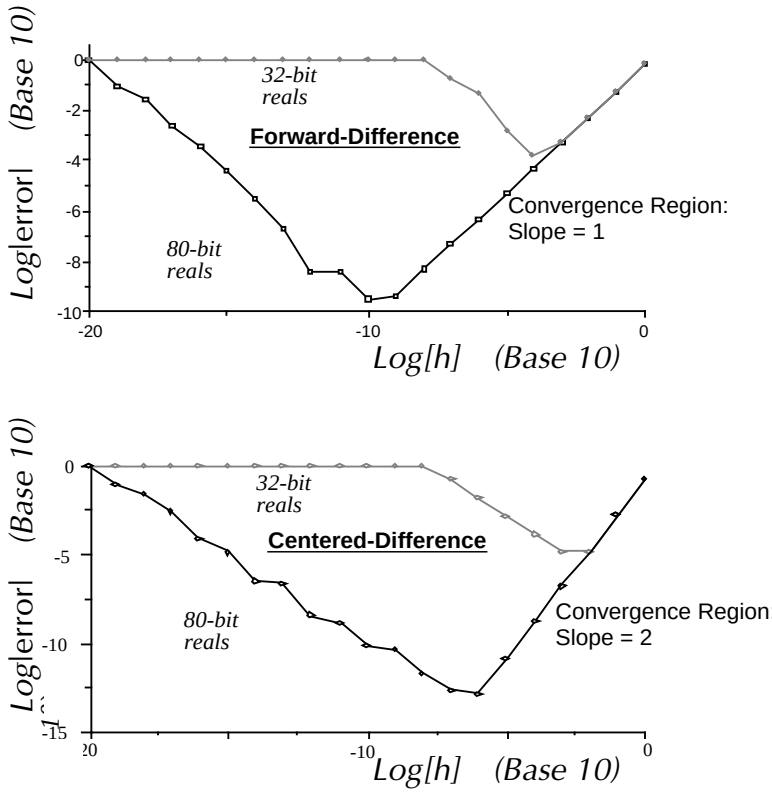

FIGURE 15.3.8 Results of finite-difference numerical experiment.

ence formula, and there exists an optimal step size for the various difference calculations where increasing the step size results in larger errors (in agreement with the rate of convergence of the approximation), and where decreasing the step size results in increased errors (due to the effects of round-off and truncation errors in the calculation of the derivative estimate).

Classification of Finite-Difference Models

As in the case of finite-element models, there are many alternative classifications available for categorizing finite-difference approximations. The first relevant classification is a geometric one, based on whether the finite-difference grid is *structured* (i.e., possesses a regularly spaced lattice structure) or *unstructured*. In order to maintain optimal convergence rates, finite-difference models must use regular spacings of grid points. This regularity is easy to maintain when the problem geometry is simple, but if the natural geometry is complicated, then the regularity of the difference grid will be compromised, with the potential for an attendant loss of convergence rate. In cases of irregular geometry, unstructured meshes are used, and if optimal convergence rates are to be realized, then a coordinate mapping from the actual problem geometry to a regularized computational domain must be constructed.

The problem with using structured grids on irregular or curved domains is diagrammed in Figure 15.3.9. Here a curved boundary is approximated using a low-order linear finite-element mesh (on the left of the figure) and a corresponding finite-difference/finite volume scheme (on the right). In order to capture the effect of boundary curvature, the structured finite-difference/finite-volume representation must approximate the boundary as a stepped pattern of rectangular subdomains. If the curvature is substantial, or if there is a considerable effect of regularizing the boundary on the physical model (a common situation in fluid and electromagnetic applications), this imposition of structure on what is

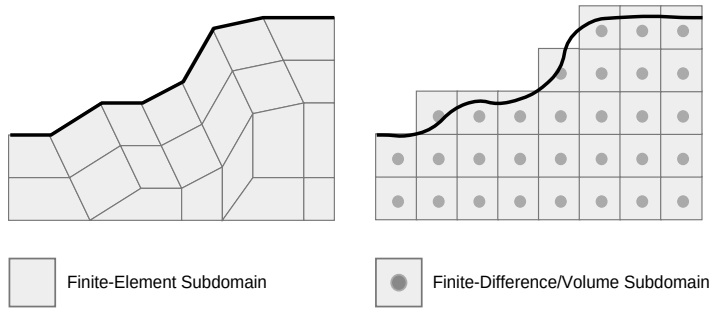

FIGURE 15.3.9 Finite-difference modeling of irregular geometry.

really an unstructured physical problem can seriously compromise the quality of the resulting computational approximation. Finite-element models, in which the presence of unstructured geometries does not substantially affect the solution quality, are thus more natural candidates for problems involving irregular boundaries or poorly structured problem domains. In fact, it is easy using higher-order finite-element approximations (e.g., locally quadratic or cubic interpolants) to approximate the boundary curvature shown in the figure to an essentially exact degree.

Another classification scheme can be based upon whether the difference formulas used are forward, backward, or centered. This classification is especially appropriate for finite-difference time-stepping methods used to solve initial-value problems in engineering and science. In this time-dependent setting, there is a coalescence of finite-element and finite-difference approaches, and the classification presented below permits one unified terminology to be used for both topics. Each class of difference estimate leads to time-marching discretization schemes that have distinctly different characteristics.

Forward difference schemes are commonly used to produce time-stepping methods that are very efficient in terms of computational effort and memory demand. The important class of *explicit* time-stepping algorithms arises largely from using forward-difference approaches: explicit schemes are defined as those requiring no equation solution effort to advance the solution to the next time step (e.g., where the coefficient matrix to be solved is diagonal). The primary disadvantage of forward-difference time-stepping is that these methods are generally only conditionally stable, so that they will converge only if the time step is relatively small. The use of explicit schemes thus involves a trade-off between reduced computational effort at each step, and the attendant requirement of a small time step. Explicit schemes based on forward-difference estimates for temporal derivatives are usually selected when the increased number of steps required is overshadowed by the decrease in the amount of effort required at each step. In some very large problems (such as complex three-dimensional models), explicit schemes are often used exclusively because of their relatively small demand for memory.

Backward difference schemes are commonly used in time-stepping applications where stability of the solution is especially important. In particular, backward-difference schemes generally provide numerical dissipation of high-frequency response, and this characteristic is often desirable in engineering practice. Many transient problems exhibit a wide range of natural time scales; for example, structural dynamics problems in aerospace engineering commonly include long-period vibrations of the entire structure as well as short-period response of individual structural components. One of the characteristics of discretization methods, in general, is that they tend to predict low-frequency behavior very accurately, while high-frequency response is predicted with considerably less accuracy. Since the high-frequency response is therefore often inaccurate (or spurious), there is a strong incentive to attenuate its effects, and choosing backward-difference temporal schemes is a good way to achieve this end. Backward-difference formulations generally require solution of a system of equations to advance the solution across a time step, and hence they are termed *implicit* time-stepping methods.

Centered-difference approximations are generally chosen in order to gain optimal convergence rates for time-stepping methods, and centered schemes are thus one of the most common choices for modeling

transient response. In practice, centered-difference schemes are a mixed blessing. They generally require equation solution to advance across a time step, so they are implicit schemes which require more computational effort and increased demand for memory. They also usually provide a higher convergence rate, so that larger steps can be taken without sacrificing accuracy. In problems where the time-dependent solution is expected to be "well behaved," such as transient heat conduction or similar diffusion problems, centered-difference methods are an excellent choice, especially if there are no spatial pathologies (such as material discontinuities or singular initial conditions) present. In problems where time-dependent response is more problematic (such as nonlinear dynamics of mechanical systems) many centered-difference schemes often give poor results, due to their general inability to attenuate spurious high-frequency discretization effects. There are a number of generalizations of centered-difference time-stepping schemes that have recently been developed to provide optimal accuracy while damping spurious high-frequency response, and these specialized schemes should be considered when complicated dynamic simulations are inevitable (see, for example, the relevant material in Hughes, 1987).

Computational Characteristics of Finite-Difference Models

Finite-difference methods possess many computational similarities to finite-element models, and so their computational characteristics are in large part similar. Both families of approximations generally result in sparse equation sets to be solved, but finite-difference models are less likely to preserve any symmetry of the governing differential equations in the form of matrix symmetry. In addition, many finite-difference molecules (such as those used to represent derivatives of order higher than two) result in equation sets that are not well conditioned and may give poor results when implemented in a low-precision, floating-point environment (such as some inexpensive microcomputers working in single precision).

Convergence rates for many families of finite-difference models can be established using appropriate Taylor series expansions of the solution function. These convergence estimates thus require the conditions under which existence of a Taylor expansion can be guaranteed, and may be compromised when the exact solution of the problem violates these existence conditions. In such cases, the precise rate of convergence of the finite-difference model is more difficult to estimate exactly, though numerical experiments on simple test problems can often be used to obtain estimates of the actual convergence rate. The most common examples of conditions where an appropriate Taylor series expansion may not exist include problems involving interfaces joining dissimilar materials, and singular problem data such as point loads or localized sources. In each of these cases, the exact solution of the underlying differential equation may not possess sufficient continuous derivatives to warrant a Taylor series expansion, and so the rate of convergence may be compromised from that obtained on better-behaved data. For many standard finite-difference schemes, this compromised accuracy is commonly localized around the region possessing the singular or discontinuous data, and outside this disturbed region, better accuracy is obtained. Estimating the extent of contamination of optimal accuracy is a task greatly facilitated by the use of integrated graphics applications for visualizing and verifying solution behavior.

It is worthwhile to contrast this latter potential convergence problem with the analogous finite-element case. Finite-element convergence proofs are generally cast in terms of least-squared error norms (such as the energy norm used for solid mechanics and diffusive flow problems) or weak convergence error measures. Each of these convergence settings is cast in an integral form, so few (if any) constraints upon the existence or continuity of the solution's derivatives are required. The end result of the dependence on integral convergence measures in finite-element modeling is that a substantially more robust mathematical framework exists for guaranteeing optimal convergence of finite-element models.

Advantages and Disadvantages of Finite-Difference Models

Finite-difference schemes possess many important computational advantages. Chief among these is the fact that finite-difference models are very easy to implement for a wide variety of problems, because much of the work of developing a finite-difference application consists merely of converting each derivative encountered in the mathematical statement of the problem to an appropriate difference estimate.

Because there are so many well-understood differential equations available in engineering and science, the scope of finite-difference modeling is appropriately broad.

Finite-difference models are also relatively simple to implement in software. Unlike finite-element models, which possess a bewildering generality that often complicates the task of software development, most finite-difference schemes are sufficiently limited in scope so that the task of computational implementation is less general and therefore considerably simpler. Because these models are easy to motivate and to implement, there is a vast body of existing finite-difference programs that can readily be applied to an equally wide range of problems in mechanical engineering. As long as the problems to be solved fit into the framework of finite-difference modeling, there is a strong incentive to use difference models in mechanical engineering practice.

The primary disadvantages of finite-difference modeling arise from engineering problems that do not fit neatly into the restrictive nature of finite-difference modeling. Real-world phenomena such as material dissimilarities, complex geometries, unusual boundary conditions, and point sources often compromise the utility of finite-difference approximations, and these complicating factors commonly arise in professional practice. Differential formulations of physical problems are inherently restrictive, as the conditions under which derivatives exist are considerably more stringent than those relating to integrability. The end result of relying on differential statements of physical problems is that finite-difference schemes are generally easier to implement on simple problems than are finite-element models, but that for more complex problems, this relative simplicity advantage disappears.

There are other disadvantages of finite-difference models including some important issues in verifying solution results. Since finite-difference models generally only calculate the primary solution parameters at a discrete lattice of sampling points, determining a global representation for the solution over the regions between these lattice points is not necessarily an easy task. If the grid used is sufficiently regular, a finite-element mesh topology can be synthesized and use made of existing finite-element postprocessing applications. If the grid is irregular, then automated schemes to triangulate discrete data points may be required before postprocessing applications can be used.

Another serious disadvantage of restricting the domain of the solution to a lattice of discrete points is that determination of secondary parameters (such as heat flux in thermal analyses or stress and strain in mechanical problems) becomes unnecessarily complicated. In a finite-element model, determination of secondary derived parameters is simplified by two properties: first, the solution is defined globally over the entire domain, which permits solution derivatives to be evaluated easily and accurately; and second, the convergence of the solution is generally cast into a mathematical framework (such as the so-called “energy norm”) that guarantees not only convergence of the primary solution unknowns, but of the derived secondary solution parameters as well. In many finite-difference applications, neither of these important finite-element advantages are easily realized.

Finally, another problem for general application of finite-difference models is in the implementation of boundary conditions. As long as the primary solution unknown is specified on the boundary (and the boundary is easily represented in terms of the finite-difference grid), then implementation of boundary conditions is relatively simple in theory. However, if derivative boundary conditions are required, or if the boundary itself is not readily represented by a finite-difference grid, then various “tricks” may be required to coerce the problem into a form amenable for finite-difference modeling (a particular example of a clever fix is the construction of phantom nodes located outside the problem domain specifically for the purpose of implementing derivative boundary conditions). Competing finite-element models generally permit trivial implementation of a wide spectrum of common boundary conditions.

The implementation of derivative boundary conditions in a simple finite-difference model (in this case, heat conduction, where the temperature function is denoted by u) is diagrammed in Figure 15.3.10. Here it is desired to implement an insulated boundary along a vertical section of the finite-difference grid, where $x = constant$, and hence the normal derivative is easily evaluated. In order to make the normal derivative vanish, which represents the condition of an insulated boundary, it is necessary either to utilize a reduced control volume (shown in gray in the figure) or to implement a fictitious solution

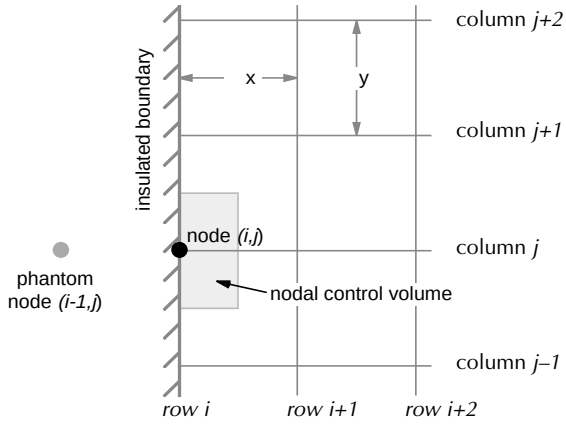

FIGURE 15.3.10 Finite-difference derivative boundary condition implementation.

node outside the problem domain (labeled as a phantom node in the figure). To simplify the resulting equations, it will be assumed that there is no heat generation taking place.

A brief overview of each implementation strategy will be presented below in order to highlight the general methods used in practice. It should be noted that implementing derivative boundary conditions on inclined or curved boundary segments is much more difficult than the case for this simple example. In addition, it is worthwhile to reiterate that derivative boundary conditions are common in engineering practice, as constraints such as insulated boundaries, specified sources, or stress-free surfaces are accurately modeled using derivative boundary conditions. Finally, it should be emphasized that *implementing derivative boundary conditions is a generally trivial task when using finite-element approximations*, a fact which lends considerable practical advantage to finite-element analysis methods.

Implementation of the derivative condition at node (i, j) in the figure is most easily developed using the rectangular control volume shown. If the steady-state conservation of heat energy is considered over this subdomain, then the heat flowing through the top, bottom, and right sides of the control volume must be balanced by heat generation within the volume and by flow through the boundary, and these last two terms are taken to be zero by assumptions of no internal heat generation and of an insulated boundary, respectively. The appropriate mathematical relation for heat conservation over the control volume is given by

$$k\frac{\partial u}{\partial y}\frac{\Delta x}{2}\bigg|_{\substack{\text{bottom}\\\text{face}}} - k\frac{\partial u}{\partial y}\frac{\Delta x}{2}\bigg|_{\substack{\text{top}\\\text{face}}} - k\frac{\partial u}{\partial x}\Delta y\bigg|_{\substack{\text{right}\\\text{edge}}} = 0$$

where k is the thermal conductivity of the material. This partial differential relationship among the heat flows can easily be converted to a discrete set of difference relations by substituting appropriate difference formulas for the partial derivatives, and letting u_{ij} denote the temperature computed at node (i,j). The result of this substitution is given by

$$k\frac{u_{ij} - u_{ij-1}}{\Delta y}\frac{\Delta x}{2} - k\frac{u_{ij+1} - u_{ij}}{\Delta y}\frac{\Delta x}{2} - \frac{u_{i+1,j} - u_{ij}}{\Delta x}\Delta y = 0$$

This single equation can be used to augment the standard difference equations for the nodes not located on the boundary, in order to embed the desired derivative boundary conditions into the complete finite-difference thermal model. For each node located on the insulated boundary (e.g., nodes $[i, j - 1]$, $[i, j]$, $[i, j + 1]$, and $[i, j + 2]$ in the figure), an appropriate difference relationship is synthesized and incorporated

into the set of difference equations governing the complete problem. Details of this procedure for the case of heat conduction can be found in Kreith and Bohn (1993). For more complex problems, appropriate derivations must be carried out to determine the correct form of the boundary relations for the finite-difference/finite-volume model.

In practice, the first two difference terms above are often combined to yield a more accurate centered-difference approximation for the solution. In this case, the third term, which captures the insulated boundary condition specification, can be seen to represent a backward-difference approximation for the boundary flux. Since such two-point backward difference schemes have been shown earlier in this chapter to possess less desirable convergence characteristics than centered-difference formulas, it is often advantageous to convert the insulated boundary derivative condition to a more optimal centered-difference form. One scheme for gaining a centered-difference derivative formula at node (i, j) can be developed by introducing the phantom node shown in the figure as node $(i - 1, j)$. A fictitious (in the sense that the node does not lie within the actual problem domain) thermal solution can be constructed at this node and utilized to gain a centered-difference relationship for the derivative boundary condition that may be more consistent with the relations used elsewhere in the finite-difference approximation. The details of this form of boundary condition implementation can be found in Ames (1977) or any other advanced text on finite-difference numerical analysis.

It is sufficient to note here that the analyst is often confronted with the choice of a feasible but less-than-optimal implementation (such as the control volume approach taken above), or a more accurate but appropriately more computationally complicated scheme for implementing a boundary derivative. Since finite-element models do not exhibit any of these difficulties in boundary-condition implementation, it is often much easier to utilize finite-element software for problems involving derivative boundary conditions.

Test Problem Suite for Finite-Difference Software Evaluation

Before purchasing or using a new finite-difference program, appropriate evaluation measures should be contemplated to insure that the proposed application is capable of solving the particular problems encountered in mechanical engineering practice. As in the case of evaluation of finite-element software, any known solution pathologies can be modeled using the new program in order to determine the quality of the solution scheme. Many of the same mathematical pathologies presented for finite-element evaluation (such as mixed problems arising from incompressible flow constraints) can occur in finite-difference models, so these standard tests may also be appropriate in the finite-difference setting. In addition, any problems commonly encountered in professional practice should be solved with the new code in order to verify that the proposed application is both easy to use and reliable.

Integrated graphical pre- and postprocessors are also important for use with finite-difference programs. Preprocessors that can plot both structured and unstructured finite-element grids are especially valuable, as verification of the coordinate transformations required to map complex physical domains to a regularized coordinate system may necessitate plotting of the finite-element grid in both its irregular physical setting and its regularized transformed computational setting. Postprocessors that automatically determine appropriate secondary solution parameters from the difference solution lattice are especially attractive, as they provide additional solution intepretation functions while minimizing the extra work required on the part of the engineer to construct the desired derived solution function.

If computational simulations of advection-dominated problems are to be generated, it is imperative to insure that the proposed application provides robust algorithms for handling the nonlinear effects of convective acceleration terms. Older computational technology (such as simple upwinding schemes used to more accurately model advective effects in fluid dynamics) often results in poorer solution quality than can be obtained from codes utilizing newer schemes from computational fluid dynamics. Comparing results from various computer programs is a good way to determine which programs implement the best means to capture nonlinear effects. In addition, if the application being evaluated is noncommercial (e.g., public domain codes commonly distributed by academic researchers or special-purpose applications developed within an engineering organization), these comparisons will help to determine whether the

application is capable of robust modeling of the engineering problems encountered in normal professional practice.

Alternative Numerical Schemes for Mechanics Problems

Finite-element and finite-difference approximations are the most common computational schemes used in mechanics, but the practice of computational mechanics is not restricted to these two discretization approaches. There are a variety of alternative methods available for solving many important problems in mechanical engineering. Some of these alternatives are closely related to finite-element and finite-difference models. Others have little in common with these general discretization schemes. A representative sampling of these alternative approaches is presented in the following sections.

Boundary-Element Models

Boundary elements are a novel generalization of finite-element technology to permit better computational modeling of many problems where finite-element methods are unduly complex or expensive (see Brebbia and Dominguez, 1989). In simple terms, boundary elements involve recasting the integral principles that lead to finite-element models into a more advantageous form that only requires discretizations to be constructed on the boundary of the body (hence the term "boundary element"), instead of over the entire solution domain. For many problems involving complicated boundaries, such as infinite domains or multiply connected three-dimensional shapes, boundary element technology is an attractive alternative to finite-element modeling. In addition, because many existing computer-aided drafting applications already idealize shapes in terms of enclosing boundary representations, boundary-element approaches are natural candidates for integration with automated drafting and design technologies.

Boundary-element schemes are not without disadvantages, however. The recasting of the integral formulation from the original domain to the boundary of the problem is not a trivial task, and this conversion substantially complicates the process of developing new boundary-element technology. One of the most important factors limiting the applicability of finite-element models is the formulation of an integral principle for a mechanical problem that is equivalent to a more standard differential problem statement. The conversion of this integral statement into a form amenable to boundary element approximation is yet another laborious task that must be performed, and each of these difficult mathematical problems represents potential errors when implemented in the setting of developing general-purpose analysis software. Many of the potentially attractive capabilities of boundary-element technology, such as the goal of accurate modeling of singular solution behavior (e.g., stress concentrations) that commonly occur on the boundaries of the domain, have not yet been completely realized in existing boundary-element software. However, it is clear that boundary-element models are promising candidates for future computational approximation schemes.

At present, boundary-element codes are most commonly found in research applications, as there is not yet a full range of commercial quality boundary element programs available for widespread use by practicing engineers. While the boundary-element method has a promising future, other advances in finite-element technology (such as robust automated mesh generation schemes that synthesize internal element information from a simple boundary representation) may compromise the demand for the considerable theoretical advantages of boundary element models. It is already feasible to combine features of finite-element and boundary-element technology in the same code, so the future of boundary element techniques may lie in integration with (instead of "replacement of") finite-element applications.

Finite-Volume Schemes

Finite-volume methods are hybrid computational schemes that have been developed to ameliorate some of the problems of finite-difference models. In simple terms, finite-volume models represent integrated finite-difference approximations, where the underlying differential equation is integrated over individual control volumes in order to obtain recurrence relations among discrete solution values. These recurrence formulas are strikingly similar to standard finite-difference approximations, but this integrated approach possesses some clear advantages over related finite-difference technology:

- Because the equations are integrated over control volumes, finite-volume schemes are better able to model material discontinuities, which may cause serious problems in standard finite-difference models.
- The integration process permits rational modeling of point sources, which are commonly implemented in an ad hoc manner in finite-difference schemes.
- The integration process permits more flexibility in modeling unusual geometries, as the individual integration volumes can be adjusted locally to provide such important effects as curved boundaries.

While these are important generalizations for finite-difference theory, in practice they do not realize many of the advantages available with finite-element models. Finite-volume schemes still require substantial regularity in the construction of the solution grid, or the construction of appropriate coordinate transformations to map the problem domain to a simpler computational setting. The integration process provides no relevant aid in the construction of secondary solution parameters such as stresses and strains. Finite-element topology must still be synthesized to enable use of appropriate solution visualization schemes, and this synthesis may be difficult when complex unstructured grids are utilized for the finite-volume model. Therefore, finite-volume schemes are most likely to be found competing with existing finite-difference models in areas where the underlying differential statements of the problem are well established, but where increased modeling flexibility is required.

Finally, the convergence setting for finite-volume methods is similar to that of finite-difference models, and the various integral convergence measures available for proving finite-element convergence are not so readily applied to finite-volume approximations. Thus finite-volume models provide a way to generalize finite-difference approximations to more realistic problem settings, but their limited utilization of integral principles does not provide a unified integral framework of the quality found in finite-element modeling applications.

Semi-Analytical Schemes

Many problems in mechanical engineering still admit solutions based on computational implementation of analytical (i.e., nonnumeric) techniques originally used for hand computation using closed-form solutions. This approach of approximating reality by simplifying the model to the point where it admits a closed-form solution (as opposed to the standard computational approach of putting a complicated model on the computer and using numerical approximations based on finite-element or finite-difference relations) has a rich history in engineering and science, and it includes such classical techniques as Fourier Series expansions for heat conduction problems, representation by orthogonal polynomials, and other eigenfunction expansion schemes.

The advent of high-performance computers has had two effects on semi-analytic schemes such as Fourier Series approximation. First, modern computers are capable of performing the trigonometric evaluations required by Fourier Series representations very rapidly, so that these eigenfunction expansion schemes are now computationally feasible to implement. On the other hand, the application of modern computers to competitive approximation schemes (such as finite-element or finite-difference models for heat conduction applications formerly solved using closed-form Fourier Series techniques) has obviated the need to consider using semi-analytical schemes, as their more general computational approximation competition are now capable of solving more complicated problems with similar amounts of computational effort.

While some applications of semi-analytical techniques can still be found, these computational implementations tend to be localized into special-purpose noncommercial codes. These classical schemes are still useful tools for such niche uses as verification of more complex computational models, but there is little likelihood that these older closed-form schemes will one day become more important relative to modern computational approaches.

Nondeterministic Computational Models

All of the computational models presented so far are completely deterministic: the computer program constructs one solution for every set of input data, and the output is completely determined by the values of the input data set (except, of course, for some differences that may be encountered when using a different computer or changing to a different precision for floating-point computation on the same computer). In some problems, the input data can be characterized with sufficient precision so that these deterministic models are sufficient for analysis. In other problems, however, the input data are not known precisely, but are instead given only in a probabilistic sense. In these latter cases, it is more reasonable not to speak of the precise values that define the solution (such as the nodal displacements of a finite-element model), but instead to consider the problem of determining the probabilistic *distribution* of these solution components.

This nondeterministic approach to finding computational solutions in a probabilistic sense is termed *stochastic* modeling. Stochastic modeling of mechanical engineering systems is still an emerging field, though related engineering disciplines have seen substantial developments in this area. For example, in the modeling of structural systems subjected to earthquake loads (a field of civil/structural engineering very similar to structural dynamics applications found in mechanical engineering practice), nondeterministic models are commonly used to represent the fact that the precise excitation of an earthquake is never known *a priori*. Engineers concerned with the reliability of structures subjected to earthquake loads often resort to stochastic modeling techniques to estimate the probabilistic distribution of forces in a structure in order to design the individual component structural members.

One area of considerable interest is in developing stochastic finite-element models that will permit using much of the existing knowledge base of deterministic finite-element models toward more general nondeterministic computations that can address directly the probabilistic distribution of finite-element response. One of the main constraints to the practical use of such schemes is that large computational models (e.g., ones with substantial numbers of displacement components) generate stochastic approximations that are computationally intractable because of the immense computational expense required to generate and solve the resulting stochastic equation set. At present, only relatively small problems are commonly solved via stochastic models, but this situation is reminiscent of early developments in computational implementation of finite-element and finite-difference schemes. As computer performance continues to improve, so will the practical utility of stochastic models in engineering.

Time-Dependent and Nonlinear Computational Mechanics

Many important problems in mechanical engineering are neither static nor linear-elastic. Mechanical systems undergoing dynamic response or materials deformed past their elastic limit require fundamentally different solution methods than do simpler static or elastic cases. In practice, static and elastic models are often used for initial analysis purposes, and depending upon the analysis results or the solution accuracy required, more complex time-dependent or nonlinear models may be subsequently analyzed. In cases that warrant these more accurate and difficult analysis methods, it is generally a good idea to perform simple static linear analyses first, in order to gain physical intuition into the more difficult problem, and to remove gross modeling errors (such as inconsistent discretizations) before more complex and expensive analyses are performed.

Practical Overview of Time-Dependent and Nonlinear Problems

While it may seem unusual to lump nonlinear and time-dependent problems into a single framework, in practice there are many common features in implementing these two disparate solution approaches. In each case, the more complex problem is solved by looping over a sequence of equivalent pseudostatic or quasilinear computational problems in order to approximate time-dependence or nonlinear behavior. In the case of time-dependent problems, the looping amounts to stepping the solution over a discretization of the time domain; in the nonlinear case, the looping represents an iteration scheme used to trade in a complex nonlinear problem for a series of simpler linear ones. In many problems, the response is both

time-dependent and nonlinear, and then nested looping schemes are generally utilized, requiring internal iterations to solve each nonlinear step composed within a larger time-marching scheme used to advance through the temporal domain of the problem.

Time-dependent problems in computational mechanics are generally solved by discretization of the problem's history into a set of distinct times, and the time-dependent analysis is carried out by stepping the solution between these discrete times. At each step, the temporal variation of the solution is combined with discrete estimates for the temporal derivatives inherent in the problem, and these composed approximations are utilized to transform the advancement across the time step into a computational form that resembles a traditional static problem. In this manner, the sequential nature of the time-dependent problem is transformed into a series of equivalent pseudostatic problems.

Nolinear problems are inherently difficult to solve, as they are commonly ill posed. Nonlinearities are generally accompanied by problems of nonuniqueness (recall that two lines intersect in at most one point, but two curves may intersect at many), and this nonunique character of the solution leads to considerable concerns as to which (if any) of the solutions represents the "real" (feasible) physical state of the problem. In addition, there is little general theory underlying nonlinear solution techniques, and so concrete guarantees that a nonlinear iteration process will converge to a desired solution are generally difficult to obtain.

Test Problems for Time-Dependent Program Evaluation

The most important issues relevant for effective solution of time-dependent problems have already been presented and are reiterated here in a high-level setting. In particular, issues of stability and convergence are especially relevant to practical time-stepping schemes, and insuring that the computed solution history is free from unstable artifacts or inaccurate components is the most important aspect of the practical use of time-stepping algorithms.

The basic trade-off in time-dependent solution processes is between the desire to minimize the number of time steps required for a particular solution history and the need to minimize the amount of computational effort required to construct the solution at each individual time step. Ideally, it would be possible to achieve both goals simultaneously, but this desirable state is seldom reached in practice. In general, increasing the length of the time step involves performing more work at each step, while minimizing the effort at each individual step is accompanied by a substantial increase in the number of steps required to construct the entire solution history. Understanding the interplay of these two desirable goals constitutes much of the practice of solving time-dependent problems. Since many commercial programs that support time-dependent analysis methods provide some form of automated selection of the time step, it is imperative for the analyst to have some idea of the trade-offs involved in the use of these various time-stepping approaches.

Implicit schemes, such as those based upon centered- or backward-difference schemes for approximating temporal derivatives, generally permit taking larger time steps than do explicit schemes, which are often based upon forward-difference approximations. Implicit schemes also require that sets of simultaneous equations be solved to advance the solution across a time step, where explicit schemes require little or no effort of this kind. Therefore, implicit schemes permit fewer steps to be taken with more work per step, where explicit approaches permit rapid advancement of the solution across an attendant larger set of time steps. In general, implicit schemes tend to be more stable than explicit schemes: most practical implicit schemes are unconditionally stable, in that their stability properties do not depend upon the time-step size. Explicit schemes tend to be conditionally stable, with a maximum step size given by a so-called *Courant condition*: step sizes larger than the critical threshold will result in solution oscillations that can easily dwarf the desired solution response.

Centered-difference schemes for time-dependent solution, such as the Crank-Nicolson method used to solve time-dependent heat conduction problems (Ames, 1977) or the Newmark algorithm used to solve structural dynamics problems (Hughes, 1987), are attractive numerical approaches because they possess optimal (quadratic) convergence rates for their time-dependent accuracy behavior. Unfortunately, these optimal error properties are commonly associated with an inability to damp spurious oscillations

that are generally present in discrete computational models. The problem is less important in heat conduction and other dispersive problems, as the spurious oscillations are generally damped over time. In dynamics applications, however, these oscillations can eventually grow and contaminate the solution, and this effect is especially pronounced in the important nonlinear time-dependent case. For this reason, various schemes have been proposed to generalize the more naive centered-difference approach to permit new schemes that damp unwanted high-frequency artifacts but preserve optimal convergence properties (for example, the Hilber-Hughes-Taylor method is a simple extension of Newmark's algorithm, but removes virtually all of the oscillation problems encountered with the latter scheme).

One of the best ways to determine whether the solution accuracy is being eroded by stability or accuracy concerns is to utilize appropriate visualization programs wherever possible. Undesirable or spurious artifacts are readily observed on many graphical displays of solution history, and such solution visualization schemes should be used whenever possible.

Classification of Nonlinear Mechanical Response

Many important problems in computational mechanics are nonlinear. Typical examples include:

- Nonlinear materials, where the material parameters (for example, the material compliances) depend upon the displacements
- Nonlinear geometry, where large deformations require consideration of deformed geometry in the strain-displacement relations, or where Eulerian coordinate formulations are used (as in fluid mechanics problems, where convection introduces strong nonlinearities into otherwise well-posed problems)
- Nonlinear boundary conditions, where the value or type of the boundary condition depends upon the solution of the problem

The different types of nonlinearities often lead to disparate solution qualititative behavior. For example, many material nonlinearities (such as the yielding of metals due to plastic deformation) tend to produce nonlinear problems that are reasonably well posed, in that they are relatively simple to solve and tend not to have serious problems with nonuniqueness of the solution or convergence of the nonlinear solution scheme. Alternatively, many geometrically nonlinear problems (such as high Reynolds' number flow, or arbitrarily large deformations of materials) are considerably more difficult to solve effectively, owing to the presence of alternative (but infeasible) solutions and strong nonlinear effects.

General Overview of Nonlinear Solution Schemes

It is possible to have problems where material and geometric nonlinearities are present simultaneously, and this situation is made commonplace by the fact that inelastic material nonlinearities are often accompanied by plastic flow, which may lead to large deformations that necessitate the use of nonlinear strain-displacement relations. Therefore, it is appropriate to consider solution schemes for nonlinear problems that do not depend upon the particular source of the nonlinearity.

There are many ways to solve nonlinear problems — it often seems like there are *too* many schemes, reflecting the important fact that *there is little general theory for solving nonlinear problems*. Even though there are a wide variety of approaches that can be used to motivate nonlinear solution schemes, one basic fact emerges from all of them: *nonlinear problems are generally solved using an iteration scheme*.

The most common nonlinear iteration schemes are based on *Newton's method*, which provides a relatively simple way to convert an intractable nonlinear equation solution process into a sequence of linear solution processes. The ultimate goal is that this sequence of linear solutions will tend to a fixed solution, and that this solution will solve the underlying nonlinear problem. Thus, Newton's method is based upon a linearization of the nonlinear problem, and it is an especially effective approach in practice because the sequence of linear solutions will often converge quadratically to the nonlinear solution (recall that quadratic rates of convergence are especially attractive, as these schemes cause the error to go to zero rapidly once a good approximation is found).

Finally, a warning on nomenclature ought to be mentioned. Some authors reserve the term *Newton's method* for the iteration scheme resulting from the minimization of a nonquadratic functional such as those that govern many nonlinear problems in solid mechanics. These authors refer to the analogous technique of solving a nonlinear system of equations (which often may not result from a functional extremization problem, as in the case of the Navier-Stokes equations) as *Newton-Raphson iteration.*

Test Problems for Nonlinear Program Evaluation

Just as there is little general theory for solving nonlinear problems, there is little general practice that can be cited to aid the engineer contemplating effective estimation of nonlinear response. Some basic principles based on empirical observations can be given, however, and adherence to these ad hoc guidelines will aid the practicing engineer working in this interesting but difficult field.

The most important observation is that it is unusual to be able to solve a complicated nonlinear problem unless one can also solve a simpler version with the intractable nonlinearities removed. This leads to the concept of "sneaking up on" a nonlinear solution by first performing a sequence of problems of increasing modeling complexity and (hopefully) increasing accuracy. For example, in order to find gross modeling errors (such as incorrect discretizations or geometric inconsistencies), it is sufficient to generate a discretization mesh for the problem, but to use a simpler linear model for approximating material or geometric nonlinearities. Once the gross modeling errors have been removed from these simpler (and computationally less expensive) analyses, more accurate material or geometric models can be constructed from the simpler input data. The results of the simplified analyses may often then be reused to verify the overall mechanical response of the final nonlinear solution.

Another important way to verify nonlinear solution behavior occurs in the setting of time-dependent problems, where the nonlinearities evolve over time from an initial linear state. Most time-dependent algorithms are obtained by trading in a complicated historical problem for a sequence of quasistatic solutions, and at each time step, a standard finite-element or finite-difference quasistatic problem is to be solved (this is especially true when implicit time-stepping schemes are used). In this setting, it is desirable to be able to use large time steps so that the entire solution history can be obtained with as little effort as is possible. However, in many problems (most notably, nonlinear stress analyses), the effect of the nonlinearities on each individual quasistatic problems decreases with the size of the time step. *As the time step gets smaller, the time-dependent component of the solution process becomes more expensive, but each nonlinear iteration scheme generally becomes easier to solve.* Therefore, when solving nonlinear time-dependent processes, it is important to balance the desire to minimize the number of time steps taken with the goal of more rapid convergence of the nonlinear iterations required at each solution step.

Finally, the use of integrated graphics postprocessing to verify solution behavior is incredibly important in the setting of solving nonlinear problems. The problems of nonuniqueness, localization of response, and solution instabilities are commonly encountered in nonlinear analysis settings, and the use of solution visualization techniques (combined with a good sense of engineering judgment and physical intuition) greatly simplifies the task of dealing with these otherwise intractable difficulties.

Standard Packages Criteria

Poor computer acquisition policies can result in spectacular losses for a variety of public and private organizations. Many of these failures arose because empirical concepts developed in the computer industry were not given proper consideration. Guidelines for acquisition of computer hardware and software are outlined below.

Functional Specifications

Regardless of whether an application is to be purchased off the shelf or developed for custom use, the process of acquiring computer software begins with a functional specification of the role of the software. The end result of this process is termed a "functional requirements document", and it is a high-level nontechnical enumeration of the goals ("functions") that the software package is designed to meet. The

language used in a functional specification is normally reasonably devoid of any references to specific technological issues. For instance, if the purchase of an application to aid in document preparation at the "XYZ Engineering" company is contemplated, the functional requirements might include such phrases as "be able to import existing documents for future modification" and "provide support for various printers and other output devices normally used at XYZ Engineering." A good functional specification would not be characterized by "XYZ Engineering should purchase the MicroWizard DocuStuff Version 9.4 software to run on a new WhizBang 9000 Supercomputer:" precise specifications of hardware and software are normally not relevant in a functional specification unless they are used only to indicate the need for back compatibility with existing computer systems.

A functional specification should provide a view of the needs of the organization that are to be satisfied. By stating these needs in broad terms, the functional specification admits the widest possible range of hardware and software solutions. Since computer technology changes rapidly, it is essential to keep technical details from creeping into the functional requirements, as these technical requirements may cause useful alternative measures to be overlooked. When the procurement process is for a government agency (where the lead time between identifying the need and purchasing the software or hardware may be a year or more), it is imperative to insulate the statement of need from technical details that may change rapidly over the course of the acquisition process, and functional specifications are an excellent approach toward this important goal.

Technical Specifications

The next step in the computer materials acquisition process is the translation of the functional requirements to a technical specification. This step is generally performed immediately before bids are sought, so that the most current technical information will be available for review. All of the relevant technical data that was carefully excluded from the functional specification belong in the technical specification, but care should still be taken to avoid unwarranted detail. It is especially important to avoid placing technical information that is inaccurate into the technical specification, or else the resulting procurement process may be compromised.

Evaluation and Testing

Once the technical specification has been finalized, it is either sent to vendors for bidding (in the case of large purchases, where the work of matching specific models and manufacturers of computers can be offloaded to the vendor) or handled internally (for small purchases), where local expertise is used to match the technical requirements with a range of computer models.

One important component of the evaluation process for software procurement is regression testing, where existing data sets are migrated to the new application (or computer), analyzed, and output results compared. This process

- Aids in evaluating whether the application is easy to use
- Provides verification of the software application's capabilities and accuracy
- Gives estimates of performance for the new application

Regression testing of computational mechanics software is greatly aided by the use of integrated visualization tools. Comparing the outputs of complex simulations from two different codes (or even two different revisions of the same code) can be an incredibly tedious process, but the use of graphical display tools provides considerable help toward accurate implementation of the regression testing process.

Overview of Computer Models for Mechanical Engineering Practice

The following outline classifies families of computational models in terms of common mechanical engineering problem characteristics. It emphasizes general "rules of thumb". Although there are instances in which the recommendations below are not optimal, the outline below represents a good starting point for picking the right computational tool for a given task.

- *Simplicity*: Finite-difference models are among the simplest computer models, as they can be derived and implemented directly from the governing diffferential equation whenever the differential form of the boundary-value problem is known. If it is desired to develop, implement, and test a computer model in a hurry, and the problem is well defined in terms of differential equations, finite-difference schemes are a very powerful simulation tool.
- *Generality*: Finite-element models are the most general computational schemes available for mechanical engineers. The mathematical framework of finite-element theory makes it easy to solve coupled problems, as well as problems with discontinuous and singular data. When the underlying problem is intractable in terms of its complexity or material constitution, then finite-element models are generally the first choice for solution.
- *Data definition*: Depending upon how the data are defined, one computer model may be better than others. If all of the data defining the problem domain are given in terms of surfaces (such as would be obtained from some surface-based CAD solid modeling applications), then boundary element technology may be a good choice if the underlying boundary element package can handle the problem encountered. Alternatively, a finite-element package that automatically generates internal element definition from the surface data would be a good choice for such surface-defined modeling. If the data are specified naturally on an unstructured grid, then finite-element schemes generally are easier to attempt than are finite-difference and finite-volume models.
- *Availability*: It is generally a lot easier to use a commercial program to solve a complex mechanical engineering problem than it is to develop the requisite modeling capabilities locally. Therefore, one of the most important starting points for solving complex problems is to become aware of the range of existing applications available. The next section provides an outline guide to a wide spectrum of commercial and public-domain computer-aided engineering tools.

Sample Mechanical Engineering Applications

The following tables (Tables 15.3.2, 15.3.3, 15.3.4, 15.3.5, and 15.3.6) represent a sampling of available software typical mechanical engineering applications. The tables include software for the following tasks:

- Computational solid mechanics and structural analysis
- Computational fluid mechanics
- Computational electromagnetics
- Computational thermal analysis
- Utility software for mechanical optimization and design

These tables only represent a sampling of the state of the software market at the time of publication of this handbook. Since the world of computation and software development proceeds at a rapid pace, it is a good idea to check the current literature (and the addresses listed) to gain a better idea of up-to-date information. Finally, there are several abbreviations given in the tables that are enumerated below:

- FE — finite-element application
- FD — finite-difference application
- FV — finite-volume application
- BE — boundary-element application
- AN — analytical or semi-analytical application
- OPT — design optimization utility (often listed with preferred computational model)

Selection of Software — Benchmarking

Benchmarks are software applications that are used to compare the performance of various computers, or of various operating environments on the same computer. While benchmarks provide a simple means of characterizing computer speed, they are commonly misused and often misunderstood. In particular,

many standard benchmarks provide information that is not always relevant to the performance issues encountered in mechanical engineering practice. Furthermore, it is easy to generate benchmark figures that are misleading by citing results out of context, since computer performance is often strongly dependent on a variety of factors not immediately apparent from simple benchmark comparisons. Therefore, in this section some representative schemes for comparing computer speed are presented to aid in the important task of accurately gauging computer performance for mechanical engineering practice.

Choice of Problem Test Suite for Benchmarking

There are many standard benchmarks commonly used in mechanical engineering applications to estimate the relative performance of various aspects of computers. In particular, there are three common types of numeric operations utilized in engineering computation:

it is generally easier to convert these binary quantities to an equivalent base 10 form, so that they are similar to more standard "scientific notation" for numeric representation used in engineering)

- Transcendental computation, involving floating-point results utilizing more complex mathematical functions, such as trigonometric functions, roots, exponentials, and logarithms (transcendental calculations can be loosely defined as those that cannot be implemented using a finite number of algebraic computational operations)

Each of these classes of numeric computation has particular characteristics: for instance, integer arithmetic is the simplest and fastest type of numeric calculation, as this class of operand does not require manipulation of exponents and mantissas (which often must be renormalized after calculations). Transcendental calculations are the most expensive native numeric operation on computers appropriate for engineering computation, and the speed of this class of operation is often independent of the performance of integer and floating-point arithmetic (owing to the presence and quality of specialized transcendental hardware available to speed up this class of computation). Most algorithms involved in any branch of computing involve substantial integer arithmetic, so nearly all aspects of computing performance increase as integer arithmetic improves. Many common forms of computer use (such as word processing or some drawing packages) require little or no floating-point calculation, so these applications have performance characteristics largely independent of the speed of a computer's floating-point arithmetic hardware.

Most mechanical engineering applications (and especially computational mechanics software) are highly dependent on floating-point performance issues, and so measuring the floating-point speed of computers is generally important in mechanical engineering settings. While many floating-point applications in mechanical engineering involve negligible transcendental calculation (for example, most finite-element or finite-difference schemes involve little or no transcendental results), there are some particular software packages that require substantial amounts of transcendental computation (for example, Fourier Series approximations, which require large-scale evaluation of trigonometric functions). Depending upon

the types of calculations expected, various benchmarks for engineering computation have been commonly used for decades, including:

- LINPACK benchmarks, which measure a mix of integer and floating-point instructions that are commonly associated with manipulation of matrices such as those resulting from many engineering and scientific applications. LINPACK benchmarks are generally reported in terms of the number of floating-point operations performed per second (generally abbreviated as FLOPS, or MFLOPS and GFLOPS, as typical modern computers execute millions or billions of these operations per second).
- Whetstone benchmarks, which (supposedly) measure an instruction mix representative of engineering and scientific computation, but with a considerably simpler implementation than that available for the complicated LINPACK estimate. (Whetstone benchmarks are reported in terms of the number of Whetstones performed per second).
- Savage benchmarks, which measure both transcendental performance and round-off error in this component of floating-point computation. The Savage benchmark is especially simple, and because of its simplicity, its performance estimates are heavily dependent upon compiler technology quality.
- Pure-integer benchmarks, such as the Sieve of Eratosthenes, which require no floating-point computation at all, measuring only the speed of integer arithmetic. Integer benchmarks are generally the most commonly quoted measures of computer performance, but these benchmarks are often only of marginal utility in “real-world” mechanical engineering applications, as the

instruction mix of engineering calculations usually involves a considerable proportion of floating-point computation.

While these and other benchmarks are commonly quoted and compared, there are many practical problems with their use. Many benchmarks may exhibit wildly different values depending upon minor modifications of the source code, and hence may lead to inaccurate results. For instance, in the C language implementation of many matrix benchmarks, various ways of declaring integer subscripts to be used as matrix indices can result in substantial changes in the performance measured. Since the C language specification includes a "register" declaration (which advises the compiler that the integer variable will be used often, and is hence best placed in a fast on-chip storage location such as a register, instead of being stored in slower main random-access-memory), the use of "register" declarations for some benchmarks will result in substantial speed-ups on many CPUs that contain many general-purpose registers. In some cases, published comparisons are based on a "lowest-common-denominator" approach, so that if one CPU doesn't support general-purpose register allocation (for example, many earlier Intel CPU designs), this feature is disallowed on all CPUs compared, which can give rise to misleading performance results.

In order to remove some of these cross-platform performance problems, better benchmarking schemes have evolved. One improved scheme involves standardized integer and floating-point calculations measured in "SpecMarks", after the computer-industry standards organization (i.e., the *Standard Performance Evaluation Corporation*) that proposes them. These benchmarks are termed the SpecInt and SpecFp, and measure integer and floating-point performance, respectively. The standards are updated every few years, as CPU manufacturers often implement design features specifically oriented to improve these important benchmarks (it should be noted that the problem of hardware manufacturers tuning designs to improve standard benchmark performance is a widespread one and is not only encountered among CPU vendors). The particular benchmark is generally suffixed with the year of its standardization (e.g., SpecInt95 for the 1995 version of the integer benchmark suite). SpecMark benchmarks are widely quoted figures available for various processors, and the SpecMark family has been evolving to model more accurately the increasingly complicated schemes available with modern CPU architectures to speed up overall computational performance. Unfortunately, many published SpecMark benchmarks are given

only for integer performance, so the important issue of floating-point speed may not be available without more detailed research efforts.

For practicing mechanical engineers, the best benchmarks are those that most accurately reflect the computational characteristics of the problems encountered. One good way to measure the relative performance of various computers is to perform large-scale simulations of typical practical problems on the individual computer platforms. The best comparisons are obtained using the same software package on each computer, but if this is not possible, different packages can be run of different machines and the overall results compared (this latter case results in a higher uncertainty, as differences between the individual software implementations may cloud issues of hardware performance). The wider the range of problems run, the better estimate of relative performance that will be obtained. These larger-scale benchmarks can be supplemented with simpler benchmarks such as those discussed above to obtain an estimate of relative computer performance characteristics.

Accurate Measurement of Program Performance

Benchmark estimates of computer performance are a useful means for evaluating computer quality, but there are additional considerations to estimate their reliability. In particular, many features available on modern computer conspire to complicate the analysis and interpretation of standard benchmark measures. Some of these issues are addressed below.

First, one must consider the hardware and software environment utilized on the computer compared. Different computers provide different support for various types of numeric computation, and these disparate levels of support may substantially alter benchmark results. For instance, many older computers store integers as 16-bit quantities, where more modern computers use 32- and 64-bit storage locations to represent integers. Other things being equal, it is a lot easier to manipulate 16-bit integers than longer representations, and so benchmarks that do not require any integers longer than 16 bits (e.g., the Sieve of Erasthosenes utilized to find all of the primes smaller than $65{,}536 = 2^{16}$) may give potentially inaccurate results, especially if problems requiring manipulation of integers larger than 65,536 will be required (this latter case occurs nearly always in engineering practice). In order to compare benchmarks accurately, it is important to know some background information concerning the range of numeric representations used in the published results, and how this range corresponds to expected computational practice and to the ranges readily implemented on a particular CPU.

In addition, different types of operating systems can also influence performance of benchmarks. Modern preemptive multitasking operating systems slightly compromise program execution speed by adding the overhead effort of a scheduler subsystem (these and other operating systems principles are detailed later in this chapter), and this additional operating system software effort simultaneously improves the overall quality of the operating environment of the computer, while potentially degrading its numeric performance. If a benchmark requires substantial amounts of random access memory (such as the LINPACK benchmarks, where large quantities of matrix storage must be allocated), then operating systems that implement protected paged virtual-memory subsystems may exhibit substantial slowdowns, especially if the computer's physical memory is smaller than the virtual memory demanded by the benchmark application. In these cases, the benchmark actually measures a complex combination of CPU, operating system, and disk subsystem performance, as the memory is paged from memory to disk and back by the virtual memory resource subsystem.

Finally, the computer language utilized to implement the benchmark may alter the results as well. This phenomenon may be due to obvious causes (such as the overall quality of available compilers, which may penalize newer but faster CPUs that do not have carefully optimized native compilers available relative to slower but more mature platforms), or more subtle effects (such as the original C language specification, which required all floating-point arithmetic to be done in more accurate but less efficient double-precision storage — this feature of the C language often results in slower performance on some benchmarks than that obtained by using single-precision arithmetic, which is the usual default in the FORTRAN language).

Cross-Platform Comparison of Benchmark Metrics

In addition to specific computer software and hardware issues outlined above, there are other important factors that govern comparisons of benchmarks run on different types of computers. When considering performance analyses of different computer platforms, it is important to account for such factors as:

- Presence or absence of specialized hardware, such as floating-point processors, vector processors, or other numeric accelerators
- Relative quality of optimizing compilers available for the individual platforms
- Differences among operating system overhead for the various computers to be compared
- Specialized hardware for auxiliary tasks, such as input/output accelerators for problems requiring substantial access to input/output subsystems (for example, mainframes and supercomputers often have only marginally better raw floating-point performance than many workstations and high-end PCs, but for more realistic problems involving substantial transfer of data, these more expensive computers are considerably faster than simple benchmarks generally indicate)

Many of these specific hardware issues are outlined in the next section of this chapter, but all of them should be investigated to insure that accurate benchmarks comparisons are measured. In all cases, the basic principle is to be able to normalize the benchmark results to account for variations in the equipment tested (vs. what might be purchased), as well as trade-offs in performance due to desirable features (such as preemptive multitasking resources in an operating system). A benchmark suite containing a range of applications that exercise the aspects of computer performance that are of practical importance in the particular mechanical engineering enterprise can be a useful tool for evaluating relative performance of different computers, different operating environments, and different software applications.

15.4 Computer Intelligence

Computer intelligence encompasses a wide variety of thought and practice, ranging from philosophical considerations of whether computers are capable of thought to the implementations of complex programs that can play chess as well as virtually any human being. On a purely pragmatic level, computer intelligence can be considered as including nearly every application of computation found in this chapter, as all of the speedy calculations inherent in large-scale computer models can be viewed as the leveraging of the natural (but slow) computational paradigms used by humans to solve problems for centuries. A more narrow and useful view of computer intelligence can be developed by considering the computer as an approximation to a thinking machine, in that computer intelligence can be limited to considerations of simulations of higher-level human activities such as judgment and decision making, instead of the rote issues of multiplication and addition. The narrowext viewpoint of computer intelligence (often connected with the concept of "strong artificial intelligence") is the belief that computers are actually capable of true thought, just as humans are.

In this section, the intermediate philosophy of so-called "weak artificial intelligence" is considered, by which computers are utilized as useful adjuncts for modeling high-level human activities such as decision making. This practical approach to machine intelligence relegates purely computational issues (such as the computational mechanics applications of the last section) to "nonintelligent" status, yet sidesteps the philosophical quagmire of whether the computer is actually thinking. In addition, there are many other topics in the field of artificial intelligence, such as autonomous robots, machine vision, and intelligent control systems, that are addressed elsewhere in this handbook. Finally, the field of artificial intelligence is one of the richest and most diverse areas of research in computer science, with applications that span the full range of human endeavor; the material presented in this section is necessarily only a brief introduction to a few specific areas of interest to practicing mechanical engineers. Broader and deeper treatments of this important field can be found in references such as Shapiro (1992) and Kurzweil (1990).

Artificial Intelligence

Considerations of artificial computer intelligence often begin with the famous "Turing test," in which a computer is judged to be capable of thought if and only if expert human judges (who are carefully insulated from being able to sense whether they are dealing with another human or with a computer) pose a series of questions and receive corresponding answers: if they cannot determine whether the questions were answered by a human or a computer, then the computer is judged to be capable of human thought. Although no computer has passed the Turing test (and it is implicitly assumed that the question "are you a human or a computer?" is disallowed), computers seem to be gaining ground.

A simpler motivation is to consider the task of making machines "intelligent", in that they behave in intuitive and predictable ways, much like people behave (or in some cases, how we *wish* people would behave). In this broader sense, artificial intelligence ranges in mechanical engineering application all the way from robotics, where machines behave as highly skilled machinists and industrial technicians, to computer interfaces, where such desirable characteristics as consistency and "user friendliness" can be seen as emulating desirable human traits in software.

Classification of Artificial Intelligence Methods

There are many facets of artificial intelligence, and only a few will be outlined below. The various threads that constitute this important field include (but are not necessarily limited to):

- Expert systems, which attempt to emulate the decision-making capacities of human experts
- Neural networks, which mimic the perceived operation of human brains in the hope that computers can become self-learning

- Fuzzy logic, which utilizes generalizations of classical mathematics to develop models capable of handling imprecise or incomplete data
- Data mining, which involves seeking implicitly defined new patterns in existing large data sets
- Symbolic mathematics, which utilizes computers to perform many of the most difficult aspects of mathematical derivations, such as integration and algebraic manipulation
- Machine vision (or computer vision), where visual pattern-seeking algorithms are used to approximate human visual processing

Comparison of Artificial Intelligence and Computational Science

Artificial intelligence and computational science are two contrasting approaches to the same problem in engineering: leveraging the productivity of human engineers by efficient utilization of computer technology. How this augmenting of human efforts is realized is vastly different between the two approaches, however. In artificial intelligence applications, the typical rationale for the computer application is to eliminate wholesale human interaction from some component of the engineering analysis or design process. As a concrete example, expert systems used in design applications have the general goal of codifying the rules and inferences made by a human engineering "expert" into a computer implementation that no longer requires that the engineer make those design decisions. On the other hand, computational science (which represents the integration of high-level engineering knowledge and judgment, relevant computer science, and mathematical numerical analysis) is motivated by the desire to immerse the engineer in the problem-solving process by off-loading the difficult or tedious aspects of the engineering workflow to the computer, while letting the human engineer make the high-level decisions supported by computer tools. This process of putting the engineer into the design/analysis loop (instead of the artificial intelligence motivation of *removing* engineers from the same process) leads to the class of computer-assisted engineering applications collectively termed "engineer in the loop" solutions. Several particular examples of engineer-in-the-loop applications to computer-aided drafting and design are presented in a later section of this chapter.

Expert Systems in Mechanical Engineering Design

Expert systems are one of the oldest and most successful applications of artificial intelligence. Expert systems have been used in such diverse fields as engineering, medicine, and finance, and their range of applicability is enormous. There is an incredible variety of software tools available for doing expert systems development, and this rich library of development tools makes this field especially productive for generating artificial intelligence applications. A substantial component of artificial intelligence practice arises from expert systems, including efforts to develop these applications as well as research in competing technologies (such as neural networks) that have developed at least in part as a reaction to the limitations of expert systems approaches to computer intelligence solutions.

Overview of Expert Systems Methods

A simple schematic of an expert system is shown in Figure 15.4.1. There are three fundamental components of the system: a knowledge base representing the concrete expression of rules known to a human expert (and previously communicated to the computer), an inference engine that encapsulates the "how" of the problem-solving process that the expert system is designed to implement, and a data base representing the data relevant to the problem at hand (such as material parameters for a mechanical design expert system, or answers to questions from a sick human patient for a medical diagnostic application). Other important components (such as input/output systems or the computer itself) are not shown in this simplified figure.

The expert system uses reasoning based on the rules present in the knowledge base, along with the data at hand, to arrive at appropriate output in the form of decisions, designs, or checks of specification. Once implemented, a well-designed expert system often works very well, but the process of programming such a system is often very difficult. In addition to the obvious aspects of the problem, including

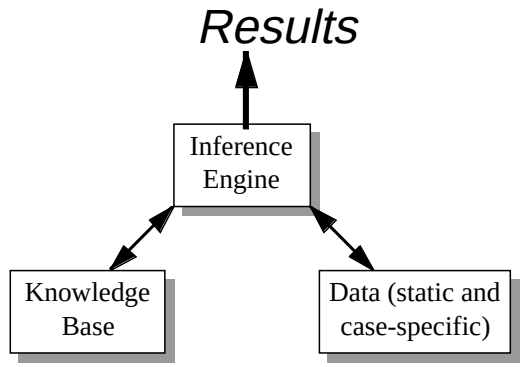

FIGURE 15.4.1 Schematic representation of an expert system.

implementing the data base, there are other nontrivial issues that must be solved, such as coaxing information out of experts who are not always sure what they are doing when they make informed judgments. While programming expert systems is a complicated task, any incomplete progress on elucidating rules for the knowledge base or implementation of an appropriate inference engine may ultimately compromise the overall utility of the resulting expert system.

Advantages and Disadvantages of Expert Systems in Engineering

The main advantage of expert systems is that they permit an incredible leveraging of human expertise. Because they are software systems, they are readily cloned (copied) and they don't forget or misrepresent what they've been taught. This amplification of the efforts of the human experts that were used to create the expert system's knowledge base is frozen within the expert system, and can be readily generalized to include new information or modified to accommodate new ways of dealing with old situations. Human beings have a certain amount of psychological inertia that often prevents them from learning "new tricks", but this problem does not affect expert systems. In addition, other human foibles, such as emotion or indigestion, can foil the opinions of human experts, but expert systems are completely consistent in their exercise of computer decision-making skills. Finally, expert systems are readily scalable to take advantage of faster computers or parallel computational resources, which permits them to solve larger or more complicated problems than human experts could possibly handle.

The biggest disadvantage of expert systems is that they represent only the knowledge base that has been programmed into them, so that such peculiarly human features as engineering judgment or creative problem-solving (which are often important components of engineering decision-making practice) are notoriously absent in this class of artificial intelligence. Another serious disadvantage of expert systems is that they require prodigious amounts of training, which makes their development and implementation costs large for appropriately complex problems. The latter trait of not being capable of autonomous learning is such an important limitation of expert systems approaches that the field of neural networks has developed in large part to remedy this important shortcoming of expert systems technology.

Sample Applications of Expert Systems in Engineering

Expert systems are among the most successful implementations of artificial intelligence, and along with this success has come a wide range of problems that have been shown to be amenable to solution using expert systems technology. Areas in which expert systems have been utilized include engineering design (usually in settings of limited scope, where the rules of practice for design can be readily articulated for programming an expert system), management (where expert systems-based decision-making tools have enjoyed considerable success), biomedicine (where expert systems for diagnostic applications have worked well in practice), and finance (where expert systems can be interfaced with computer models for financial modeling to elicit information that would be too complex for most humans to discern). In addition, research oriented toward using expert systems in conjunction with fuzzy logic has shown

considerable promise for generalizing expert systems approaches to handle noisy, poorly specified, or incomplete data.

Neural Network Simulations

Neural networks represent a promising approach to developing artificial intelligence applications in engineering, and neural nets have many characteristics that are very different from traditional expert system-based solutions. The basic principles of neural networks are derived from inquiries into the nature of biological neural networks such as the human brain. These biological systems are not well understood, but are believed to function efficiently because of the web-like system of interconnected nerve cells ("neurons"), which differs markedly from the regular topology of most conventional computers. Artificial computer-based neural networks represent an attempt to capture some of the beneficial characteristics of human thinking, such as autonomous programming and simple pattern-based learning, by mimicking what is known of the human brain. There are many good introductory references to the basic principles of neural network modeling, including books by Fausett (1994) and Wasserman (1989).

Overview of Neural Network Modeling

A computational neural network can be idealized as a three-layer system, consisting of individual processors, termed units, and a web of communications circuitry, called connections. The topology of the network is diagrammed in Figure 15.4.2. The individual processors operate only on the data that they store locally or that they send and receive via the communications web. This distributed memory architecture makes neural network computing readily parallelizable. In practice, the hidden layer that connects the input and output layers may be composed of a variety of individual component layers, but this aspect of the hidden layer's internal structure can be ignored in this elementary overview of neural networks.

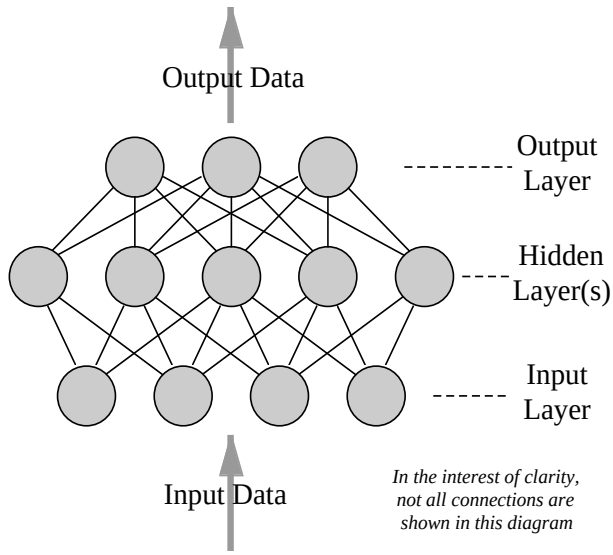

FIGURE 15.4.2 Schematic representation of a neural network.

While neural networks are theoretically capable of performing standard deterministic computation (such as the numeric algorithms used in computational mechanics), in practice neural schemes cannot presently compete with traditional computer architectures for these relatively straightforward tasks. It is in artificial intelligence applications that neural networks are used primarily, because they have an important advantage over virtually every other computational model: neural networks *learn* in a very natural and relatively autonomous fashion. In many regards, neural networks are self-programming, and

this incredible characteristic makes them very useful in practical computer intelligence applications. In simple terms, they learn by example and develop the capacity to generalize what they have learned to new situations.

The mechanism by which the most common forms of neural networks learn to solve a problem is relatively straightforward and similar to human learning: a battery of training examples are fed into the inputs of the neural network, while corresponding outputs are compared to known "correct" values. An alternative mathematical interpretation of this learning is that a weighted sum of the inputs is computed and filtered in a nonlinear manner through the hidden layers to the output layer, and this output response is compared to known output patterns in order to compute an error measure. This learning process is repeated many times utilizing some form of error minimization process to perform a nonlinear regression on the problem data, until the response of the network is sufficiently close to the desired response on all of the sample learning cases. At this point, the system has been trained to solve some set of problems, in that it can generate outputs for any set of input data. The technique described above is termed "backpropagation of error" and is commonly used to develop and train neural network models.

In practice, neural networks are not quite this simple to program, as there are many practical issues that must be contended with, and solving these difficult problems is an area of active research in the neural network intelligence field. The whole issue of how the weights are assigned, propagated through the model, and how they evolve to yield an accurate regression of output response upon input data has been glossed over, as has the more vexing problem of how best to train the network to learn autonomously instead of simply memorizing the peculiarities of the training ensemble; this last undesirable trait is termed overfitting and is an important stumbling block in autonomous neural network development. Regardless of these practical considerations, the fact that neural networks are easy to construct and straightforward to program has made them one of the fastest-growing and most important areas of application of computer intelligence.

Advantages and Disadvantages of Neural Networks in Engineering

The most obvious advantage of neural networks is that they are very simple to implement and to program. Since they are readily parallelizable and extremely simple to train, they can be easily applied to a wide variety of useful applications requiring pattern matching and machine recognition skills. Neural networks are also inherently scalable, in that their distributed architecture makes them easy to adapt to large problems.

One of the most important disadvantages of neural-network systems is that they are presently used only for certain classes of artificial intelligence problems: this limitation arises from their simple architecture and the difficulty of a completely rigorous understanding of how neural networks work. Other important disadvantages include difficult considerations of topology, number and type of connections, training methods, and avoidance of pathological behaviors such as overfitting. As neural networks become more commonplace and well understood, some of these disadvantages should become less important.

Sample Applications of Neural Networks in Engineering

In addition to the obvious examples of pattern matching in production and quality control, neural networks have found wide acceptance in a variety of important engineering roles. Other pattern-matching applications commonly occur in imaging problems, and neural networks have performed well in these cases. In addition, neural networks are natural candidates for use in computer-aided decision-making applications, including management and business decision-making cases. In these settings, other computer programs (such as computer analysis programs) may be utilized to generate case studies to be used to train the neural network, and the resulting artificial intelligence application can readily determine reasonable results from generalization of the training examples. When decisions are to be made based on running very expensive computer programs (such as nonlinear transient engineering analysis programs discussed in the computational mechanics section of this chapter), it is often more efficient to run a suite

of training problems, and then let a large neural network handle the prediction of results from other values of input data without rerunning the original analysis application.

Fuzzy Logic and Other Statistical Methods

Fuzzy logic represents an extension of the principles of classical mathematics and statistics to handle "real-world" systems, which are often imprecisely defined and poorly delineated. In simple terms, fuzzy logic achieves this generalization of traditional logic by replacing Boolean values of "either true or false" with a continuous spectrum of "partially true and partially false." A common analogy is to think of traditional statistical principles as based on black and white issues (each premise is either true or false), while fuzzy logic allows premises to take on different shades of gray (ranging continuously from black to white) and permits more realistic responses to be captured within its conceptual framework. For example, such imprecise and yet common qualifiers as "slightly" and "extremely" are readily handled within the framework of fuzzy methods, yet cause considerable difficulties for many traditional alternative modeling schemes.

Engineering systems based on fuzzy logic represent an intermediate state between traditional mathematical representations, such as standard deterministic design and analysis techniques, and purely rule-based representations, such as expert systems. In principle, fuzzy logic methods are superficially similar to expert systems in that they are both dependent upon artificial intelligence and both remove the engineer from many aspects of the design process. In practice, however, fuzzy systems are more closely related to neural networks than expert systems, as fuzzy models permit considerable automation of the process of converting descriptions of system behavior into a corresponding mathematical model. There are many good references on fuzzy logic fundamentals (e.g., Klir and Folger, 1988).

Overview of Fuzzy Set Theory and Fuzzy Logic Principles

In traditional set theory, objects are categorized as either members of a set or of its complement (i.e., everything in the universe except the set in question). In real-life applications, it is much more difficult to categorize whether anything is a member of a set. In most practical applications, engineers are interested in determining quickly whether objects are members of a set, and such determinations are naturally "fuzzy," both in the fact that they may be imprecise in their underlying definitions, and in the recognition that the test for set membership may be carried out only on small samples taken from a larger product population. In order to permit modeling mathematical constructs based on such incomplete, poorly defined, or noisy data, fuzzy set theory and fuzzy logic were developed (see Section 19.15).

In a similar manner, traditional mathematical logic represents premises as either true or false. Fuzzy logic recasts these extremes by considering the degree of truth of individual premises as a spectrum of numbers ranging from zero to one. The theory of fuzzy logic is based on extending more complex principles of traditional logic, such as logical inference and Boolean operations, to a wider realm that preserves the structure of the classical approach, yet permits an astonishing amount of realistic behavior by permitting considerable flexibility to model poorly defined systems. There are many connections between fuzzy set theory and fuzzy logic, including the obvious one of logical test of membership in fuzzy sets. Many principles of one field (such as statistical clustering applications from fuzzy set theory) are readily utilized in the other.

Advantages and Disadvantages of Fuzzy Principles in Engineering

One of the most important advantages of fuzzy applications in mechanical engineering is their flexibility. Many industrial models represent engineering systems that are either not perfectly characterized or are continuously evolving to better suit changing needs. In these settings, fuzzy systems are often excellent candidates for control and decision making, because the resulting fuzzy model is simpler than traditional approaches, owing to its intrinsic ability to adapt to poorly defined, incomplete, or changing data. Fuzzy inference systems, which are similar to expert systems in that they are utilized for rule-based decision making, are similarly flexible to specify and to implement, especially for engineers experienced in applications of fuzzy principles to engineering control systems.

Another important advantage of fuzzy models is that they are relatively simple to develop and implement. This advantage is primarily due to the fact that they can more accurately model realistic engineering systems which are difficult to specify either completely or accurately. In general, simpler models are less expensive to develop, and the simplicity of fuzzy models for engineering applications is often directly correlated to improved economies in implementation and maintenance.

Probably the most serious disadvantage of fuzzy methods in practice is that they are a relatively new approach to artificial intelligence applications. Because of their novelty, there is not much professional experience with these methods, and a critical mass of software tools for specifying and developing fuzzy models has only recently become available. Until these methods are commonly utilized and understood, it is difficult to categorize their practical advantages and disadvantages.

Sample Applications of Fuzzy Methods in Mechanical Engineering

One of the first successful commercial applications of fuzzy logic in an engineering system was developed for autofocusing features in video camcorders. Early autofocus systems for consumer-grade video recorders failed to work in a wide variety of settings, as it is difficult to design a control system for such a complex and dynamic system. In addition to the technical optical issues of rangefinding and focus control, there are other pertinent (and naturally fuzzy) questions that must be solved to enable such automatic devices to work robustly in a motion-recording setting:

- What do you focus on when there are many objects in the field of view?
- What if some or all of these objects are moving through the field?
- What should be done when some objects are approaching and others receding from the viewer?

Each of these issues is readily modeled using fuzzy logical principles, and recasting such device control problems into a fuzzy statistical setting often transforms the underlying engineering system into a much simpler formulation. Since simpler models are generally easier to implement and to modify, the cost of developing and extending fuzzy-based engineering models is often substantially lower than the cost of competing traditional control systems.

The range of problems thought to be amenable to fuzzy implementations is enormous. Examples range from automotive applications, where sensors generally reflect continuous response instead of Boolean extremes, to tasks requiring categorization of objects as representatives of sets, such as pattern-matching applications or quality-control applications. Many household appliances now incorporate fuzzy methods for control, and the growth of this component of artificial-intelligence engineering applications is expected to be rapid. In general, the more imprecise the data available from an engineering system, the more likely a fuzzy approach will work well in comparison to more traditional artificial intelligence approaches.

15.5 Computer-Aided Design (CAD)

Joseph Mello

Introduction

The computer is a powerful tool in the design of mechanical components and entire mechanical engineering systems. There are currently many diverse computer applications that were created to augment the mechanical design process. The development of a mechanical component or system can generally be divided into three tasks: design, analysis, and manufacturing.

Historically, the design task was restricted to describing the part geometrically. This task included conceptual sketches, layouts, and detailed drawings, all of which were created on a drawing board. The designer or draftsman generally created drawings using orthographic or axonometric projections of the three-dimensional object being designed or developed. These drawings served to illustrate the mechanical part, and in the case of a detailed dimensional drawing, served as a data base for transferring the design information to the manufacturer or to the shop floor.

The drawing performed in the design process has been automated and is now performed using the computer and dedicated software. This automation process is termed computer-aided design, or CAD. CAD generally refers to the geometric description of the part using the computer, but as the computer and its corresponding software have evolved, other tools have been integrated within contemporary CAD systems which are historically categorized as analysis or manufacturing tasks. This form of design, analysis, and manufacturing integration will be discussed later in this section.

CAD systems presently fall into two general categories: those based on entities and those based on solids or features. This classification refers to the basic tools used to describe a mechanical part. The entity-based system can be thought of as a three-dimensional electronic drawing board. The designer in this case uses lines, arcs, and curves to describe the part in a manner similar to the way objects were defined on the drawing board. Solid modeler CAD systems take a different approach: the designer in this latter case must think and work more like a manufacturer. The part is created or described using more complicated solids or volumes, for example. Both of these systems are discussed in the following sections.

Entity-Based CAD Systems

The entity-based CAD system, as mentioned earlier, can be thought of as a powerful electronic implementation of the drawing board. These systems have been designed for nearly all computer platforms and operating systems. Currently, their low cost and portability allow them to run on an Intel-based personal computer or on an Apple Macintosh, and these advantages result in their availability at a majority of small or medium-sized design engineering or manufacturing firms. The workhouse and a typical example system is the AutoCAD application running on an Intel-based microcomputer using a Pentium microprocessor. Some of these CAD systems have optional digitizer pads that are used in the design process, while most use standard keyboard and mouse hardware for input.

Overview of Modeling and Drafting

There are a variety of ways to describe a mechanical component using an entity-based CAD program. For a simple well-defined part, the designer or draftsman may elect to make a two-dimensional (2D) engineering drawing directly. This work is analogous to using a drawing board, in that the designer or draftsman uses basic commands to draft and dimension the part. For a more complex component, the designer may choose to create a three-dimensional (3D) wireframe model of the component, which can be meshed with surfaces. The motivation to do this may be for visualization purposes or for the export of the geometry to an analysis package or a computer-aided manufacturing application. The following material briefly outlines the use of an entity-based CAD system.

Two-Dimensional Modeling

User Interface. The user interface varies among different systems, but some common user-interface elements include pull-down menus, iconic menus, and dialog boxes for input of data. Menu systems are manipulated using the mouse and keyboard. Some systems may use a digitizer tablet with icons to select different drawing operations. The software may also provide the experienced user with a command line input prompt as an alternative option to pulling down menus or dialog boxes.

Coordinate Systems. The key element of any entity-based CAD application is the Cartesian coordinate system. All such applications have a default or global system and also allow the user to specify any number of user-defined coordinate systems relative to the global system. Systems usually also offer the user polar coordinate systems. All geometric entity data are referred to a particular coordinate system.

Basic Drawing Entities. The designer or draftsman at the drawing board uses a drafting machine to draw straight lines, a compass or circle template to draw circles and arcs, and a French curve to draft smooth curves. The entity-based CAD system has analogous basic entities which are the line, circle or arc, and spline.

Lines are drawn by a variety of methods. The line is defined by its end points in the system coordinates. Basic line construction is often accomplished by pulling down a line construction menu, selecting the option to define the line's global coordinate end points, and then typing in the Cartesian coordinate pair. Another method for line construction is to use the control points of existing geometry: control points are a line's or arc's end or midpoints. All systems allow the user to "snap to" or select control points. Given two lines defined by coordinate end points, one can close in a box with two more lines by selecting the end points of the existing entities.

Circles and arcs are constructed in a manner similar to line definition. The most common circle construction is to specify the center point in terms of an active coordinate system and either the radius or diameter. Some other circle construction methods are to define three points on the circumference or two diameter points. There are generally various ways to construct entities in addition to these methods. Arcs are constructed in the same fashion as circles. Some examples of arc construction methods include: start, contour, and end point definition, start and end point radius, or start and end point and angle of arc. This list is not inclusive and of course is system dependent. One important class of arc is the fillet. Most systems offer the user the ability to round a corner by selecting two lines with a common end point and then simply defining the fillet radius.

The spline is the mathematical equivalent of using the French curve to fit a smooth curve between points. The CAD user defines the curve's points and the system fits a cubic spline to these points. There are generally options for specifying a spline's end point tangents or other end conditions.

Design Aids. The utility of a CAD system can be realized when the user appeals to the myriad functions designed to aid in drawing on the computer. Some typical tools are discussed below.

- Layering or layer control gives the designer significant advantages when compared to the drawing board. Layers can be thought of as electronic consecutive sheets of tracing paper. Entities can be placed on different named or numbered layers. Thus the designer can put a whole system design in one file with each component on its own layer. These layers can be turned on or off, and therefore are visible and active or are visible for reference only.
- Entity color, thickness, and line type can be set and later changed or modified. Thickness refers to the displayed and plotted line, arc, or spline width. Type is reserved for hidden, centerline, or phantom line types which are generally a variety of dashed lines.
- Selection control determines how entities are picked and created. Systems have orthogonal grids analogous to graph paper which can be used to sketch parts. Entity end points can be made to snap to grid points. Grid scales can be modified to suit. Angles can be set to force all geometry to be drawn at an angle to an active coordinate system. When building geometry by selecting end

points of existing geometry one can filter selections. An example would be to set the appropriate filters so that only entities red in color may be picked or selected.

- View control refers to windowing, viewing, zooming, and panning. Generally all parts are created at full scale in a CAD system. One then uses view control to look at the whole part or to zoom in on a small portion of it. These view controls are essential, as even a large computer monitor is deficient in view area compared to an "E" sheet on the drawing board.
- Design information menus or calculations are built into CAD systems. These features can be as simple as showing what layer an entity is on or measuring its length or location in Cartesian space. Even the most simple systems can determine the area between groups of entities. Some systems similarly calculate centroids and inertias.

Drafting

Drafting is defined herein as operations such as dimensioning, tolerancing, hatching cross-section views, and writing notes and title blocks in the creation of engineering drawings. These tasks are usually performed after the model geometry has been completed.

Basic Dimensioning. Using a CAD system does not change where dimensions are placed on a drawing. The drafter still applies the traditional rules, but the process of creating dimensions changes completely. Since the component's geometry has been drawn to scale very accurately, a drafter needs to only tell the CAD system where to start, stop, and place the dimension. The system automatically determines the dimension value, draws extension/dimension lines and arrows, and places the dimension text.

There are generally five different types of dimensioning commands. Linear dimensions can be aligned with horizontal or vertical geometry. Angular dimensions measure the distance between two nonparallel lines. Radius and diameter commands dimension arcs and circles. Ordinate dimensioning commands call out Cartesian coordinates of entity features such as spline points. These features, combined with the ability to attach notes, allow the drafter to define the part formally.

Dimensioning Variables and Standards. Dimensioning variables are system standards that control dimension format. Examples are arrowhead size, text location, and text size. These are generally controlled by a set of dimensioning subcommands. Most systems' default settings conform to ANSI Y14.5 standards. CAD systems also are designed to automate geometric dimensioning and tolerancing. Menus and commands create and label reference data. There is usually an extensive ANSI Y14.5 symbol library so that a drafter may add features such as control references, symbols, and finish marks.

Drafting Aids. CAD systems are usually equipped with tools or commands to create drafting entities. These entities include section and center lines. Cross-hatching is generally automated to some degree and a large library of ANSI hatch styles are usually available. If the part drawings are created from a 3D wire frame model as some systems allow, hidden line detection or removal may be automated. This is a very powerful perceptual cue for aiding in the visualization of 3D entities.

Libraries and Data Bases

CAD systems are designed to build up data bases and libraries; for example, special symbol libraries can be created. Any component drawn or modeled can be grouped or blocked together, and the resulting part can be saved and imported into future components or drawings as a single entity. It may then be ungrouped or exploded into distinct entities if the designer wishes to modify it to create a different version of the component.

Three-Dimensional Wireframe and Mesh Modeling

Entity-based CAD systems generally allow the designer to model in three dimensions. Historically, three-dimensional (3D) drafting augmented standard engineering drawings with an isometric or oblique view of the component being described. CAD systems have in a sense reversed this process, as complex parts are now modeled in 3D and then rendered onto engineering drawing views from the 3D data base.

3D modeling is a simple extension 2D drawing and modeling using CAD systems. Any of the basic entities of lines, arcs, circles, and splines can be drawn using X, Y, and Z Cartesian coordinates for control points. The basic entities can thus be used to create a "wireframe model". The wireframe model essentially has every edge of the component or part defined by basic entities. This extension to 3D is simple in theory but is somewhat complex in practice because the interface and display capabilities are two dimensional.

Key tools in productive 3D CAD efforts are coordinate system and view angle manipulation. Some systems also allow definition of construction planes which defines a 2D plane in space where all current entities are placed. In addition, some systems allow computer hardware-assisted rotation of viewing which makes visualization of the part in 3D extremely fast.

Surfaces. Points, lines, arcs, and splines are used to create wireframes, but surfaces are used to represent an object accurately. Surfaces can be shaded to render objects in order to make them look realistic or they can be exported to analysis or manufacturing systems. Surfaces on a entity-based system can be idealized as complex entities, as they can be created from wireframe entities such as lines, arcs, and splines or specified directly by input of the particular defining surface parameters.

Meshes are arrays of faces. Through the use of meshes, engineers can define multifaceted surfaces as single entities. Some common surface types are

- Ruled surface: a surface between two defined curves such as lines, arcs, or splines
- Tabulated surface: a surface created by projecting a drafting curve some distance in space
- Surface of revolution: a surface created by revolving a generator curve about an axis
- Edge-defined coons surface patch: surface created by interpolating with a bicubic function from four adjoining edges defined by lines, arcs, or splines

Solid or Feature-Based CAD Systems

CAD systems that are based on solid modeling or feature modeling are significantly different in appearance and use from entity-based systems. There is generally no means to draft a simple part in 2D using a feature-based system, so descriptions of feature-based CAD begins with solid modeling.

Overview of Solid Modeling

The design process starts with creating a solid model using solids, primitive shapes, or features. Examples of these include solid extrusions, revolved solids, or solids created from general surfaces. There are also solid removal features such as holes, cuts, and chamfers. One way to build a solid model is to extrude a block and then to cut, make holes, and round the edges in a manner analogous to actual manufacturing, where a block of material may be sawed, drilled, and milled into the desired shape. Some details of creating a solid model follow in a simple case study. It should be noted that some solid modelers are parametric. This allows the part to be reshaped by changing key dimensions. The parametric CAD system automatically reshapes the model or part when the dimensions or parameters are modified.

After creation of the solid model the designer can combine solid models or parts to create assemblies. The assembly process with a solid modeler also has analogies to the actual manufacturing assembly process. For example, part surfaces can be mated and aligned to create an assembly.

The solid modeler usually has a separate drafting or drawing module that is used to create engineering drawings. Views are generated nearly automatically from the solid model. Reference dimensions can be added along with symbols and other drafting details. In the most powerful systems the drawing, assemblies, and parts are associative; the designer can make changes in parts at the drawing or assembly level, and these changes are automatically reflected in the model. The part, assembly, and drawing features are separate entities but are associated to insure a consistent data base.

An important advantage of solid modelers is that one essentially "builds" the parts and assemblies. Shading and viewing from all sides are generally accomplished using simple keyboard commands and standard mouse movements. Complete design information is available from a solid model, including

such parameters as volume, weight, centroids, areas, and inertias. Clearance and interference-checking algorithms prove or test assembly function prior to manufacturing. If detailed computational analyses are to be done or the parts to be made use computer-controlled machinery, complete part or neutral (i.e., intermediate transfer) files can be used to transfer information to analysis or manufacturing applications. The current trend is to integrate CAE and CAM functions with the solid modeler, thus eliminating the need for neutral files.

Hardware and Operating System Requirements

The CAD solid modeler generally requires significant hardware and software resources. The typical large CAD system runs optimally on UNIX-based workstations with significant graphics hardware. The recent increased power of personal computers and the availability of Windows NT operating system with its integrated graphic libraries have resulted in the availability of solid modeling on lower-cost RISC workstations and Pentium-based personal computers. This is currently giving small- and medium-sized companies design tools once reserved for aerospace and automaking industries. The software is expensive, but many companies realize payoff if accounting is made for shorter, more efficient design cycles and fewer errors that result from the use of such a system.

Part Solid Modeling Details

A case study of the design of a connecting rod will be used in the following section as a concrete demonstration of how solid modeling systems are utilized in practice. The system used in this case study was Parametric Technology Corporation's Pro/ENGINEER, which is currently considered to be one of the best CAD systems. The hardware used was a Silicon Graphic Indy workstation equipped with a MIPS R4400 processor and 64 megabytes of random access memory.

Datums, Sections, and Base Features. Pro/ENGINEER (Pro/E) uses what is termed "feature-based modeling" to construct a part. This refers to the fact that the part is designed by creating all the features that define the part. One generally begins the model of a part by creating default orthogonal datum planes. Next, a base feature or solid is typically constructed: this is a solid that is approximately the size and shape of the component to be created. Other features are then added to shape the base solid into the part that is desired.

The connecting rod's base feature in this case will be an extrusion that is defined by a section normal to the axis defined by the connecting rod holes. The section for the extrusion is sketched on a default data plane. Mouse and menu picks allow the engineer to sketch the shape using the "sketcher" mode. This part of the process is somewhat similar to entity-based CAD drafting, except that the sketch initially need not be exact. The section is then dimensioned: once again this task is similar to dimensioning on an entity-based system. The part is then "regenerated" or solved mathematically, assuming the given dimensions and alignment to datums are adequate to define the part. The dimensions or "parameters" are then modified to shape and size the part: see Figure 15.5.1 for the connecting rod's dimensioned section. The resulting extrusion is shown in Figure 15.5.2 as a wireframe plot. The designer has the option of viewing wireframes or shaded solids during the model creation process.

Rounds, Holes, and Cuts. The connecting rod can be made lighter in weight with a cut, in this case, that involves an extrusion that removed material leaving the rod cross section in the form of an "H". The dimensioned cut section and resulting solid are shown in Figure 15.5.3. Given the cut base feature, rounds can be added in this case to smooth out stress concentrations. These "edge rounds" are constructed by selecting an edge and defining a radius. The solid modeler adds material in the form of a round. Figure 15.5.4 shows the cut and rounded extrusion produced using this approach.

Hole features are now used to create the bores for the piston wrist pin and the crankshaft. These hole features are created by defining the hole location, setting the parameters for the diameter, and describing a bore depth or, in this case, by instructing the modeler to drill "through all."

The connecting rod is finished with a collection of cuts, rounds, and chamfers. A shaded image of the finished connecting rod is shown in Figure 15.5.5. Two different versions of the rod are shown. The

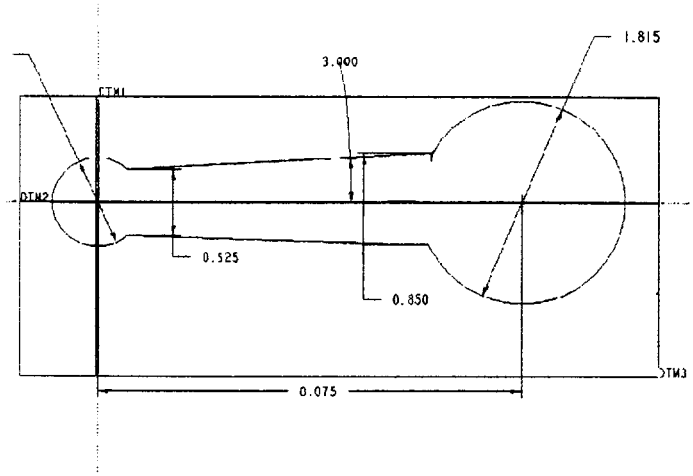

FIGURE 15.5.1 Connecting rod dimensioned section.

FIGURE 15.5.4 Edge rounds added to extrusion.

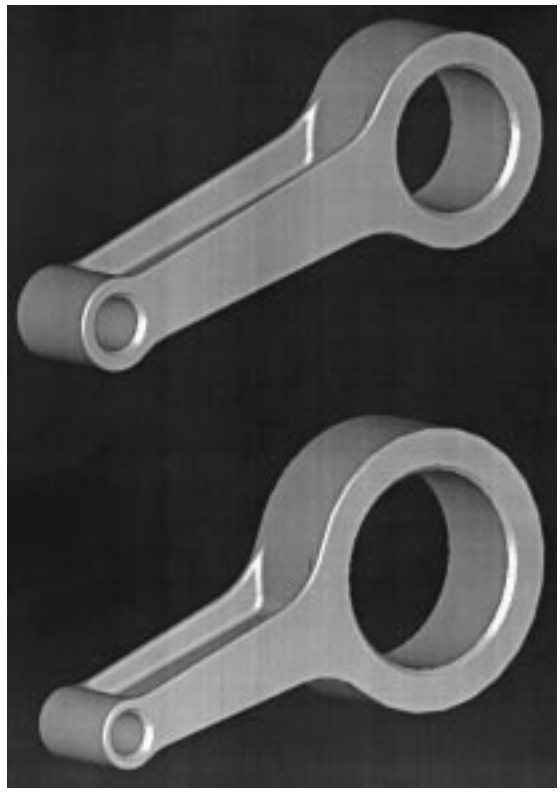

FIGURE 15.5.5 Finished connection rod.

second rendering is a shorter rod with larger main bore and a smaller wrist pin bore. This part was created simply by selecting and changing a few of the defining dimensions and telling the modeler to regenerate the part. This example illustrates the parametric nature of the modeler, which permits design changes to be easily visualized and accommodated.

Other Features. The features used to create this simple example are obviously not an inclusive enumeration of the solid features available to the designer. A brief list of other key features and corresponding descriptions follows to aid in summarizing the solid modeler's capabilities.

- Surface: extrude, revolve, sweep, or blend sections to create a surface
- Shaft: a revolved addition to the part using a specified section
- Slot: create a slot from a sketching plane
- Protrusion: boss created from the sketching plane by revolving, extruding, sweeping, or blending
- Neck: create a groove around a revolved part using a specified axial section
- Flange: create a ring around the surface of a revolved part using a specified axial section
- Rib: create a rib from a specified sketching plane
- Shell: remove the inside of a solid to make it a thin shell
- Pipe: create a 3D tube/pipe/wire
- Tweak: create part draft, dome, offset, or other surface deformation features

Part Modeling Tools. The solid modeler contains a large assortment of tools that can be used to manipulate the features or solids that comprise the component being designed. A description of a few of these functions follows.

Solids modelers generally provide a layer control similar to that discussed for entity-based CAD systems. This function is particularly useful for controlling the large number of datums and other features created by a solid modeler. Features may be redefined, reordered, and suppressed or blanked.

There are also capabilities built in to allow features to be patterned, copied, or mirrored. Patterns can be used to create splines in a shaft or hole arrays in a flange, for example. Solid protrusions can also be patterned to create spokes on a vehicle wheel.

Cross sections can be created by building or selecting a datum plane that passes through the part. The system automatically creates the cross section at this plane. This information can be later used in the drawing mode to create section views at key locations.

Pro/ENGINEER has a very powerful utility termed "relations." A feature's geometric dimensions can be made functions of other features or geometry. This is similar to having a spread sheet controlling the geometry. Relations can be expressed in terms of algebraic or trigonometric functions as needed. Logic can be built into these relations, as well as utilizing the solution of systems of simultaneous equations.

Assemblies

Parts or solid models that have been created can then be put together to form "assemblies." This process is analogous to assembling actual components in a manufacturing environment. The process starts by placing a base part or component in the assembly. This base part could be the connecting rod example discussed previously. After placement of the base part one can, for example, add or assemble components to the base part such as a wrist pin and piston in this case study. Components are added by defining appropriate constraints. Some typical assembly constraints are

- Mate: Planar surfaces are constrained to be coplanar and facing each other.
- Align: Planar surfaces are constrained tube coplanar and in the same direction.
- Insert: The axis of a feature male part is constrained to be coaxial with a female feature on a parts axis.
- Coordinate system: Two data coordinate systems on different components can be aligned.

The wrist pin is added to the connecting rod by mating the bore of the rod to the cylindrical surface of the pin and aligning the datum plane at the middle of each component. The piston is added to the assembly in the same way. Figure 15.5.6 shows a shaded view of this example subassembly. It should be noted that changes to any of the components can be made at the assembly level and the associated part is automatically updated even though they are separate entities.

There are some advanced tools provided at the assembly level. Material may be added or subtracted from one set of parts to the other set of parts in the assembly. For example, the connecting rod could be added to a block of material such as a mold base. Then the blank could be cut using the connecting rod to form a mold with which to forge or cast the rod. Parts can also be merged at the assembly level, thus becoming essentially one part.

Design Information Tools

Pro/Engineer provides utilities that calculate engineering information for both parts and assemblies. There is an option to assign material properties directly or they can be picked from a data base. Given the material data the modeler can generate the mass properties for a part: Figure 15.5.7 shows the mass property results for the connecting rod example. Basic measurement and surface analysis functions are also available, and cross-section properties can also be generated. Assembly mass properties can be calculated in the assembly mode. Powerful clearance and interference calculations can be performed for any combination of subassembly parts, surfaces, or entities — these serve to check the function of hardware before committing to actual manufacturing. In general, the added effort of building solid models is more than offset by the information and checking that are provided.

FIGURE 15.5.6 View of example subassembly.

Drawing

Documenting designs by creating engineering drawings with a solid modeling system such as Pro/E is done using a drawing module. Since the part is completely described by a solid model, most of the work normally associated with drafting or drawing is already completed. The process of creating a drawing from a part or solid model is outlined briefly below.

The first step in drawing creation is to name the drawing, select the drawing size or sheet, and retrieve the appropriate format. Formats are essentially borders and title blocks. A format mode editor exists to create standard or custom formats with any drafting geometry, notes, and call outs desired. Views of the desired model are then placed within the format. The user first places what is called a general view and orients it with view control menu commands. Now the user can place projected views off the first view. The system automatically creates the projected views from the model selected.

View types can be projections, auxiliary, or detailed portions of the geometry. View options include full views, broken views, x-sections, or scale settings to scale a particular view independently. Views can subsequently be moved, resized, and modified in a variety of ways. The most important is the drawing scale which the system calculates automatically depending on model size and sheet selected. A new scale can be defined from a modify menu and all drawing views are rescaled accordingly.

Dimensions are now placed within the drawing. Since the solid model is dimensioned in the design process, this step simplifies to that of instructing the drawing module to “show all” detailed dimensions. The system then automatically places dimensions on the views defined. The real effort of dimensioning becomes that of cleaning up the dimensions in order to have them to meet traditional drafting standards. Sometimes the dimensions used to model the part are inadequate in a detailed drafting sense, so a complete drafting utility exists to create what are essentially reference dimensions.

FIGURE 15.5.7 Mass properties calculated for example cross section.

As discussed previously for entity-based CAD systems, the solid modeler drawing or drafting utility has detailed functions designed to create basic dimensions, specify geometric tolerances, and to set data as reference. Large ANSI symbol libraries are also available to aid in the detailing.

The part and the drawing exhibit "bi-directional associativity": if the engineer completes the drawing and then goes back to the part to make modifications, the drawing geometry associated with these changes is automatically updated. In a similar manner, the part definition is changed if a defining dimension is modified on the drawing.

CAD Interface Overview

All contemporary CAD systems have utilities to import and export design data. These utilities have translators which support many types of file formats. The most common interfaces and files will be discussed in the following paragraphs. Since the CAD system usually defines the part the focus will be on, export of data and Pro/Engineer will be used as an example.

Printing and Plotting. A very important interface is with printing and plotting hardware to get hard copies of shaded images, wireframe plots, and drawings for use in design reviews and for archiving. Shaded images are commonly written in PostScript page-description format for printing on a color printer with such capabilities. Plot files of objects or parts, drawings, or assemblies can be done with the standard

HPGL (Hewlett-Packard Graphics Language) or PostScript formats. Pro/ENGINEER, for example, has specific configuration files for a variety of Hewlett-Packard, Calcomp, Gerber, Tektronix (for shaded images), and Versatec plotters.

Computer-Aided Engineering (CAE). It is often desirable to export CAD geometry to other CAD systems or analysis packages. Example destinations are

- Thermal/Structural Finite Element Analysis
- Computational Fluid Dynamics Analysis
- Moldflow Analysis Packages
- Kinematics and Dynamics Programs
- Photorealistic Graphics Rendering Programs

The most common format to transfer graphic and textual data is the Initial Graphics Exchange Specification (IGES) file format. It is important to determine what type of IGES entities the receiving system desires, then adjust the IGES configuration prior to creation of the file. As an example, a variety of Finite Element Analysis (FEA) packages use an IGES trimmed surface file as opposed to wireframe entities where part edges are output. A finite element model of the case study connecting rod was formulated using an exported IGES trimmed surface file of the Pro/E solid model part file. A stress contour plot of a simple static analysis of this rod model is shown in Figure 15.5.8. The model was automeshed with hexahedral elements directly from the surface files with little user intervention. The meshing procedure took 30 to 40 min to initiate and the automesh time was about 10 hr on a Silicon Graphics Workstation. Most production-quality finite element codes either already have or will eventually possess such capabilities.

FIGURE 15.5.8 Stress contours and geometry of optimized rod.

Data exchange format (DXF) files are also very common and are used to export model and drawing data to products such as AutoCAD or to products that were designed to interface with AutoCAD. Pro/E also has its own neutral file which is a formatted text file containing more design information than an IGES file. Part geometry is formatted so other software packages can use the complete design data.

Pro/E also directly writes other software package neutral files such as PATRAN geometry files (PATRAN is a generalized finite element pre- and postprocessor).

This is only a partial list of export options available. There exists a crucial problem with export, however: associativity is lost. If the part is, for example, exported and analyzed, any subsequent part modification renders the analysis model inaccurate. This is a problem as the current trend is to use computational analysis tools early in the design process instead of using them only as a final check. Presently, there are software package alliances and cooperatives forming that are addressing this problem.

This direct integration of analysis packages has been accomplished by Structural Dynamics Research Corporation I-DEAS and Pro/Engineer Mechanica, among others. Once again the Pro/Mechanica integration will be used as an example to review the current capabilities of such systems. The Mechanica packages are thermal, motion simulation, and structural analysis packages that are completely integrated with Pro/E's solid modeler. Analysis is thus another large set of pull-down menus and dialog boxes within the CAD package. The beauty of the system is that it is a complete bi-directional link, in that design changes made in Pro/E automatically update finite element models or vice versa. This feature greatly simplifies the task of structural design optimization. Mechanica has routines which will optimize and change model geometry based on static stress and structural dynamic considerations. There are practical limitations as Mechanica is currently limited to linear elastic structural analysis. The Mechanica analysis package uses an adaptive p-element, where the order of the tetrahedral finite element is adjusted until convergence is achieved. The adaptive scheme uses up to a ninth-order polynomial in the element formulation. If the model does not converge, the mesh can be refined and the analysis tried again.

Computer-Aided Manufacturing (CAM)

Parts that are modeled in 3D are generally fabricated with CAM. This fabrication task can involve rapid prototyping, directly machining the part, or mold making to support casting, forging, or injection molding.

Rapid Prototyping

Rapid prototyping is a relatively new manufacturing technology which is complementary to CAD solid modeling. A CAD design file of an object is converted into a physical model using special computer-controlled sintering, layering, or deposition processes. SLA stereolithography machines by companies such as 3D Systems convert 3D CAD data of objects into vertical stacks of slices. A computer-controlled low-power ultraviolet laser then traces across photocurable resin solidifying the part one layer or slice at a time. Selective laser sintering and fused deposition processes operate in a similar manner. In all cases, an accurate nonstructural model is created which can be used in design reviews, mock-ups, and prototype assemblies. A physical model such as this is a very powerful tool in early product design reviews and marketing efforts.

The interface to rapid prototyping is an SLA or (*.stl) file. SLA files represent the solid model as groups of small polygons that make up the surfaces. The polygons are written to an ASCII text or binary file. Pro/E has an SLA selection in its interface menu. It is important to note that the designer partially controls the quality of the prototype through two variables, the chord height of the tessellated surface and an angle control variable. The connecting rod example is again used to demonstrate the effects of chord height setting in Figure 15.5.9, which shows the polygon surfaces for SLA files with two different chord heights.

Computer Numerical Control Machining

Numerical control machining refers to created parts using computer-controlled machines such as mills, lathes, or wire electric discharge machines. Parts or molds are made by machining away material. In the case of complex parts it is essential to transfer CAD geometric data to a machining software package and finally to the computer-controlled machine.

A typical machining center has a numerical control machine wired directly to the serial port of a microcomputer. This configuration is termed computer numerical control or CNC, as it allows the machinist to program the machine tool off-line using specialized machining programs. Most CAD

FIGURE 15.5.9 Polygonal representation for stereolithography.

systems have optional integrated manufacturing modules similar in architecture and use to their integrated analysis packages. There are also a variety of stand-alone machining software packages which accept a spectrum of CAD input in the form of neutral, IGES, and DXF files. These packages or modules can import and create geometry, as well as determine and simulate cutter paths. As with many CAD programs, these machining applications now have 3D interactive graphic environments. As the programmer generates steps for the machine tool path, 3D models show the part being cut by the tool. Line-by-line programming in a text mode is presently being replaced by graphically selecting geometry, tools, and tool paths. These programs have postprocessors to write the "G and M code" specific to the machine tool being used ("G and M" code is a standard language for programming machine tools). These ASCII text files based on numerical codes using G and M as prefixes form an instruction list for a wide variety of machine tool operations.

Further Information

There are a wide variety of excellent references available that summarize many of the principles found in this chapter. For practical discussions of computer technology, the Internet-based UseNet newsgroups form the most detailed and up-to-date sources of information on programming languages, computer architecture, and software engineering. Most UseNet groups provide a list of Frequently Asked Questions (FAQs), which often address introductory issues in considerably more detail than elementary textbooks, and consulting such UseNet FAQs is a good way to begin more detailed study of most of the computational topics outlined in this chapter. Sample UseNet newsgroups include comp.ai (for general information on artificial intelligence research and application), comp.object (for general information on object-oriented programming), and comp.sys.intel (for information regarding Intel hardware). These general UseNet topics are generally further specialized toward more detailed discussions, such as the philosophical information regarding computer intelligence that can be found in comp.ai.philosophy. Since UseNet groups are created (and sometimes disappear) at near-random intervals, it is best to use standard Internet browsing tools to determine the best newsgroups for researching a particular topic.

More traditional printed works are available for all the topics found in this chapter. The history and philosophy of software engineering are presented in engaging detail in Yourdon's *Writings of the Revolution: Selected Readings on Software Engineering* and Brooks's classic *The Mythical Man-Month*. The classic modern reference on object-oriented programming is Booch's *Object-Oriented Analysis and Design*, which also contains good descriptions of procedural programming models. An excellent overview of artificial intelligence can be found in Kurzweil's *The Age of Intelligent Machines*.

One of the most detailed treatments of finite-element modeling available is Hughes' *The Finite Element Method: Linear Static and Dynamic Finite Element Analysis*, which presents a comprehensive and detailed view of finite-element modeling as oriented toward mechanical engineering applications, and does an excellent job of presenting time-dependent solution techniques amenable to any numerical discretization approach (including finite-difference methods). There are many standard references on finite-difference methods, including the well-known book by Ames, *Numerical Methods for Partial Differential Equations*.

Terms and Associated Acronyms

Artificial Intelligence (AI): a spectrum of ideas on the general topic of computer modeling of human intelligence, ranging from "Strong AI" (defined as the premise that computers are capable of emulating human intelligence) to "Weak AI" (defined as the premise that computer can be utilized as useful adjuncts for modeling high-level human activities such as decision-making).

Benchmarks: application programs specifically designed to quantify the performance of a particular computer system, or of its component subsystems. Benchmarks provide a convenient means to compare measures of system performance obtained from disparate computer platforms.

Boundary-Element Method (BEM): a numerical approximation technique based upon integral equations and related to the finite-element method. Boundary elements possess the advantage of requiring only surface-based representations of the problem domain, in contrast to the volume-oriented data required by finite-element methods.

Central Processing Unit (CPU): the main processor (i.e., the "brain") of a computer, consisting of the hardware necessary to perform the low-level arithmetic and logical operations that form the building blocks of computer software.

Compressor/Decompressor (CODEC): a pair of computational algorithms designed to compress the bandwidth required to process large streams of data. The most common applications of CODECs are in computer video/animation applications, where it is physically impractical to process the uncompressed raw data needed to maintain the illusion of continuous motion within a computer animation.

Computational Mechanics: the field oriented toward integrating principles of mechanics with tools from computer science and mathematics toward the goal of constructing accurate numerical models of mechanical systems.

Computer-Aided Design (CAD): a general term outlining areas where computer technology is used to speed up or eliminate efforts by engineers within the design/analysis cycle.

Computer-Aided Engineering (CAE): application of the computer toward general tasks encountered in mechanical engineering, including analysis, design, and production.

Computer-Aided Manufacture (CAM): the integration of the computer into the manufacturing process, including such tasks as controlling real-time production devices on the factory floor.

Computer-Assisted Software Engineering (CASE): software development tools oriented toward utilizing the computer to perform many rote programming development tasks.

Computer Numerical Control (CNC): the creation of mechanical parts using computer-controlled machinery such as lathes, mills, or wire electric discharge machines.

Convergence: in the setting of computer-aided engineering, convergence is taken as a measure of how rapidly the computer approximation tends toward the "exact" solution, measured as a function of increased computational effort. Ideally, as more computer effort is expended, the computational approximation rapidly becomes appropriately more accurate.

Data base Management: computational techniques specifically oriented toward allocation, manipulation, storage, and management of organized data structures.

Discretization: the fundamental tenet of most computational models for physical systems, in which a complex continuous real system is approximated by a simpler discrete replacement. In theory, as the level of refinement of the discretization is increased (i.e., as the discrete components get simultaneously smaller and more numerous), the discrete system more closely approximates the real one.

Distributed Multiprocessing: a parallel computer architecture characterized by independent processors working cooperatively on a distributed set of resources (for example, a network of computers, each equipped with its own local memory and input/output devices). In a distributed multiprocessing system, the communication bandwidth of the network connecting the individual CPUs is often the limiting factor in overall performance.

Engineer-in-the-Loop: a class of computer-aided design applications oriented toward immersing the engineer into the computational simulation with the goal of separating the rote calculation components of the task from the decision-making processes. The latter efforts are handled by the engineer, while the former are dealt with by the computer.

Eulerian Reference Frame: a reference frame attached to a region of space, to be used for constructing computational mechanics approximations. Eulerian reference frames are generally used for fluids, though they may also be profitably utilized in modeling the large deformations of solids.

Expert Systems: a class of artificial intelligence applications based on emulating the decision-making capacities of human experts by using specialized computer software for inference and knowledge representation.

Expressiveness: the desirable characteristic of a program language's facility for controlling program execution and abstracting programming functions and data.

Finite-Difference Method (FDM): a family of numerical approximation methods based on replacing the differential equation-based statement of a physical problem by a set of discrete difference equations that directly approximate the underlying differential equations.

Finite-Element Method (FEM): a family of numerical methods based on approximation of integral statements of the problems of mathematical physics. This emphasis on integral formulations (in contrast to the differential formulations used by finite-difference models) provides considerable numerical advantages, such as better convergence properties and the ability to model discontinuous problem data.

Finite-Volume Method (FVM): a family of numerical methods based on integrating the differential statements of physical problems over small subdomains. Finite-volume modeling is essentially a means to maintain the simplicity of formulation of finite-difference models, while permitting realization of some of the advantages of integral finite-element schemes.

Fuzzy Methods: computational methods for artificial intelligence that generalize the simple Boolean logical theories that traditionally form the basis of deterministic computer programs. These methods are based on more qualitative (i.e., "fuzzy") representations of data and instructions than commonly found in conventional computer programs.

Graphical User Interface (GUI): a model for software design that emphasizes graphical human/computer interaction through the desired characteristics of responsiveness, intuitiveness, and consistency.

Inheritance: a feature of object-oriented programming languages that permits derivation of new objects using a child–parent hierarchy. Inheritance makes is possible to express relationships among objects in a flexible manner that facilitates programmer productivity and the reuse of code.

Lagrangian Reference Frame: a reference frame attached to a physical body, to be used for constructing computational mechanics approximations. Lagrangian reference frames are primarily used for solids (where it is relatively easy to track the deformation of the underlying physical domain), and generally result in a simpler formulation of the conservation laws used in engineering mechanicsmultitasking

Multiprocessing: the process of distributing threads of execution over different processors on the same computer, or over different computers connected over a network. The various flavors of multiprocessing form the architectural divisions among different types of parallel processing.

Multitasking: managing the execution of separate computer programs concurrently by allocating processing time to each application in sequence. This sequential processing of different applications makes the computer appear to be executing more than one software application at a time.

Multithreading: managing the execution of separate concurrent threads of program execution by allocating processing time to each thread. This low-level software resource management model forms the basis of many multitasking operating systems and permits various forms of parallel computation by distributing distinct threads over different processors.

Neural Networks: a class of largely self-programming artificial intelligence applications based on webs of interconnected computational processes. The aggregate goal of the interconnected network of computation is to emulate human thought patterns, and especially the autonomous programming routinely exhibited by humans and notably lacking in computers.

Newton-Raphson Iteration: the basic algorithm for solving nonlinear problems, in which a nonlinear equation set is traded for a sequence of linear equation sets, with the ultimate goal of rapid convergence of the linear equation sequence to the solution of the underlying nonlinear problem.

Object-Oriented Programming: a standard for software development that emphasizes modeling the data and behavior of the underlying objects that define the program. Object-oriented programs are comprised of a collection of cooperating software objects, with these objects derived from an underlying hierarchical organization of generic classes. Contrast this concept with procedural programming, which uses algorithms as the fundamental component of program architecture.

Operating System: the software layers that provide low-level resources for execution of computer programs, including file services for input/output, graphical display routines, scheduling, and memory management.

Polymorphism: a feature of object-oriented programming languages where a single name (such as the name of a variable) can be recognized by many different objects that are related by class inheritance. Polymorphism is one of the most important features of object-oriented programming, as it permits many different objects to respond to a common event, a process that is considerably more difficult to implement using procedural programming languages.

Portability: the highly desirable program characteristic of ease of implementation on different types of computers. Portable programs are generally written in higher-level computer languages, such as C.

Procedural Programming: computer software development oriented toward abstraction of programming function by subdividing the overall task into successively smaller subtasks, which are generically referred to as procedures. Procedures represent the software implementation of algorithms, and hence procedural programming is oriented toward modeling the algorithms of the underlying system.

Random Access Memory (RAM): the collection of semiconductor hardware used for memory storage on modern computers. The main memory of a computer is usually composed of Dynamic Random Access Memory (DRAM), which is volatile and does not persist when the power is turned off.

Rapid Application Development (RAD): programming tools oriented specifically designed to aid in development of prototype software applications for demonstration and initial application design.

Relational Data Base: a standard for data base management emphasizing modeling data by using flexible relations among the various data structures of the program.

Schema: the structure of a data base (the term schema generally is taken to mean the structure and organization of the tables in a tabular data base).

Software Engineering: the profession concerned with the effective specification, design, implementation, and maintenance of computer programs.

Solvability: mathematical conditions relating to the existence and uniqueness of solutions to problems in mathematical physics. Problems that do not possess unique solutions often lead to pathological behavior when implemented on the computer, so determining the solvability characteristics of a problem is an important first step in computational engineering applications.

Spiral Model: a standard for the incremental design and implementation of computer programs, characterized by applying regular updates to a flexible design during prototyping and delivery phases.

Stability: the numerical characteristic by which errors can be guaranteed not to increase in magnitude as they propagate throughout the mathematical domain of the problem. Unstable methods permit errors to grow until the computed solution may become hopelessly corrupted, while stable methods provide some insurance against this unfortunate outcome.

Stress Analysis: a family of computational schemes oriented toward determining the state of stress and deformation of a physical medium. Stress analysis is normally associated with solid mechanics, though its methods can be successfully applied to fluid systems as well.

Structured Grid: used to characterize finite-difference and finite-volume discretizations, where considerable regularity (such as an evenly gridded rectangular geometry) is imposed on the topological structure of the underlying grid. Structured grids are generally associated with optimal convergence characteristics, but may not accurately represent the geometry of the underlying physical problem.

Structured Query Language (SQL): SQL is a standard and portable language for creating and modifying data bases, retrieving information from data bases, and adding information to data bases.

Symmetric Multiprocessing (SMP): a parallel computer architecture generally characterized by independent processors working cooperatively on a shared set of resources, such as memory or input/output devices. In a symmetric multiprocessing system, the issue of contention for resources is often the limiting factor in overall performance.

Unstructured Grid: used to characterize finite-difference and finite-volume discretizations, where little regularity is imposed on the geometric and topological structure of the underlying grid. Unstructured grids are more easily adapted to realistic problem formulations, but require more effort and often result in poorer convergence characteristics.

Vectorization: a process by which certain types of numeric computation (most notably, those involving well-defined operations on vectors) can be internally pipelined on a computer's processing units, leading to considerable efficiencies in performing the associated vector operations.

Virtual Memory: an operating system characteristic where some contents of main memory are temporarily cached on a persistent storage device in order to permit allocation and management of memory exceeding the physically available supply.

Virtual Reality: a class of computer graphics applications specifically designed to maintain the illusion of an artificial world in which the user is immersed.

Visualization: the graphical representation of data in order to facilitate understanding by human observers. The art and science of visualization exist independently of computers, but their principles are widely used in computer graphics to display the data sets that are commonly encountered in large-scale computation.

Waterfall Model: a standard for the sequential design and implementation of computer programs, characterized by long lead times to delivery and limited scope for substantial modifications to the program's function or architecture.

16.1 Introduction

Environmental Engineering and the Role of Mechanical Engineers

Ari Rabl and Jan F. Kreider

The subject of environmental science and management is vast and interdisciplinary, ranging from highly technical matters such as the design of emission control equipment to socioeconomic matters such as the valuation of the impacts of pollution. The goal is to prevent or reduce undesirable impacts of human activities on the environment. Within this endeavor there are several different areas where mechanical engineers can make important contributions. One type of contribution concerns the design of equipment, in particular for the control of emissions; an example is an electrostatic precipitator to reduce emissions of particulates from the flue gas of a boiler or furnace. Another type of contribution concerns the modeling of the dispersion of pollutants in the environment. This chapter covers air pollution, surface water pollution, and groundwater pollution. Since space is limited and since mechanical engineers are most likely to be involved in air pollution analysis and abatement projects, the emphasis is on air pollution problems.

Environmental Burdens and Impacts

Ari Rabl

As general guidance to the field of environmental engineering, it may be helpful to present the most important environmental burdens and impacts in the form of a matrix, as in Figure 16.1.1. Burdens, e.g., the emission of a pollutant, are listed in the column on the left; impact categories are listed as a row at the top. Each element in this matrix corresponds to a specific impact of a specific burden. An X indicates that the impact from the corresponding burden is likely to be significant. Particulate air pollution, for instance, has been shown to cause a significant increase in mortality.

As an added feature we have indicated the spatial and temporal extent to the burdens. The classic air pollutants (particulates, NO_x, and SO_x) are dispersed over distances on the order of a thousand kilometers, and they affect essentially only the present generation; thus, the second and third columns show the letters R (for regional) and P (for present generation). Global warming from greenhouse gases, on the other hand, affects the entire globe and will persist over decades or centuries, hence the letters G (for global) and P, F (for present and future generations).

The classification in Figure 16.1.1 is not without ambiguities or problems. For example, we have indicated the impact of greenhouse gases as "climate change" only, even though this category includes such effects as deaths from flooding. The relative importance of impacts may change with improved scientific understanding and with the evolution of societal preferences. One should also note that the assignment of effects to causes is in many cases quite uncertain; for instance, the observed mortality from air pollution could be due to particulates or due to SO_2.

Some impacts, especially thermal pollution and noise, can be highly site dependent. The cooling water from a power plant, for instance, could damage the ecosystem of a river or it could be used to improve the output of a fishery.

Each of the categories in Figure 16.1.1 could be broken down into subcategories:

- Health
  - Mortality
  - Injury
  - Cancer
  - Respiratory illness
- Natural environment
  - Recreational value of land (including forests)
  - Recreational value of water (including fishing)
  - Biodiversity
- Agricultural environment
  - Crops
  - Cattle (milk, meat, fur, …)
  - Wood production by forests
  - Commercial fishing
- Man-made environment
  - Functional buildings
  - Historical buildings
  - Other objects (bridges, cars, …)
  - Noise

	Impacts						
	Extent				Environment		
Burdens	**Space**	**Time**	**Climate**	**Health**	**Natural**	**Agricultural**	**Man-Made**
Primary air-pollutants							
CO_2	G	P, F	X				
CH_4	G	P, F	X				
Other greenhouse gases	G	P, F	X				
Particulates	R	P		X			X
SO_2	R	P		X	X	X	X
NO_x	R	P		X	X	X	X
CO	R	P		X			
Heavy metals (Pb, Hg, Cd, …)	R	P, F		X	X		
Toxic organic compounds (e.g., dioxins)	R	P, F		X	X		
VOC (volatile organic compounds, etc.)	R	P		X			
Secondary air pollutants							
O_3 (from NO + VOC)	R	P	X	X	X		
Acid rain (from NO_x, SO_x)	R	P		X	X	X	X
Aerosols (from NO_x, SO_x, etc.)	R	P	X	X	X	X	X
Liquid residues							
Heavy metals (Pb, Hg, Cd, …)	L, R	P, F		X	X		
Toxic organic compounds (e.g., dioxins)	L, R	P, F		X	X		
COD (chemical oxygen demand)	L, R	P, F		X	X	X	
BOD (biological oxygen demand)	L, R	P, F		X	X	X	
Solid residues	L	P, F		X	X	X	
Other							
Thermal	L	P			X		
Noise, odor	L	P					

Impacts: X = potentially important; blank = usually not important. **Extent:** L = local (up to tens of kilometers); P = present generation; R = regional (hundreds to thousands of kilometers); G = global; F = future generations.

FIGURE 16.1.1 Overview of environmental burdens and major impact categories, with approximate indication of typical geographic extent and typical importance of impact.

16.2 Benchmarks and Reference Conditions

Ari Rabl, Nevis Cook, Ronald R. Hewitt Cohen, and Tissa Illangasekare

Natural Environment

Air Basins

Unpolluted air is an idealization, but its composition has been defined as indicated in Table 16.2.1. Unfortunately, measurements of truly unpolluted air were not and can never be made because measurement techniques and even the interest in measurements did not exist when air was unpolluted. Now even the most remote sites have mildly polluted air.

TABLE 16.2.1 Gaseous Composition of Unpolluted Air (dry basis)

	ppm (vol)	μg/m^3
Nitrogen	780,000	8.95×10^8
Oxygen	209,400	2.74×10^8
Water	—	—
Argon	9,300	1.52×10^7
Carbon dioxide	315	5.67×10^5
Neon	18	1.49×10^4
Helium	5.2	8.50×10^2
Methane	1.0–1.2	$6.56–7.87 \times 10^2$
Krypton	1.0	3.43×10^3
Nitrous oxide	0.5	9.00×10^2
Hydrogen	0.5	4.13×10^1
Xenon	0.08	4.29×10^2
Organic vapors	~0.02	—

Although measurements of the undisturbed atmosphere were not made, we can gain some insight into trends of air pollutant burden growth by examining emissions over the last century. Figure 16.2.1 shows the growth of emissions of the classical air pollutant species since 1900. The latter two panels of the figure show that emissions from regulated sectors in the United States have abated in the past 20 years. Those regulations are described later. Note that Table 16.2.1 uses two sets of units for gaseous pollutants, one volumetric, the other mass based. To convert from one to the other the ideal gas law is used with the result (at 1 atm and 25°C):

$$1 \text{ ppm} = \text{MW} * 40.9 \ \mu\text{g/m}^3$$

where MW is the molecular weight.

Surface Water Basins

Human activity has also dramatically altered the distribution, quantity, and quality of Earth's water, especially since the industrial revolution. Accurate measurement of many water impurities, particularly trace impurities, has only become possible in the latter part of the 20th century. Given the quantities and wide distribution of human-generated wastes delivered directly or indirectly (via atmospheric deposition or surface runoff and erosion) to water bodies, recent water quality surveys might not be representative of truly "natural" conditions. As an example, a "pristine," undeveloped alpine lake may show traces of plutonium that are residuals of 1950s through 1960s atmospheric testing of nuclear weapons. Lead from automobile emissions can be detected in the bottom sediments of the Atlantic Ocean, more than 1500 km from the nearest landmass. A tabulation of the averages and ranges of concentrations of many naturally occurring substances detected in minimally impacted waters can serve

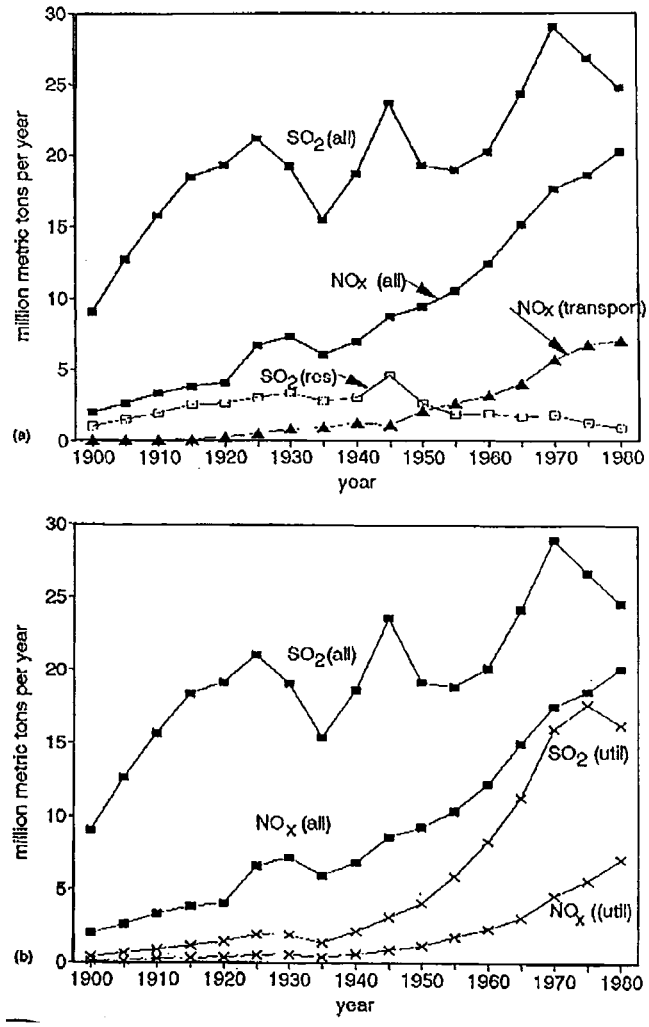

FIGURE 16.2.1 Trends in U.S. national emmissions of air pollutants. (a) SO_2 and NO_X ,1900–1980, all sources, residential SO_2 and transportation NO_X. (b) SO_2 and NO_X, 1900–1980, all sources and electric utility sources. (c) SO_2 and NO_X, 1970–1990, all sources, transportation and electric utility sources. (d) SO_2 and NO_X, and particulates, 1970–1990. (Data from EPA annual reports; Gschwandtner et al., 1985.)

as a benchmark, admittedly imperfect, against which to compare "polluted" waters, water quality criteria, and regulatory standards.

Choice of Reference Conditions. The authors propose as reference conditions, the concentrations of measured impurities in the oceans, "average" rainwaters, and "average" river waters. This choice of reference waters was based on two distinct criteria:

1. Either the volume of water was so large (such as the open oceans) that human activity has had little detectable effect on average water quality conditions, or
2. The waste input is small and the water body is rapidly and continuously renewed by unpolluted sources (such as a tributary to a major river).

The major and minor constituents of water and their quantities are easily presented in tables. The use of the word "major" indicates materials present or required in large quantities. Table 16.2.2 summarizes data on the constituents of selected natural waters. Note that the concentration data for major constituents

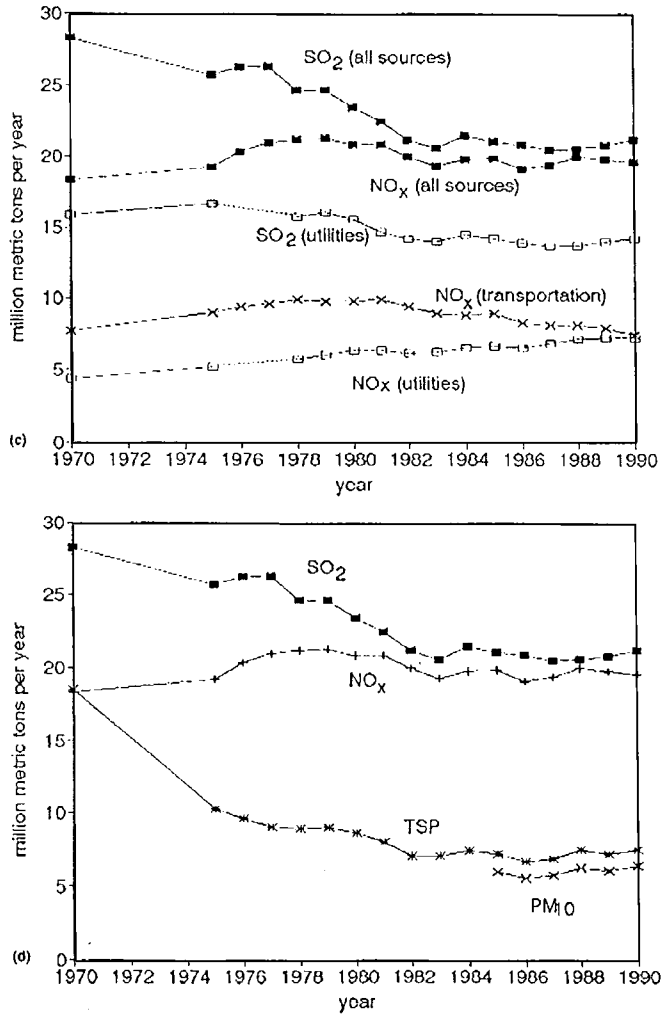

FIGURE 16.2.1 continued

(Table 16.2.2) is given in milligrams per liter and the concentration data for the minor constituents (Table 16.2.3) is given in micrograms per liter. Inclusion of boron and fluoride as major constituents is somewhat arbitrary and was based on their occurrence at greater than 1 mg/L in seawater. In these tables, individual entries are *average values* reported by U.S. regional or national surveys. *Ranges* are derived from the majority of the data from similar surveys, excluding data obtained from waters apparently contaminated by pollution. Some surveys presented results by stating that "very few" samples exceeded certain concentration values or simply reported measurements as "less than" due to analytical detection limits. These results are preceded by the symbol < in the tables. Although the data given are believed to be representative of water found in natural settings, it should be appreciated that, especially for industrially important trace constituents, the upper limits of the concentration ranges may include some small level of **anthropogenic** inputs.

There are additional categories of natural and contaminant components of water. There are complex, difficult to characterize, organic humic materials in natural water bodies that represent the end point of decay of formerly living organic matter. There are synthetic chemicals by the thousands, produced currently and in the past, by the chemical industry. Some of these compounds and polymers are completely new to the natural environment. Many are considered toxic to aquatic organisms and/or

TABLE 16.2.2 Major Constituents and Characteristics of Natural Waters (constituent concentrations in mg/L, unless otherwise noted)

Constituent	Oceans	Rivers	Rain
Cl^-	19,000	5.8, 7.8	0.2–0.6
Na^+	10,500	5.3, 6.3	0.2–0.6
SO_4^{2-}	2,700	8.3, 11	1.1, 2.2
Mg^{++}	1,350	3.4, 4.1	0.3–1.5
Ca^{++}	410	13.4, 15	0.05–1.5
K^+	390	1.3, 2.3	0.07–0.11
HCO_3^-	142	52, 58	1–10
Br^-	0.67	<20	<0.15
Sr^{++}	8	0.06–0.11	—
SiO_2	6.4	10.4, 13	0.1
B^{3-}	4.5	0.3	—
F^-	1.3	<1	—
pH (units)	8.2	6, 7.2, 7.5	5.7
Hardness (total)	—	10–200	—
Ammonia, as N	—	0.05–0.5	—
Nitrate, as N	—	0.1–2.0	—
BOD	—	2–4	—

Note: BOD is biochemical oxygen demand, mg/L oxygen; nitrate is NO_3^-, ammonia is NH_3.

TABLE 16.2.3 Minor Constituents of Natural Waters (constituent concentrations in μg/L)

Constituent	Oceans	Rivers	Rain
N	670	0–1000	0–620
C (organic)	100	3, 6, 19	—

Pb	0.03	<1	<1

humans. For lists of contaminants considered toxic and their effluent limitations, there are many documents available from the U.S. Environmental Protection Agency (USEPA) and other sources.

Soils and Water Basin Definitions

The unconsolidated sediment that covers a comparatively thin mantle of the land surface in general is referred to as soil. Soils are complex mixtures of solid, liquid, and gases. The solid phase consists of a mineral inorganic fraction that is produced by weathering of rocks or transported material. The predominant inorganic elements are silicon, aluminum, and iron. The organic fraction consists of partially or fully decomposed products of flora and fauna. The liquid phase is the water that occupies the pore spaces between and within grains of the solid material. In its natural form this water, which is referred to as

soil water, contains dissolved substances introduced from the solids or transported from the ground surface. The pore spaces that are not occupied by water will be filled by water vapor, gases, and air. The complexity of soil systems derives from the fact that the mixture of the solid, liquid, and gases is very heterogeneous and that the composition of the individual phases and the mixture changes in space and with time.

The soils in their natural environment can be subjected to drastic changes not only as a result of the interaction among the solid, liquid, and gas phases but also by external factors that are controlled by pressure, temperature, and light. The physical and chemical characteristics of the changing solid phase have a significant influence on the thermal behavior, water retention and flow, adsorption and entrapment of chemicals and wastes, and transport of dissolved substances. All of the above processes are of importance in the study, understanding, and solution of problems in environmental sciences and engineering associated with soil contamination.

The physical characteristics of soils as a porous medium are affected by the shape, size and size distribution, and the arrangement of the solid phase or the soil grains. The *shapes* and *sizes* of the soil grains vary widely from small colloids to large sand and gravel. Particles that are less than the arbitrary size of 2 μm are the clay fraction that is formed as a secondary product of weathering of rocks or derived from the transported deposits. These particles are platelike or disk shaped. The non-clay fraction formed from inert minerals and fragments of rock consists of silt, sand, and gravel. In a particle size classification used by agricultural scientists that was developed by the U.S. Department of Agriculture (USDA), non-clay particles that are in the size range 2 to 50 μm are classified as silts, in the range 50 to 2000 μm as sands, and above 2000 μm as gravel. In this classification system the sands are further divided into subgroups of very fine, fine, medium, coarse, and very coarse sands. A second system, by the International Society of Soil Science (ISSS) that is also used by agricultural scientists, classifies silts to be in the range 2 to 20 μm, fine sands 20 to 200 μm, and coarse sands 200 to 2000 μm. The American Society of Testing and Materials (ASTM) classifies colloids as particles that are less than 0.1 μm in size.

The surface area of the solid particles contained in a known volume of the soil has a significant influence on the physical and chemical processes that occur on the surfaces of the soil grains. The ratio of the internal solid surface area to the total volume is referred to as the *specific surface*. This parameter is also sometimes expressed as the ratio of the surface area to the mass of the soil grains. This parameter of the soil is affected by the size and shape of the individual soil grains. Because of the platelike or disk-shaped nature of small clay particles, clays in general have very large specific surface compared with the non-clay particles (silts, sand, and gravel). For example, the three common clay minerals kaolinite, illite, and montmorillonite have specific surface of 45, 175, and 800 m^2/gm, respectively (Corey, 1994). Because of these enormously large surface areas, the clay fraction in soils has a significant influence on the chemical reactive processes that are controlled by the surface area of the soil grains. The silt and sand fraction will not have a significant influence on the chemical processes, and also the smaller surface areas result in small water retention capacities as compared with clay.

The spaces between the grains that are referred to as intergranular pore spaces control the flow behavior and capacity to hold water by a soil. A physical parameter that is known as the *average porosity* or *porosity* characterizes the secondary pore space enclosed between the aggregates. The porosity of a soil sample is defined as the ratio of the volume of interconnected pores to the total volume of the sample. Soil porosity depends on many factors that include its structure, shape of soil grains, size distribution of the grains, the degree of mixing of the various-sized particles, and the way the soil grains are packed. Under conditions of normal packing the porosities of unconsolidated sand vary in the range 0.39 to 0.41 and soil with structure in the range 0.45 to 0.55. The organic matter in soil binds the inorganic fraction to form larger aggregates. The primary pore spaces within the soil aggregate play a significant role in retardation and attenuation of dissolved chemicals that are contained in the aqueous phase.

The subsurface soil–water environment that exists below the ground surface is divided into two zones, namely, the *unsaturated* or *vadose zone* and the *saturated zone*. In the unsaturated zone pore spaces contain both water and air. The capillary forces created by the surface tension in the water–air interfaces produce water pressures that are less than atmospheric (suction). The water flowing through

the unsaturated zone is subjected to capillary driving forces in addition to the gravitational forces. In the saturated zone, the water pores are fully saturated with water and the water pressures are greater than atmospheric. The water in the saturated zone is driven by gravitational forces. The surface that separates the unsaturated and saturated zones is referred to as the *water table*. By definition, the water pressure at the water table is atmospheric. The location of the water table below the ground surface at waste and spill sites becomes critical in determination of the fate and transport of pollutants in the subsurface soil–water environment as described later. Figure 16.2.2 shows the essentials of the situation schematically.

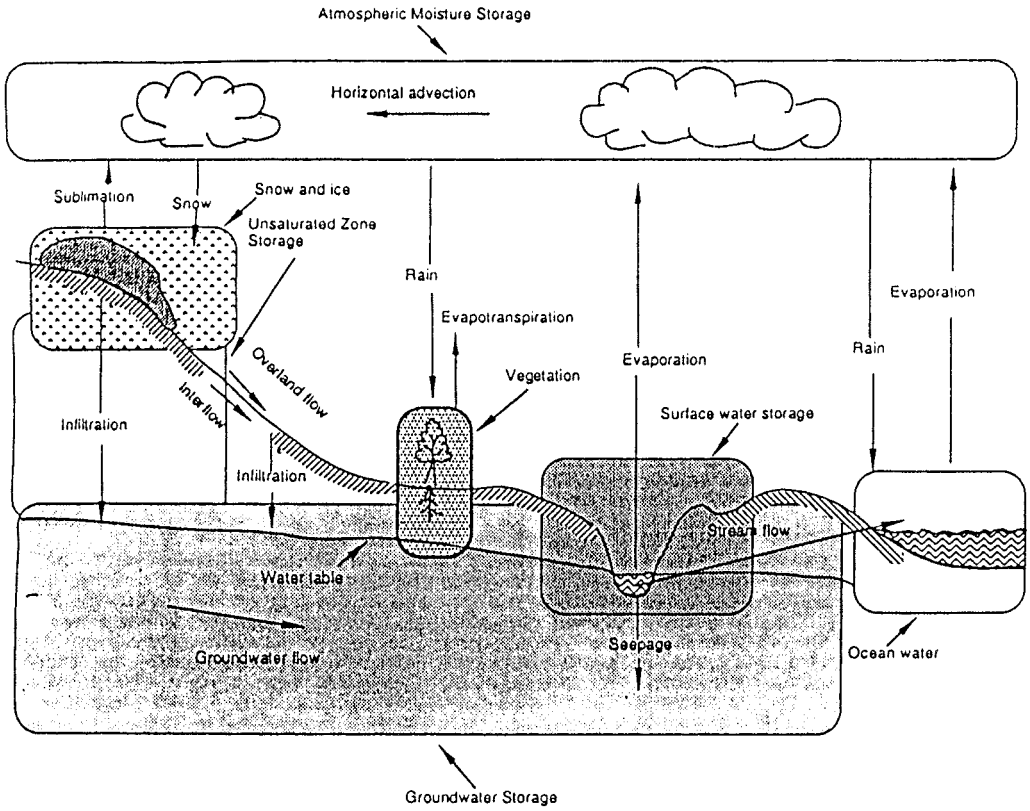

FIGURE 16.2.2 A column of Lagrangian boxes simulating atmospheric dynamics.

Acceptable Levels of Pollutants

Water

Criteria vs. Standards. The *objective* of water quality control programs, for example, is to protect current or potential *beneficial uses* of water. Criteria define the specific characteristics necessary to protect such uses. Criteria are not absolute, but are based on a combination of experience, current scientific knowledge, and the judgment of experts. Toxicological data for many of the water components often are limited. There may be results of tests for acute, or immediate, impact to organisms (including humans), but little information on impact on reproduction, long-term health or tolerance at low concentrations, organism adaptability, acclimatization, or interaction with other substances. General criteria are intended to protect sensitive species subjected to long-term exposure and may be overly conservative in specific situations. The aquatic life column of Table 16.2.4 presents typical, continuous, maximum concentration criteria for freshwaters intended to support a variety of aquatic life. Surface water quality criteria and their

TABLE 16.2.4 Water Quality Criteria and Standards (inorganic contaminants in μg/L)

Constituent	Beneficial Use or Protection Category

[a] Considered beneficial in drinking water at somewhat lower concentrations.
[b] Temperature and pH dependent, only unionized form (NH_3) is toxic to aquatic life.
[c] Secondary standards based on use impacts (tastes, staining), not health related.
[d] Controversial, based on toxicity of Ag^+, rarely present in natural waters.
[e] Extremely low levels partly due to food chain bioaccumulation potential.

relationship to permitted discharges are further discussed later in this chapter. The irrigation criteria given in Table 16.2.4 are intended to protect the yields of agricultural crops.

Due to resource limitations (time, money, data, or a shortage of knowledgeable experts), conservative criteria are often adopted as *standards*. Standards development should, however, include considerations of actual local needs and conditions, economics, technical feasibility, and the defined objectives of environmental policy. In contrast to criteria, standards are usually incorporated into laws and regulations and are often absolute. Either standards are violated or they are not.

Summarized as simple, USEPA (1979) definitions follow:

1. *Water Quality Criterion:* That concentration of a water quality measure that will meet a specific water use.
2. *Water Quality Standard:* The translation of a water quality criterion into a legally enforceable mass discharge of effluent limitation.

The drinking water column of Table 16.2.4 presents a subset of the current U.S. National Standards for drinking water supplied to the public. The health-based standards are enforceable. It should be noted that the drinking water standards list in Table 16.2.2 is not comprehensive. Maximum concentration levels (MCLs) for some inorganics, microbial contaminants, and the many regulated toxic organics have been omitted. Many drinking water MCLs are controversial because they rely on dose–response models which cannot be directly verified at the low levels of exposure that are typical.

Air

Tables 16.2.5 to 16.2.9 summarize the current U.S. ambient air quality standards for carbon monoxide, sulfur dioxide, nitrogen dioxide, ozone, and particulate matter. These criteria represent myriad effects depending on the receptor, species of pollutant, and duration and severity of impact. These criteria are

TABLE 16.2.5 U.S. Ambient Air Quality Criteria for Carbon Monoxide

CoHb in Blood, %	Associated Human Symptoms
80	Death
60	Loss of consciousness; death if exposure is continued
40	Collapse on exercise; confusion
30	Headache, fatigue; judgment disturbed
20	Cardiovascular damage; electrocardiographic abnormalities
5	Decline (linear with increasing CoHb level) in maximal oxygen uptake of healthy young men undergoing strenuous exercise; decrements in visual perception, manual dexterity, and performance of complex sensorimotor tasks
4	Decrements in vigilance (i.e., ability to detect small changes in one's environment that occur at unpredictable times); decreased exercise performance in both healthy persons and those with chronic obstructive pulmonary disease
3–6	Aggravation of cardiovascular disease (i.e., decreased exercise capacity in patients with angina pectoris, intermittent claudication, or peripheral arteriosclerosis)

CoHb = carboxy hemoglobin.

descriptive and are used for emission and air quality standards that are summarized briefly. As better data become available, these tables may change.

TABLE 16.2.7 U.S. Air Quality Criteria for Nitrogen Dioxide

Concentration of NO_2 in Air (ppm)	Exposure Time	Human Symptoms and Effects on Vegetation, Maerials, and Visibility
300	—	Rapid death
150	—	Death after 2 or 3 weeks by bronchiolitis fibrosa obliterans
50	—	Reversible, nonfatal bronchiolitis
10	—	Impairment of ability to detect odor of NO_2
5	15 min	Impairment of normal transport of gases between the blood and lungs in healthy adults
2.5	2 hr	Increased airway resistance in healthy adults
2	4 hr	Foliar injury to vegetation
1.0	15 min	Increased airway resistance in individuals with bronchitis
1.0	48 hr	Slight leaf spotting of pinto bean, endive, and cotton
0.3	—	Brownish color of target 1 km distant
0.25	Growing season	Decrease of growth and yield of tomatoes and oranges
0.2	8 hr	Yellowing of white fabrics
0.12	—	Odor perception threshold of NO_2
0.1	12 weeks	Fading of dyes on nylon
0.1	20 weeks	Reduction in growth of Kentucky bluegrass
0.05	12 weeks	Fading of dyes on cotton and rayon
0.03	—	Brownish color of target 10 km distant
0.003	—	Brownish color of target 100 km distant

TABLE 16.2.8 U.S. Ambient Air Quality Criteria for Ozone

Concentration of O_3 in Air (ppm)[a]	Human Symptoms and Vegetation Injury Threshold
10.0	Severe pulmonary edema; possible acute bronchiolitis; decreased blood pressure; rapid weak pulse
1.0	Coughing; extreme fatigue; lack of coordination; increased airway resistance; decreased forced expiratory volume
0.5	Chest constriction; impaired carbon monoxide diffusion capacity; decrease in lung function without exercise
0.3	Headache; chest discomfort sufficient to prevent completion of exercise; decrease in lung function in exercising subjects
0.25	Increase in incidence and severity of asthma attacks; moderate eye irritation
0.15	For sensitive individuals, reduction in pulmonary lung function; chest discomfort; irritation of the respiratory tract, coughing, and wheezing. Threshold for injury to vegetation
0.12	U.S. National Primary and Secondary Ambient Air Quality Standard, attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is equal to or less than 1, as determined in a specified manner

TABLE 16.2.9 U.S. Ambient Air Quality Criteria for Particulate Matter

Concentration of Particulate Matter in Air ($\mu g\ m^{-3}$)				
TSP < 25 μm	**TP < 10 μm**	**FP < 2.5 μm**	**Exposure Time**	**Human Symptoms and Effects on Visibility**
2000	—	—	2 hr	Personal discomfort
1000	—	—	10 min	Direct respiratory mechanical changes
—	350	—		Aggravation of bronchitis
	150	—	24 hr	U.S. Primary National Ambient Air Quality Standard as of September 1987
180	90	—		Increased respiratory disease symptoms
	150	—	24 hr	U.S. Primary National Ambient Air Quality Standard as of September 1987
110	55	—	24 hr	Increased respiratory disease risk
	50	—	Annual geometric mean	U.S. Primary National Air Quality Standard as of September 1987
	50	—	Annual geometric mean	U.S. Secondary National Ambient Air Quality Standard as of September 1987
—	—	22	13 weeks	Usual summer visibility in eastern U.S., nonurban sites

TSP = total suspended particulates; TP = thoracic particulates; FP = fine particulates.

16.3 Sources of Pollution and Regulations

Sources

Jan F. Kreider, Nevis Cook, Tissa Illangasekare, and Ronald R. Hewitt Cohen

Air

Air pollutants are found in the form of gases (e.g., SO_2) and particulate matter (e.g., fine dust). They are emitted into the atmosphere from natural sources (e.g., volcanoes) and *anthropogenic* sources (e.g., industrial activities). These pollutants are called "primary" because they are directly emitted from local sources. Primary pollutants may undergo chemical reactions that result in the subsequent formation of other species called "secondary" pollutants (e.g., O_3).

Air pollution is found at all spatial scales, ranging from a few meters (e.g., indoor pollution) to local, urban, regional, and global scales (Milford and Russell, 1993). *Indoor pollution* is of great concern because a large fraction of our time is spent indoors. Indoor sources of pollutants include combustion processes, aging materials (e.g., formaldehyde emitted from particleboard and plywood), and radon — a natural indoor pollutant which migrates through the soil and may penetrate and accumulate inside buildings. The *local scale* ranges from 100 m to a few kilometers. At this scale, pollution dynamics are dominated by atmospheric diffusion and the role of primary pollutants. The local scale is the one where we experience major exposure to toxic substances and flammable compounds during catastrophic and emergency releases.

The *urban scale* ranges from 10 to 100 km and is characterized by both primary and secondary pollutants. In fact, characteristic residence times are on the order of 1 or a few days, thus, allowing enough time for chemical transformation to play a role. Two types of urban smog are well known: the "London" smog and the "Los Angeles" smog. The former is characterized by stagnant, foggy meteorological conditions in winter which allow a buildup, over a few days, of SO_2 and particulate matter. The latter, which has become the most common type of atmospheric pollution throughout the cities of the world, is a **photochemical** smog associated with clear, sunny days. Photochemical smog is a mixture of many gaseous compounds and particulate matter, among which the two most important constituents are ozone (a colorless secondary pollutant) and fine secondary particulate matter (such as sulfates, nitrates, and organic particles), which is responsible for most of the visual haze.

The *regional scale* ranges from hundreds to thousands of kilometers (the upper regional scale is also called *continental scale*). Characteristic residence times are on the order of 1 week. At this scale, pollution dynamics are dominated by chemical transformation and ground deposition phenomena. Acidic deposition, often referred to as *acid rain,* is a phenomenon in which acid substances, such as sulfuric and nitric acid, are brought to Earth by dry and wet deposition. Some lakes are very sensitive to acidic deposition because of their limited buffering capacity. *Global air pollution* is characterized by relatively unreactive compounds, such as CO_2, methane (CH_4), and chlorofluorocarbons (CFCs). The long lifetime of these pollutants allows their global dispersion and accumulation.

Air pollution at any scale creates several adverse effects. Air pollution can just be a nuisance (e.g., odors) or be aesthetically offensive (e.g., visibility impairment). Some adverse effects, however, are of fundamental importance to the welfare of the population and public health. For example, many pollutants cause respiratory effects; some pollutants have mutagenic effects; others have shown carcinogenic effects; some pollutants also have synergistic effects (e.g., the damage of SO_2 to the human respiratory system can be greatly enhanced by the presence of fine particles).

In the rest of this chapter, an overview is presented of analytical and numerical techniques for simulating air pollution phenomena. Air quality modeling is an essential tool for most air pollution studies today. Models can be divided into **deterministic** models, based on fundamental mathematical descriptions of atmospheric processes, and statistical models, based upon semiempirical relationships extracted from data and measurements. Deterministic models, in particular, have become a major tool

in providing objective assessment of air pollution scenarios and evaluating the effectiveness of different air pollution control measures. In fact, only deterministic models provide an unambiguous assessment of the fraction of responsibility of each pollution source in each receptor area, thus, allowing the definition and implementation of the most cost-effective cleanup strategy. Statistical models, instead, are useful in situations where deterministic models do not perform well, e.g., for real-time forecasting of air pollution episodes.

Waterborne

Table 16.3.1 summarizes important sources of surface water pollution species by economic or technical sectors of the U.S. economy. An X indicates a key source and no entry indicates a second-order effect at most. Table 16.3.2 lists groundwater pollution sources by cause, extent and waste type.

Soil and Groundwater

Various waste products and chemicals are generated from industrial, agricultural, commercial, and domestics activities. Unmonitored and uncontrolled long-term application on the land, accidental spillage, and improper storage and disposal result in these chemicals and wastes acting as potential sources of soil and groundwater contamination. La Grega et al. (1994) use an engineering classification system in which hazardous wastes are grouped under six categories, namely, inorganic aqueous waste, organic aqueous waste, organic liquids, oils, inorganic sludges/solids, and organic sludges/solids. In addition to these, pathogens and nuclear wastes act as sources of contamination. As most of these materials are fully or partially soluble in water, they ultimately will contaminate the water phase contained within the soil pores and the water passing through the soil both in the unsaturated and saturated zones of the subsurface. Figure 16.3.1 shows in schematic form how groundwater pollution occurs.

Inorganic aqueous wastes generated from manufacturing activities involving galvanizing, metal finishing, electroplating, etc. mostly contain acids, alkalis, or concentrated solutions of inorganic wastes such as heavy metals. Organic aqueous wastes are liquids that primarily contain mixtures of dilute concentrations of organic substances such as pesticides. Organic liquid wastes are complex mixtures or concentrated solutions of **organic compounds**. A common example of organic liquid wastes is halogenated solvents that are used in metal degreasing. Most of the oily wastes are derived from petroleum. Oils are used as fuels, lubricating oils in engines, and cutting oils in manufacturing. Inorganic sludges/solids wastes are produced from wastewater treatment, smelters, coking, and metal fabrication. Tars and sludges that are produced from manufacturing activities are some of the examples of wastes that are in the form of organic sludges.

Waste materials and chemicals are released to the soil and groundwater from various sources. The most common sources are leaking underground chemical storage tanks, septic tanks, municipal landfills, industrial landfills, surface impoundments, and abandoned hazardous waste sites. In addition, injection wells, regulated hazardous waste sites, land application, road salting, saltwater intrusion, and oil and gas brine pits contribute to soil and groundwater contamination.

The most frequent use of underground tanks is for storage of gasoline in service stations. Hazardous wastes and chemicals and oils are also stored in buried tanks at industrial sites, farms, and homes. The potential for leakage exists when these tanks corrode internally or externally. In addition, chemicals can leak from pipe joints or holes in the pipes that are connected to the tanks.

Older landfills that were not properly designed for containment of liquids or leachates were used to dispose of garbage, sludges from wastewater treatment plants, construction wastes and debris, incinerator ash, waste from foundries, and many other industrial and domestic hazardous and nonhazardous waste products. The chemicals in the landfill become a source of contamination when rain or surface water infiltrating through the landfill produces leachate. These leachates containing the dissolved constituents of the waste, eventually contaminate the underlying soil and groundwater. Modern well-designed landfills have synthetic liners and leachate-collection systems.

Surface impoundments in the form of open pits, lagoons, or ponds are designed to accept liquid wastes or mixed solids and liquids. The chemical wastes in these temporary storage sites are treated and

TABLE 16.3.1 Sources of Water Pollution vs. Contaminant Emission Categories

	General Emissions Type or Category

Notation: BOD = biochemical oxygen demand; TSS = total suspended solids; TDS = total dissolved solids; synthetic organics = synthetic organic compounds; volatile organics = volatile organic compounds; metals = industrial metals; pH = high (alkaline) or low (acid) pH.

TABLE 16.3.2 Groundwater Pollution Sources

Source	Cause	Extent	Chemical/Wastes
Underground storage tanks	Hole due to internal and external corrosion leaks chemical into soil and groundwater	• 2.5 million • 47 states • 35% of 800,000 fuel tanks leaked	Gasoline Oil Hazardous chemicals Waste products
Landfills	Rainwater leaching chemicals to groundwater	• 2,395 open dumps • 24,000–36,000 closed or abandoned landfills • 75,000 on-site industrial landfills • 12,000–18,000 municipal landfills contain hazardous wastes	Garbage and trash Sludge Incinerator ash Foundry waste Hazardous substances
Surface impoundments	Direct infiltration to the saturated zone of aquifer	• 180,000 waste impoundments (1982) • 37,000 municipal • 19,400 agricultural • 27,912 industrial • 25,000 mining • 65,688 brine pits for oil and gas • Industrial sites evaluated 95% within 1 mile of drinking wells, 70% unlined, 50% on top of aquifers	Settling ponds from municipal wastewater and sewage treatment Animal feed lots and farms Oil and gas industries Mining Paper Chemical operation
Waste-disposal injection wells	Direct dumping through wells to aquifers	• Groundwater contamination in 20 states • Millions of tons through thousands of wells	Toxic Hazardous Radioactive Metals Wood Preservatives Petroleum
Septic systems	Surfacing and flooding due to failure; leaching into aquifers	• 22 million in U.S. • 0.5 million installed every year • 30% of population served	Variety of organic and inorganic compounds Fecal coliform Nitrates and nitrites Trichloroethylene, benzene, and methylene chloride
Agricultural waste	Leaching through unsaturated zone to groundwater	• 50,000 pesticides with 600 active ingredients • 10 million t of nitrogen	Nitrates Salts Dissolved solids
Land application	Leachates reaching groundwater	• Major threat to groundwater in 20 states • 40% of hazardous wastes in California treated by land farming	Heavy metals Toxic chemical Nitrogen Pathogens
Radioactive contaminants	Potential migration to groundwater	• Massive production of radioactive isotopes after World War II	Uranium Plutonium

After Bedient, P.B., Rifai, H.S., and Newell, C.J. 1994. *Ground Water Contamination: Transport and Remediation*, Prentice Hall, Englewood Cliffs, NJ, 541.

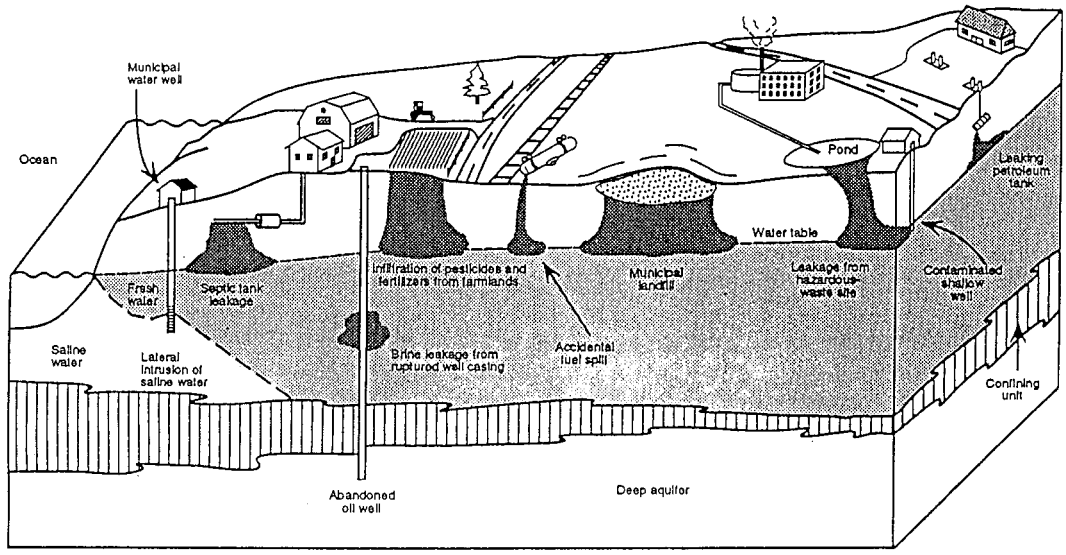

FIGURE 16.3.1 Mechanisms of groundwater contamination (From Fetter, 1993).

discharged or allowed to evaporate or infiltrate into the ground. In addition, to store and dispose of wastewater and products from sewage treatment, surface impoundments are used in paper, mining, and oil and gas industries. They are also used in farms and large feed lots. In unlined impoundments, the liquids leak, and when undetected, can result in soil and groundwater contamination in large zones of the subsurface.

Because of the large number of septic tanks that are in operation in homes, small businesses, service stations, laundries, and industry, septic tanks have become a major source of soil and groundwater contamination. When these systems fail, the sludges or septage floods the drainage field and leachates that are generated act as a source of contamination. The discharges from septic tanks contain many organic and inorganic chemical products, suspended solids, fecal coliform, pathogenic bacteria and viruses, nitrates, and nitrites. Industrial septic systems used in commercial operations discharge hazardous waste chemicals that include synthetic organics (e.g., trichloroethylene, tetrachloroethylene, toluene, etc.) and heavy metals (e.g., lead, copper, and zinc).

Injection wells that are drilled into deep aquifers or aquifers that are not used for water supply are used to discharge liquid wastes into the subsurface. Large volumes of toxic, hazardous, and radioactive wastes that are generated in chemical, petroleum, metals, mining, and wood-treatment industries are disposed of using this method. The contamination of aquifers that are used for drinking water can occur when the injection wells are not designed properly and are placed in formations where the hydrogeolgic conditions are not well known or understood.

Many types of agriculture-related activities use chemicals and produce wastes that contaminate soil and groundwater. Among these products are pesticides, fertilizer, and feed lot waste. Various types of pesticides are used in farming, golf courses, gardens, and parks to control insects and weeds. Many of the modern-day pesticides are biodegradable, but some of the stable ones are carried by rain and irrigation water through the soil to the groundwater. Fertilizers primarily contain nitrogen, potassium, and phosphorus. Because of comparatively high mobility in soil, nitrogen leachates are the primary contaminant of concern that is associated with application of fertilizers. Waste generated at large feed lots can introduce nitrogen, bacteria, and salts to the underlying aquifers. In addition to the above sources, the salts that get accumulated in soils from long-term application of irrigation water act as a source of soil and groundwater degradation.

In a treatment and disposal method known as land treatment, the wastewater and sludges that are generated from treatment plants and industrial operations are directly applied on the ground surface. Contamination of the soil and groundwater occurs when heavy metals, toxic chemicals, nitrogen, and pathogens leach through the unsaturated zone.

Another source of soil contamination is the radioactive wastes that are produced in the weapons and nuclear industries. These wastes are primarily associated with the elements uranium and plutonium. The ionizing radiation in the form of alpha and beta particles and gamma rays are damaging to human and animal life. As these contaminants follow a first-order exponential decay law, they remain hazardous for very long time periods on the order of hundreds to thousands of years. Table 16.3.2 summarizes several of the key sources of groundwater pollution, their extent and the major associated pollutants.

Pollutant Monitoring

Jan F. Kreider and Tissa Illangasekare

Groundwater

Contaminants that are released to the aqueous phase from the soil or external sources move with the flowing groundwater creating a solute plume. Monitoring the groundwater flow velocity and the propagation of the solute plume is necessary to design schemes and strategies to protect the quality of groundwater that is used for drinking.

Monitoring wells are installed in aquifers to measure water pressure and to sample groundwater water quality. Wells in general consist of a standpipe with a screened interval. The screened interval allows for the aquifer water to flow into the well pipe. The water pressures are used to determine the head gradients, which in turn can be used to estimate the magnitude and direction of groundwater flow. Water samples that are collected at monitoring wells can be used to obtain information on the quality of groundwater.

Piezometric head is the sum of pressure and the elevation heads. The pressure head at any point in the aquifer intercepted by the screen is the height of the water surface in the well bore (or standpipe) above the point on the screen. The elevation head at a point is the elevation of the point above or below a datum. The gradient of the piezometric head determines the magnitude and direction of groundwater flow. By measuring the piezometric heads at many monitoring wells it is possible to draw the contour lines of equal piezometric head or potential. A flow net is obtained by constructing a set of flow lines that are orthogonal to the equipotential lines. The groundwater flow direction at a point is determined by drawing a tangent to the flow line passing through the point. By constructing the flow net so that the intersection of equipotential lines and the flow lines form curvilinear squares, it is possible to estimate the groundwater flow velocities and discharge in an aquifer. The monitoring well data can also be used to calibrate a groundwater model that then can be used to estimate and monitor groundwater flow.

Groundwater samples collected from monitoring wells can be analyzed in the laboratory to determine the chemical contents. Probes can be inserted into the monitoring wells for the *in situ* measurement of conductivity and pH.

Process Emissions Monitoring. Methods and instrumentation for the monitoring of industrial waste discharge streams are discussed in detail in the USEPA *Handbook for Sampling and Sample Preservation of Water and Wastewater.* ASTM publishes a frequently updated *Annual Book of ASTM Standards* that extensively details recommended sampling techniques.

The topic of sampling is complex and includes sampling timing and frequency; sample preservation (until analyses can be done); sample preprocessing (i.e., filtering to separate particulate and dissolved components); questions of whether waste streams are continuously monitored for particular environmental variables or whether discrete samples are taken; whether a single "grab" sample is taken or a series of samples in time or space are retrieved and composted into a single "representative" sample; whether there is a single, worker-sampled, grab sample of an automated, continuous sampling apparatus; whether there is retention of volatile compounds for later analysis. Additionally, there are issues of

laboratory analytical techniques, quality control, and quality assurance from the moment of sampling through the reporting of the data, acceptable detection limits, sample contamination, materials used to sample particular chemicals. The only way to account for all these variables is to know thoroughly the data-reporting requirements of the industrial discharge permits or agreements. Also, the objectives of the sampling and the compounds of concern will dictate the entire structure of the sampling regime. The authors will discuss, briefly, some of the above topics.

The ideal characteristics of a process waste discharge stream for monitoring are steady, uniform flow that is chemically homogeneous throughout the cross section. Under such conditions, several grab samples over the day may yield representative results. In many industries, the waste streams vary due to process switching, change of shifts of workers, and cleaning and preparation of process equipment and machinery. Several specified times a day a local beer brewery flushes process wastes from the floor using high-pressure hoses. Occasional grab sampling might miss completely this pulse of waste load to the treatment system. There are continuous sampling devices that take a grab sample at specified time periods, then rotate to another sample bottle in preparation for the next sample. There are more-sophisticated samplers that draw in a sample at time intervals proportional to stream discharge. Often, the type and frequency of discharge sampling is specified in the discharge permit. For best results, the sampling planner or coordinator should know the plant operation cycles in order to be able to characterize the time variation of discharges.

The material of which a sampling device and storage vessel is constructed must be matched to the materials sampled. Some organics require the use of tetrafluoroethylene (Teflon) tubing and glass storage vials that have been washed with an organic-free cleanser. Using the wrong tubing may result in the leaching of plasticizers into the sample. It is recommended that metal sampling devices *not* be used for collection of metal-laden discharge samples that require later analysis for metal ions. Samplers must be washed between samplings to avoid sample cross contamination.

Environmental Quality Monitoring. Most of the mechanics and issues of sampling discussed just above for monitoring discharges hold true for environmental sampling, i.e., after the discharge has entered a stream or lake. Detailed sampling plans must be prepared. Existing data is gathered (from company files; land use maps; USEPA; U.S. Geological Survey gauging and water quality station results; state departments of environment, resources, and health; other federal and local agencies). It helps to have site characteristics prior to the inception of the waste discharge.

The data collection for environmental monitoring often is governed by legal considerations concerning the validity and admissibility of the data. To this end, a quality assurance/quality control (QA/QC) plan must be prepared according to USEPA or state guidelines. These plans will specify the frequency of taking duplicate samples (taken at approximately the same time and place), split samples (one sample is split into two, separate containers), spiked samples (an additional injection of chemicals anticipated to be in the environmental sample are added to a duplicate sample, and the recovery of that known amount of spike is reported). A good QA/QC operation will ensure that the best effort is being made to

1. Obtain representative samples,
2. Use appropriate sampling methods,
3. Use appropriate analytical methods,
4. Ensure adequate records of chain of custody of samples, and
5. Develop a sound and acceptable database.

The USEPA can be contacted to send *Interim Guidelines and Specifications for Preparing Quality Assurance Project Plans* (or QAPPS — pronounced “kwaps”).

Other documents that may be required include

1. Sampling plans;
2. Site background information;
3. Planned sampling locations;

4. Planned sampling methodology and sample preservation (some chemicals decay on exposure to light, microbes may induce decomposition of organic compounds at ambient temperatures, chemically reduced compounds may oxidize on exposure to a head space of air, volatile compounds may escape from an insufficiently sealed vial, solid materials may dissolve, or dissolved materials may precipitate);
5. Health and safety plans;
6. Plans for sample-handling procedures and chain of custody of samples;
7. Request forms for sample analyses;
8. Frequency and format of data reports.

Air Quality Monitoring

Air quality monitoring has many of the same goals and general techniques as water quality monitoring. A stationary monitoring network should yield the following information:

1. Background concentration
2. Highest concentration levels
3. Representative levels in populated areas
4. Impact of local sources
5. Impact of remote sources
6. Relative impact of natural and anthropogenic sources

Spatial scales range from micro- (up to 100 m) to regional scales (tens to hundreds of kilometers). Site selection is a key part of network design because microclimates can affect readings and cause them to be nonrepresentative of the region.

Mobile monitoring is useful when sites not monitored with the fixed network need assessment. The key drawback of such systems is the sparsity of equipment suitable for reliable and durable mobile monitoring. Remote sensing offers a second alternative to stationary networks.

Quality assurance is a continuous concern of monitoring systems. Good instrumentation installation and maintenance practice with careful record keeping is essential.

Space precludes presentation of further details on air quality monitoring, but Boubel et al. (1994) has a thorough overview.

16.4 Regulations and Emission Standards

Water

Nevis Cook and Ronald R. Hewitt Cohen

The Clean Water Act (CWA) of 1972 and its amendments establish the framework of current U.S. water pollution control. This act is sometimes referred to as the Federal Water Pollution Control Act Amendments after the original 1965 act which the CWA amended. The objective of the CWA is to "restore and maintain the chemical, physical, and biological integrity of the nation's waters." The CWA regulates both nonpoint (runoff from farmlands, roads, and city streets) and point sources (discharges from pipes conveying pollutants to surface waters) of water pollution. The discussions in this chapter are limited to regulation of point sources of pollution to *surface* waters. Discharges to groundwaters are regulated under the Safe Drinking Water Act (SDWA) underground injection control (UIC) program and are beyond the scope of this chapter. The discussion is still quite broad, since all domestic and industrial wastewater discharges are considered point sources under the CWA.

Discharge Permits. The CWA prohibits point source discharges to surface waters unless a *discharge permit* is obtained. Permits typically are issued at the state level and are known as state pollution discharge elimination standards (SPDES) permits. If the state has not taken over this responsibility, national (NPDES) permits are issued by the USEPA. The permit for each point source prescribes allowable discharges in terms of amount and concentration of flows and pollutants. In some cases, an industrial facility may avoid obtaining its own permit by discharging into the local public sewer system. Control of these *indirect discharges* is accomplished by requiring publicly owned treatment works (POTWs) receiving such discharges to enter into formal *pretreatment agreements* with industrial users of the sewer. Such pretreatment agreements are intended to prevent industrial discharges to POTWs which would represent a hazard to the sewer system or its workers, interfere with treatment operations or sewage sludge disposal, or pass through the treatment process causing a violation of the POTW discharge permit.

Permitted Discharges. Prior to the CWA of 1972, point source water pollution control laws were established at the state level and permitted discharge of pollutants on a discharger-by-discharger and water-body-by-water-body basis. This approach worked poorly in most states, demonstrating the need for enforceable *federal minimum effluent standards*. For this reason, the CWA and subsequent amendments have established *technology-based* national minimum pretreatment and discharge standards. Technology-based standards reflect the current state of the art with respect to controlling specific pollutant discharges from specific pollution sources. Since technology-based standards represent the capabilities of typical "well-operated" facilities and are not issued on the basis of in-stream water quality, it is not surprising that in some cases compliance with national minimum standards does not adequately protect all potential uses of a water body. In such cases the uses of the receiving water body are said to be *water quality limited,* and *local discharge limits*, more stringent than national limits, may be imposed. In addition, pretreatment agreements reflect the capabilities of local treatment works with respect to pass through, destruction, or partitioning of nondegradable toxic metal pollutants into POTW sludges. Following the development of local water quality–based limits, these are compared with national minimum technology-based standards and the more restrictive criteria are imposed as discharge permit or pretreatment limitations. Further considerations with respect to setting permit values are presented below.

Industrial dischargers may obtain an industrial NPDES permit and directly discharge wastewater to a receiving water body. Alternatively, where municipal sewer service is available, industries may choose to negotiate a pretreatment agreement with the local sewer authority permitting discharge of industrial wastewater to the sewer system. Most industrial facilities employing either discharge option (direct or indirect) are subject to national technology-based minimum effluent standards. In addition, more-stringent standards may be imposed at the state or local level.

State permits containing discharge constraints more stringent than the national minimum standards are commonly derived from local water quality considerations. Ideally, local water quality–based

standards are developed from science-based use protection criteria, wastewater flow data, and actual receiving water characteristics (such as low-flow conditions for streams). Rational direct discharge permits to streams or rivers can be developed by application of the following procedure: convert use-based, in-stream quality criteria to standards according to local policy; obtain data on upstream water quality and low-flow conditions (conditions at which the waste assimilative capacity of a stream is at a minimum) and determine potential for dilution of the wastewater flow by the receiving water body; compute the allowable water quality–based industrial discharge on a pollutant-by-pollutant basis and compare with national minimum standards; finally, impose permit restrictions according to the most stringent of the two types of standards developed.

Development of water quality–based permits for direct discharges to lakes, estuaries, bays, or oceans follows a procedure similar to that outlined above. However, estimates of mixing patterns and the dilution potential of these water bodies are likely to be more difficult because of the complex flow patterns involved. Water quality–based pretreatment standards for discharges to sewers also follow the same general procedure. However, in this case, the application of use criteria, policy, and potential for in-stream dilution lead to a pollutant-by-pollutant permit for the *local* POTW. Based on this permit and the removal capabilities of the treatment facility, maximum allowable (usually daily) loading of pollutants arriving at the plant is determined on a pollutant-by-pollutant basis. Allowable loads are then allocated to the various municipal and industrial users of the sewer. Setting water quality–based pretreatment standards is obviously complicated by the presence of multiple sewer uses and users. Thus, POTWs receiving significant industrial discharges are required to set up formal programs to negotiate industrial pretreatment agreements and monitor compliance.

Air

Jan F. Kreider

The U.S. Clean Air Act Amendments of 1977 set forth two air quality standard types:

- Primary (protect health)
- Secondary (protect health and prevent other adverse impacts)

Table 16.4.1 summarizes the present primary and secondary standards in the U.S. The amendments also specified for certain geographical areas further standards to prevent significant deterioration (PSD areas). These are standards that are to be considered increments over baseline air quality but are more stringent than secondary or primary standards in most cases. Table 16.4.2 lists these PSD standards.

TABLE 16.4.1 U.S. Federal Primary and Secondary Ambient Air Quality Standards

				Concentration	
Pollutant	**Type of Standard**	**Averaging Time**	**Frequency Parameter**	**μg/m³**	**ppm**
Sulfur oxides (as sulfur dioxide)	Primary	24 hr	Annual maximum	365	0.14
		1 year	Arithmetic mean	80	0.03
	Secondary	3 hr	Annual maximum	1,300	0.5

16.5 Mitigation of Water and Air Pollution

This section discusses the methods for abating or mitigating air and water pollution burdens on the environment. Because mechanical engineers are most concerned with air pollution control systems and civil engineers deal with water treatment systems, this section emphasizes the air pollution mitigation side.

Overview

Jan F. Kreider

There are several methods for controlling air- or waterborne pollution:

- Process change
- Fuel change
- Pollution removal and disposal
- Pollution prevention

Process change includes everything from modifications that reduce emissions to substitution of a less polluting one for a more polluting one. The latter could be classified as pollution prevention, described shortly. In many cases, for example, in the steel industry, it has proved most economical to replace completely old plants with totally new ones. Likewise, complete substitution has been widely adopted in the pulp and paper industry.

Fuel change as a control strategy is based on the fact that airborne pollutants often are related to the combustion aspects of a process. For example, coal-fired power plants emit SO_2 because coal contains sulfur. Substitution of natural gas for coal eliminates any sulfur in the fuel and, therefore, any oxides of sulfur in the stack gases.

Fuel changes must consider fuel supply, capital cost, and competition for clean fuels among many industries before an engineering design decision can be made. Life cycle methods that consider all parts of the life of a plant are necessary. For example, a nuclear power plant may produce very low emission electricity but after decommissioning may cause long-term waste disposal problems.

Pollution removal is necessary when process or fuel changes cannot provide adequate emission control. A physical, chemical, or electrical feature of the pollutant to be removed must differ from those types of characteristics of the carrying gas or liquid stream. An example is a baghouse or electrostatic precipitator for particulate emissions. Not only collection of pollutants but also disposal of the collected pollutant must be considered by the design engineer. A whole systems viewpoint is necessary for a successful pollution removal design.

Pollutant disposal is governed by different criteria depending on whether it is hazardous or not. Hazardous waste disposal is covered by the Resource Conservation and Recovery Act of 1976, which established the Office of Solid Waste with the USEPA. On the other hand, nonhazardous waste disposal is governed by the states. Table 16.5.1 categorizes the ultimate disposal methods for classes of hazardous wastes. Many of the methods apply for nonhazardous wastes as well.

Pollution prevention is the ultimate solution to abatement. This can be accomplished at the source by various technical means, depending on process specifics. This approach is currently the most commonly used term by the USEPA. The Pollution Prevention Act of 1990 stated these policies:

- Prevent or reduce pollution at the source whenever possible;
- Recycle to the environment pollution that cannot be prevented in a safe manner whenever possible;
- Pollution that can neither be prevented nor recycled should be treated in as environmentally safe a manner as possible;
- Disposal or other release into the environment should be used as only a last resort.

TABLE 16.5.1 Ultimate Waste Disposal Methods

Process	Purpose	Wastes	Problems (Remarks)
Cementation and vitrification	Fixation	Sludges	Expensive
	Immobilization	Liquids	
	Solidification		
Centrifugation	Dewatering	Sludges	—
	Consolidation	Liquids	
Filtration	Dewatering	Sludges	Expensive
	Volume reduction	Liquids	
Thickening (various methods)	Dewatering	Sludges	—
	Volume reduction	Liquids	
Chemical addition (polyelectrolytes)	Precipitation	Sludges	Can be used in conjunction with other processes
	Fixation	Liquids	
	Coagulation		
Submerged combustion	Dewatering	Liquids	Acceptable for aqueous organics
	Major Ultimate Disposal Methods		
Deep well injection	Partial removal from biosphere	Oil field brines; low toxicity, low-persistence wastes; refinery wastes	Monitoring difficulty; need for special geological formations; groundwater contamination
	Storage		
Incineration	Volume reduction	Most organics	If poor process control, unwanted emissions produced
	Toxicity destruction		Can produce NO_x, SO_x, halo acids
Recovery	Reuse	Metals	Sometimes energy prohibitive
		Solvents	
Landfill	Storage	Inert to radioactive	Volatilization
	Major Waste Disposal Methods		
Land application	Isolation		Leaching to groundwater
Land burial	Dispersal		Access to biota
Ocean disposal	Dispersal	Acids, bases	Contact with ocean ecosystem; containers unstable
	Dilution	Explosives	
	Neutralization	Chemical war agents	
	Isolation(?)	Radioactive wastes	
	Minor Disposal Methods		
Biological degradation	Reduction of concentration	Biodegradable organics	Most hazardous wastes do not now qualify
	Oxidation		
Chemical degradation (chlorination)	Conversion	Some persistent pesticides	—
	Oxidation		
Electrolytic processes	Oxidation	Organics	—
Long-term sealed storage	Isolation	Radioactive	How good are containers?
	Storage		
Salt deposit disposal	Isolation	Radioactive	Are salt deposits stable in terms of waste lifetimes?
	Storage		

Air Pollution Control

Jan F. Kreider

The most common method of meeting emission standards in industries that must control air pollution is by *pollution removal*. This section describes the most widely used approaches. Table 16.5.2 lists the important characteristics of control systems for airborne pollutants.

Dry particulate matter is removed by

TABLE 16.5.2 Key Characteristics of Pollution Control Devices and/or Systems

Factor Considered	Characterisitc of Concern
General	Collection efficiency
	Legal limitations such as best available technology
	Initial cost
	Lifetime and salvage value
	Operation and maintenance costs
	Power requirement
	Space requirements and weight
	Materials of construction
	Reliability
	Reputation of manufacturer and guarantees
	Ultimate disposal/use of pollutants
Carrier gas	Temperature
	Pressure
	Humidity

- Filters — baghouse, fixed beds, or mats
- Electrostatic precipitators — plate-type, tube-type; see Figure 16.5.1
- Inertial collectors — cyclones and baffles; see Figure 16.5.2
- Scrubbers — wet or dry

Table 16.5.3 lists the key characteristics of these technologies, where they are best applied, and annual operating, capital, and maintenance costs in $1994. Of course, a design is needed upon which a quotation for final cost studies can be based.

Liquid droplets and mists are controllable by

- Filters — more loosely knit than for dry filters
- Electrostatic precipitators — wetted wall type
- Inertial collectors — cyclones and baffles
- Venturi scrubbers

[a] Includes water and power cost, maintenance cost, operating cost, capital, and insurace costs (in $ 1994).

Finally, gaseous pollutants can be controlled using

- Absorption materials — wet scrubber, packed tower, or bubble tower; see Figure 16.5.3, for example;
- Adsorption materials — porous media such as activated charcoal, silica gel, and alumina;
- Condensers — widely used in the chemical process industries;
- Chemical conversion to contaminants — oxidize hydrocarbons to CO_2 and H_2O, for example.

Table 16.5.4 compares gaseous pollutant removal systems.

Cataloging of industry-specific designs is beyond the scope of this handbook because of space limitations. The reader is referred to Boubel et al. (1994) for details. One must make an inventory of emissions and then identify the most appropriate control methods based on operating and capital costs considerations. For example, Table 16.5.5 shows common emissions and control methods for the petrochemical industry. The energy, power generation, incineration, ferrous and nonferrous metallurgical, agricultural, and mineral/mining industries produce considerable emissions that must be controlled in accordance with federal regulations.

TABLE 16.5.4 Comparison of Gaseous Pollutant Removal Systems

Type of Equipment	Pressure Drop (cm H_2O)	Installed Cost (U.S. \$/m³)	Annual Operating Cost (U.S. \$/m³)
Scrubber	10	9.80	14.00
Absorber	10	10.40	28.00
Condenser	2.5	28.00	7.00
Direct flame afterburner	1.2	8.20	8.40 + gas
Catalytic afterburner	2.5	11.60	28.00 + gas

Water Pollution Control

Nevis Cook and Ronald R. Hewitt Cohen

Control of waterborne pollutants is at present undertaken by nine distinct techniques:

- Biological oxidation
- Chemical oxidation
- Chemical reduction
- Conventional treatment
- Precipitation
- Air stripping
- Activated carbon

TABLE 16.5.5 Air Pollution Emissions and Controls: Petrochemical Processes

Petrochemical Process	Air Pollutant Emissions	Control Methods in Use
Ethylene oxide (most emissions from purge vents)	Ethane, ethylene, ethylene oxide	Catalytic afterburner
Formaldehyde (most emissions from exit gas stream of scrubber)	Formaldehyde, methanol, carbon monoxide, dimethyl ether	Wet scrubber for formaldehyde and methanol only; afterburner for organic vent gases
Phthalic anhydride (most emissions from off-gas from switch condensers)	Organic acids and anhydrides, sulfur dioxide, carbon monoxide, particulate matter	Venturi scrubber followed by cyclone separator and packed countercurrent scrubber
Acrylonitrile (most emissions from exit gas stream from product absorber)	Carbon monoxide, propylene, propane, hydrogen cyanide, acrylonitrile, acetonitrile NO_x from by-product incinerator	Thermal incinerators (gas-fired afterburners or catalytic afterburners)
		None
Carbon black (most emissions from exit gas stream from baghouse, some fugitive particulate)	Hydrogen, carbon monoxide, hydrogen sulfide, sulfur dioxide, methane, acetylene	Waste heat boiler or flare (no control for SO_2)
	Particulate matter (carbon black)	Baghouse
Ethylene dichloride (most emissions from exit gas stream of solvent scrubber)	Carbon monoxide, methane, ethylene, ethane, ethylene dichloride, aromatic solvent	None at present, but could use a waste heat boiler or afterburner, followed by a caustic scrubber for hydrochloric acid generated by combustion

- Ion exchange
- Reverse osmosis

Table 16.5.6 summarizes these approaches and their applications by contaminant type. The letter A in the table indicates the best available technology, whereas a B indicates an alternative that may apply to a subclass of industries. The reader is referred to the notes to the table for further details.

TABLE 16.5.6 General Effectiveness of Treatment Technology vs. Contaminant Type

Constituent	Biological Oxidation	Chemical Oxidation	Chemical Reduction	Conventional Treatment	Precipitation	Air Stripping	Activated Carbon	Ion-Exchange	Reverse Osmosis
BOD	A	—	—	—	—	—	—	—	—
COD	B	B	—	—	—	—	B	—	—

As, Se	—	P	I	B	A	—	—	A	A
CN	—	A	—	—	—	I	—	—	B
Phenols	B	A	—	—	—	—	B	—	—
SOC[e]	B	B	—	—	—	—	A	—	A
VOC[f]	B	B	—	—	—	A	B	—	B

A = treatment technology commonly applied to reduce contaminant to acceptable levels; perhaps best conventional technology. **B** = treatment technology that has been used to remove a particular contaminant, but might not be fully effective under all conditions. **I** = substance could interfere with efficient removal of other contaminants. **P** = pretreatment required if technology is to be used.

[a] MO = microbiological contaminants including pathogenic bacteria, protozoa, and viruses.

[b] Turb. includes fine colloidal matter and suspended solids, for true suspended solids use sedimentation.

[c] Total dissolved solids (TDS) includes removal of the highly soluble ions: Na^+, K^+, Cl^-, SO_4^{2-}.

[d] Includes the valence +2 transition metals: Cu^{++}, Ni^{++}, Pb^{++}, Zn^{++}.

[e] SOC = synthetic organic compounds, including pesticides.

[f] VOC = volatile organic compounds, including solvents.

16.6 Environmental Modeling

Air Pollution Dispersion Modeling

Paolo Zannetti

To understand air pollution, it is mandatory, at any scale, to simulate correctly the dispersion characteristics of the emissions. Therefore, the role of meteorology is essential. Pollutants are typically transported by two types of flows: an "ordered" flow, which is characterized by average wind speed and direction, and a semirandom, turbulent flow, which is characterized by wind fluctuations. All dispersion models aim at simulating these two components. As further discussed below, dispersion modeling techniques can be categorized into four general classes: (1) Gaussian models; (2) Eulerian grid models; (3) Lagrangian box models; and (4) Lagrangian particle models.

Gaussian Models

All Gaussian models assume that the concentration of pollutants maintains a Gaussian distribution in space. The Gaussian distribution, as illustrated in Figure 16.6.1, is a symmetrical bell-shaped distribution which is described at any given point x by two parameters: the location of the peak (in this case, the centerline of the plume indicated by the segmented line) and the standard deviation (in this case, the spread of the plume mass about its center). Therefore, the dilution rate of the plume is fully characterized by the two standard deviations, σ_y and σ_z, expressed as a function of the downwind distance, x.

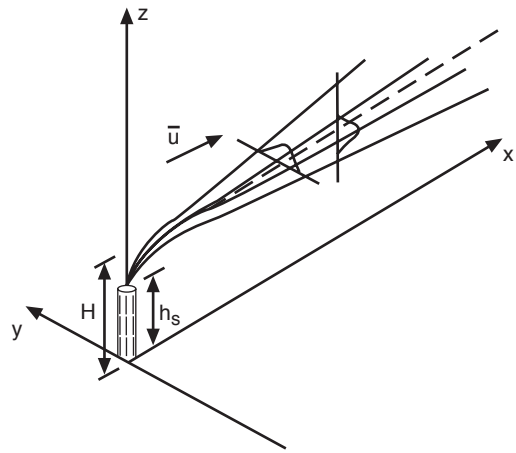

FIGURE 16.6.1 The Gaussian plume in a wind-oriented coordinate system (i.e., the wind is blowing toward the x axis). The plume is released from a source located at (0, 0, h_s) and possesses an initial buoyancy. Therefore, the plume behaves as if it were originated from (0, 0, H), where H is the effective emission height and $\delta h = H - h_s$ is the plume rise. The plume is advected by the average wind speed $\bar{\mathbf{u}}$ and expands in the horizontal and the vertical direction while maintaining a Gaussian distribution along both.

In mathematical notation, the Gaussian plume formula in Figure 16.6.1 can be written as

$$c = \frac{Q}{2\pi\sigma_y\sigma_z\bar{u}} \exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right] \exp\left[-\frac{1}{2}\left(\frac{H-z}{\sigma_z}\right)^2\right] \tag{16.6.1}$$

where c is the concentration computed at the receptor (x, y, z), Q is the emission rate, $\bar{\mathbf{u}}$ is the average horizontal wind speed, H is the effective emission height, and σ_y and σ_z are functions of the downwind

distance, x, with parameters that vary with the meteorological conditions (in fact, the stronger the turbulence intensity of the atmosphere, the larger the growth rate of σ_y and σ_z with x).

As can easily be seen, Equation (16.6.1) refers to a stationary state (i.e., c is not a function of time), uses meteorological parameters that must be considered homogeneous and stationary in the modeled area (i.e., between the source and the receptors at which concentrations are computed), and cannot work in calm conditions where the wind speed approaches zero (in general, the wind speed cannot be less than 1 m/sec when Equation (16.6.1) is applied). In spite of these limitations, the simplicity of the Gaussian approach, its relative ease of use, and, especially, the elevation of this methodology to the quantitative decision-controlling level in the United States (USEPA, 1978) have stimulated research aimed at removing some of the limitations of the Gaussian theory in modeling the real-world situations.

Equation (16.6.1) has been modified and expanded to incorporate, among others, the following factors: ground reflection, multiple reflections, hourly simulations, deposition and decay, chemical transformation, fumigation, complex terrain, gravitational settling, calm conditions, nonstationary and nonhomogenous conditions, and long-term simulations. We summarize below some of these improvements.

Reflection terms can be added to Equation (16.6.1) to account for partial or total reflection of concentration at the ground. Similarly, reflection can be added at the top of **the planetary boundary layer, PBL** (typically, about 500 to 1000 m above the ground). If both reflections are implemented, the plume is trapped inside the PBL. Equation (16.6.1) is generally applied for periods of 1 hr. This allows the incorporation of time-varying emission and meteorological parameters. Chemistry and decay can be incorporated by introducing exponential decay terms (for example, it can be assumed that an emission of primary gaseous SO_2 is transformed into particulate matter SO_4^{2-} at a rate of 1% per hour). Gravitational settling will affect a plume of primary particulate matter. In this case, the plume centerline can be tilted to account for the settling velocity of the particles, which is a function of both particle size and density.

In addition to the Gaussian plume model, Gaussian segment and puff models can be used (Zannetti, 1986a). These models break up the plume into independent elements (plume segments or puffs) whose initial features and time dynamics are a function of time-varying emission and meteorological conditions encountered by the plume elements. These techniques allow us to account properly for nonhomogeneous, nonstationary conditions. Gaussian puff models, in particular, have the additional advantage of being able to simulate calm or low-wind conditions.

Complex terrain conditions affect the plume dynamics, both the motion of the centerline trajectory and the growth of σ_y and σ_z. Finally, the Gaussian plume model equation can be rewritten in a way to simulate long-term concentration averages (e.g., annual averages) by incorporating the joint frequency of occurrence of a predetermined set of emission and meteorological conditions.

Other Models

Eulerian grid models (Lamb [from Longhetto], 1980) simulate pollutant diffusion by superimposing a grid over the computational domain and numerically solving a mass-balance equation (typically, a partial differential equation, PDE, or a set of PDEs) in each grid cell at each time step. This is also called numerical integration. In general, the smaller the grid and time intervals, the more accurate the numerical solution.

Difficulties may be encountered in simulating atmospheric diffusion with the K-theory. In particular, the application of the K-theory to simulate vertical dispersion during daytime, unstable meteorological conditions is highly questionable. To improve the simulation ability of Eulerian grid models, equations of high-order moments of concentration, wind, and temperature fluctuations can be solved simultaneously. This approach is called high-order closure and requires the definition of more-complex, nonlinear relationships between the turbulent fluxes and the concentration fields.

Lagrangian box models are mostly used to perform fast simulations of photochemical smog. These models define a set of "boxes" (e.g., a column of boxes as illustrated in Figure 16.6.2) which are advected horizontally according to the local wind speed and direction. Each box encounters emissions along its trajectory. These emissions inject new pollutants inside the box. A full set of chemical reactions inside

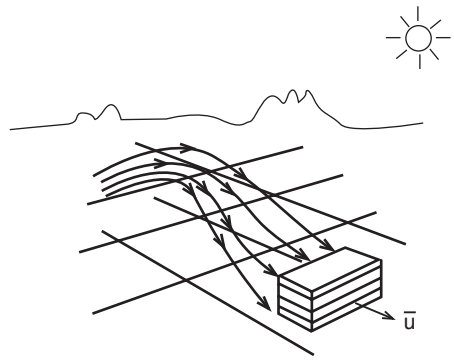

FIGURE 16.6.2 Lagrangian box modeling.

each box allows the simulation of the photochemical smog and the formation of secondary pollutants, such as ozone.

Lagrangian particle models provide a very interesting alternative method for simulating atmospheric diffusion. Particle motion can be produced by both deterministic velocities and semirandom pseudovelocities generated using Monte Carlo techniques. In the latter case, the trajectory of a single particle represents a realization from an infinite set of possible solutions, and, if enough particles are used, important characteristics can be inferred from the computation of particle **ensemble average** properties.

When using Lagrangian particle models to simulate air pollution, pollutant emissions (both gases and particulate matter) are represented by the injection of fictitious particles into the computational domain. Each particle represents a specified amount of pollution and is moved at each time step by a pseudovelocity that is time and space dependent. Zannetti (1990) discusses alternative modeling approaches in more detail than is possible here.

Atmospheric Chemistry

Atmospheric chemistry deals essentially with four major issues (Seigneur, 1987): (1) photochemical smog in sunny, urban areas; (2) **aerosol** chemistry; (3) acidic deposition; and (4) air toxics. Chemical reactions can be simulated in two ways: (1) with simple first-order terms (e.g., a decay term) and (2) with a full chemical reaction scheme.

First-order terms for simulating atmospheric chemistry can be easily incorporated into any of the models previously discussed. For example, a radioactive pollutant with a specified decay rate (or half-life) can be simulated by introducing the following multiplicative term in any concentration equation

$$\exp\left(-t/T\right) \tag{16.6.2}$$

where t is the travel time and T is the time scale of the decay (easily related to the half-life of the chemical species). Similarly, chemical transformation from a primary to a secondary pollutant (e.g., from gaseous SO_2 to sulfate particulate matter, SO_4^{2-}) can be accomplished by introducing two exponential terms— $[\exp(-t/T)]$ and $[1 - \exp(-t/T)]$ — having the effect of simultaneously decreasing the SO_2 concentration and increasing the SO_4^{2-} concentration as time increases. First-order schemes, though relatively simple, may use parameters that are space and time dependent; for example, the SO_2-to- SO_4^{2-} conversion rate may vary as a function of relative humidity and solar radiation.

Photochemical smog, which in the past only affected large cities at low latitudes, such as Los Angeles, has become today the most important and common air pollution problem in urban areas throughout the world. Overall, the photochemical smog reactions can be summarized as

$$\text{ROG} + \text{NO}_x + \text{sunlight} \rightarrow \text{O}_3, \text{PAN}, \text{HCHO}, \text{HNO}_3, \text{PM}, \ldots \tag{16.6.3}$$

where ROG are primary reactive organic gases and NO_x include primary NO and mostly secondary NO_2. This smog includes carbon monoxide (CO), ozone (O_3) formaldehyde (HCHO), peroxyacetyl nitrate (PAN), nitric acid (HNO_3), particulate matter (PM; especially secondary particles, such as nitrates and organic particles), and other products.

A full chemical reaction scheme is required to simulate complex phenomena, such as the photochemical smog described above, and can be incorporated today only inside Eulerian grids or Lagrangian box models. A typical reaction set, applied in each grid cell at each time step, can be written in terms of linear combinations:

$$\sum_{m=1}^{M} r_{nm} C_m \rightarrow \sum_{m=1}^{M} p_{nm} C_m \qquad n = 1, 2, \ldots, N \tag{16.6.4}$$

where M species participate in N reaction steps, c_m is the concentration of the mth species, and r_{nm} and p_{nm} are numerical constants. Each reaction rate is generally expressed as a product of the concentrations of the species involved, with a temperature-dependent rate constant.

The main difficulty in using Equation (16.6.4) to simulate the photochemical smog is the treatment of **organic compounds**. In fact, due to the very large number, organic species cannot all be included explicitly. Three different types of gas-phase chemical mechanisms are generally used: (1) surrogate mechanisms, which use the chemistry of one or two compounds in each class of organics to represent the chemistry of all species in that class; (2) lumped mechanisms, in which the grouping of chemical compounds is done on the bases of their similar structure and reactivity; and (3) the carbon bond approach, which splits each organic molecule into functional groups using the assumption that the reactivity of the molecule is dominated by the chemistry of each functional group. Each classification technique necessarily introduces a simplification and, therefore, a potential simulation error.

Some key reactions involve the **photolysis** of such species as NO_2, HCHO, and nitrous acid (HONO). These one-specie reactions require the calculation of the photolysis rate constant which is a function of, among other things, of solar elevation and temperature.

Aerosol chemistry is particularly difficult to simulate and computationally expensive. However, inclusion of aerosol dynamics within air quality models is of primary importance because of the health effects associated with fine particles in the atmosphere, visibility impairment, and the acid deposition problem. Simple first-order reaction terms can be used to simulate the transformation of SO_2 into sulfates and NO_x into nitrates. These terms can be included in any model. However, a comprehensive simulation of aerosol processes can only be performed within an Eulerian grid or a Lagrangian box model and must include the following fundamental equation of aerosol dynamics (Milford and Russell, 1993) which describes aerosol transport, growth, coagulation, and sedimentation

$$\frac{\delta n}{\delta t} + \nabla \cdot \bar{\mathbf{u}} n + \frac{\delta I}{\delta \nu} = \frac{1}{2}\int_0^{\nu} \beta(\bar{\nu}, \nu - \bar{\nu}) n(\bar{\nu}) n(\nu - \bar{\nu})\, d\bar{\nu} - \int_0^{\infty} \beta(\bar{\nu}, \nu) n(\bar{\nu}) n(\nu)\, d\bar{\nu} - \nabla \cdot \mathbf{C} n \tag{16.6.5}$$

where n is the particle size distribution function, $\bar{\mathbf{u}}$ is the wind velocity, I is the droplet current that describes particle growth and nucleation due to gas-to-particle conversion, ν is the particle volume, β is the rate of particle coagulation, and $\mathbf{C}$ is the sedimentation velocity.

The simulation of heterogeneous and aqueous-phase chemistry is of key importance for regional-scale acid deposition and **stratospheric** ozone models, but is usually neglected in urban photochemical applications where the main goal is the simulation of **tropospheric** ozone.

Deposition

Chemical species are removed from the atmosphere by two mechanisms: reaction and deposition. While chemical reactions may produce new pollutants, deposition is the real process in which the atmosphere cleans itself. Some pollutants are highly reactive and, consequently, have short lifetimes. For example,

ozone has a typical lifetime of 2 min and, therefore, its concentration will drop unless it is continuously regenerated. Other pollutants have longer lifetimes. For example, SO_2 has a typical lifetime of 13 days. Therefore, under certain circumstances, it can easily accumulate during multiday episodes (e.g., the "London" smog). Finally, there are pollutants with very large lifetimes. Because of their low reactivity, they do not cause adverse effects on human health but, nevertheless, can diffuse on a global scale and affect the thermal balance of the Earth. Methane and carbon dioxide are a good example, both with a typical lifetime of 7 years.

Deposition terms can be introduced in any model discussed above. For example, dry deposition can be described by the following formula

$$F_i = V_d c_i \tag{16.6.6}$$

where F_i is the flux of a species i to the ground, c_i is the concentration of the species i at some reference height (e.g., 1 m), and V_d is the deposition velocity. The term V_d has been measured under various meteorological conditions and for a number of surface types (Wesley et al., 1985). Therefore, the calculation of F_i is straightforward.

Wet deposition (i.e., precipitation scavenging) depends upon the intensity and size of raindrops. Fog and cloud droplets can also absorb gases, capture particles, and accelerate chemical reactions. Wet deposition is quantified by computing the wet flux of pollution to the surface. This calculation requires the estimate of the washout coefficient, which can be inferred (Scott, 1982) as a function of storm type and precipitation amounts.

Because of dry and wet deposition, acidic components such as sulfuric acid particles, particulate nitrate, and nitric acid gas are transferred from the atmosphere to the Earth. Areas which are tens and hundreds of kilometers downwind of large SO_2 and NO_x sources (e.g., power plants and smelters) suffer the greatest impact.

Statistical Models

Statistical models are often used in air pollution studies. They include frequency distribution studies, time series analysis, Kalman filters, receptor-modeling techniques, and others. A general distinction between statistical and deterministic approaches is that air pollution deterministic models initiate their calculations at the pollution sources and aim at the establishment of cause/effect relationships, while statistical models are characterized by their direct use of air quality measurements to infer semiempirical relationships. Although very useful, especially for real-time short-term forecasting, statistical models are generally unable to provide cause/effect relationships, with the exception of receptor modeling.

The basic concept of the receptor-modeling approach is the apportionment of the contribution of each source, or group of sources, to the measured concentrations without reconstructing the dispersion pattern and trajectory of the pollutants. Typically, receptor models start with *observed* ambient aerosol concentrations measured at a receptor and seek to apportion the concentrations among several source types (e.g., industrial, transportation, soil, etc.), based on the known chemical composition (i.e., the chemical fractions) of source and receptor materials.

In mathematical notation, the concentration c_{ik} of the species i in the kth sample at a certain monitoring station can be written as

$$c_{ik} = \sum_{j=1}^{p} a_{ij} D_{jk} E_{jk} \tag{16.6.7}$$

where p sources (or groups of sources) are assumed to contribute to c_{ik}, a_{ij} is the fractional amount of the component i in the emission from the jth source, D_{jk} is the atmospheric dispersion term, and E_{jk} is the emission rate (i.e., $D_{jk}E_{jk} = S_{jk}$ is the total contribution of the source j to the kth sample at the receptor location). Dispersion models assume a_{ij}, D_{jk}, and E_{jk} to be known (or obtainable from emission and

meteorological data) and estimate the output c_{ik}. For receptor models, the concentrations c_{ik} and source "profiles" a_{ij} are measured instead, and the $D_{jk}E_{jk}$ products are computed as a model result.

Ground Water Pollution Modeling

Tissa Illangasekare

Saturated Groundwater Flow

The description of the exact movement of fluid particles in a porous medium is difficult (or impossible) as it is not practical to define exactly the flow domain that is described by the geometry of the internal solid surfaces. The problem can be treated at the molecular level, microscopic level, or macroscopic level.

The treatment of the behavior of a system of molecules using theories of classical fluid mechanics is extremely difficult because of the large number of molecules involved and the difficulties in identifying all forces and defining the exact pore geometry. Instead of treating individual molecules, the statistical properties of a very large number of molecules may be inferred from laws governing the motion of individual molecules. Still, this approach will also have similar limitations with respect to the need to define the exact pore geometries. A coarser treatment at the microscopic level where fluid is treated as a continuum is feasible, but most applications in groundwater flow may not require this level of refinement. This approach will also require the accurate definition of the pore geometry.

A coarse level of averaging at the macroscopic level that is referred to as the *representative elementary volume (REV)* is used in most applications in porous media flow analysis. Porous medium is defined as a portion of a space occupied partly by a solid phase (solid matrix) and partly by voids. The voids in general are occupied by one (single phase) or more fluid phases (multiphase). This level of treatment assumes that the solid phase is distributed throughout the problem domain and it should be possible to define an REV such that no matter where we place it within the porous media domain, it will contain both solids and voids.

At the macroscopic scale, the rate at which the water flow in a soil is quantified using a variable that is referred to as the *Darcy velocity* or *specific discharge*. This variable, which has the dimensions of velocity, is defined as the discharge per unit gross area of soil that includes both the pore space and the grains in a flow section. For incompressible fluids a relationship that is referred to as *Darcy's law* expresses the Darcy velocity in terms of a parameter referred to as hydraulic conductivity, K, and the gradient of the piezometric head, h. Darcy's law for saturated flow (a single fluid filling the pore space) in soils is given by

$$\mathbf{q} = -K\nabla h \tag{16.6.8}$$

where $\mathbf{q}$ is the specific discharge or Darcy velocity (L/T) and h is the piezometric head (L).

In groundwater flow, as the velocities are generally very small, the velocity head is neglected and the driving head becomes the sum of the elevation and the pressure heads. The piezometric head is defined as

$$h = h_z + h_p = z + \frac{p}{\rho g} \tag{16.6.9}$$

where ρ is the density of water.

In anisotropic aquifers where the hydraulic conductivity changes with flow direction, $\mathbf{K}$ is a second-rank tensor given as

$$[K] = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix} \tag{16.6.10}$$

It can be shown that it is always possible to find three mutually orthogonal directions in space such that

$$K_{ij} \neq 0 \quad \text{for all} \quad i = j$$

$$K_{ij} = 0 \quad \text{for all} \quad i \neq j$$

These directions in space are called the principal directions of the anisotropic porous medium. When principal directions are parallel to the axes of the coordinate system, the tensor reduces to a hydraulic conductivity vector given as,

$$[K] = \begin{bmatrix} K_{xx} & 0 & 0 \\ 0 & K_{yy} & 0 \\ 0 & 0 & K_{zz} \end{bmatrix} \tag{16.6.11}$$

For conservation of mass,

$$-\nabla \cdot \rho \mathbf{q} = \frac{\partial n \rho}{\partial t} \tag{16.6.12}$$

For homogeneous, incompressible fluid and a nondeformable porous medium,

$$\nabla \cdot \mathbf{q} = 0 \tag{16.6.13}$$

Introducing head, the mass conservation equation can be written as

$$\nabla \mathbf{q} + S_s \frac{\partial h}{\partial t} = 0 \tag{16.6.14}$$

where S_s is the specific storage, defined as the volume of water added to storage, per unit volume of porous medium, per unit rise in piezometric head. This is given as

$$S_s = \rho g(\alpha + n\beta) \tag{16.6.15}$$

where β is the compressibility of water and α is the compressibility of the soil matrix.

Combining Darcy's law and the equation of mass conservation, the general equation of saturated groundwater flow is obtained as

$$\nabla \cdot K \nabla h = S_s \frac{\partial h}{\partial t} \tag{16.6.16}$$

The initial and boundary value problem obtained by combining the above second-order partial differential equation with the initial head in the aquifer and the head or flux conditions at the aquifer boundary is solved to obtain the unknown head in the aquifer. The head distribution can then be used with Darcy's law to obtain the groundwater flow velocity in the aquifer.

Solute Transport in Groundwater

Transport of dissolved chemicals in aquifers is generally considered to be the result of two processes, namely, advection and dispersion. Advection is the process by which the solute gets transported due to the average motion of water through the intergranular pore spaces of the porous medium. In the mathematical representation of this process in the REV, a macroscopically average velocity that is referred

to as the *average linear pore velocity* is used. An approximate value for this average pore water velocity for granular material based on macroscopic variables is given as

$$v = \frac{q}{n} \tag{16.6.17}$$

where n is the effective porosity. The average liner pore water velocity is also referred to as the *average solution velocity.*

The advective solute transport is given by

$$\mathbf{J}_a = Cq \tag{16.6.18}$$

where $\mathbf{J}_a$ is the vector of solute mass flux (mass per unit time per unit area, $[MT^{-1}L^{-2}]$) and C is the mass concentration of solute per unit volume of the solution (ML^{-3}).

Dispersion is the result of two processes that occur in the pore scale, namely, molecular diffusion and mechanical (or hydrodynamic) mixing. Due to molecular diffusion the solute will move from the high-concentration to low-concentration regions in the fluid phase. Fick's first law modified to account for the presence of the solid phase is used to represent the solute flux as a function of the concentration gradient by

$$J_d = -nD_d \cdot \nabla C \tag{16.6.19}$$

where $\boldsymbol{J_d}$ is diffusive flux, $[MT^{-1}L^{-2}]$, n is the porosity, $\boldsymbol{D_d}$ $[L^2T^{-1}]$, a second-rank tensor is the effective diffusion coefficient of the solute in the porous medium and C is the solute concentration, $[M/L^{-3}]$.

The component of dispersion due to mechanical mixing is the result of velocity variation at the microscopic scale. These velocity variations are the result of three basic mechanisms that occur within the pores: (1) viscous shear forces that produce velocity gradients across flow channels, (2) pores size variations produce pore channels with different sizes transmitting water at different pore velocities, and (3) the changing flow directions due to the tortuosity of the flow channels. The combined effect of these variations results in the solute being mixed at the macroscopic scale and producing mass flux along decreasing concentration gradients. As this process is analogous to the diffusion in the microscopic scale, an equation similar to the Fick's first law is used to describe mass flux due to mechanical mixing. This analogous equation is given as

$$J_m = -nD_m \cdot \nabla C \tag{16.6.20}$$

where J_m is the flux due to mechanical mixing, $[MT^{-1}L^{-2}]$ and D_m is the coefficient of hydrodynamic (mechanical) dispersion.

The total flux due to molecular diffusion and hydrodynamic dispersion is given as

$$J = J_d + J_m \tag{16.6.21}$$

Substituting for J_d and J_m, we have

$$J_m = -n\left(D_d + D_m\right) \cdot \nabla C \tag{16.6.22}$$

Define the dispersion coefficient D as

$$D = D_d + D_m \tag{16.6.23}$$

Equation (16.6.24) reduces to

$$J = -n(D)\cdot\nabla C \tag{16.6.24}$$

In a three-dimensional system the dispersion coefficient is a second-order tensor that takes the form,

$$[D] = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix} \tag{16.6.25}$$

By orienting the x′ axes of the local coordinates at the aquifer point along the direction of groundwater flow (longitudinal direction), the dispersion coefficient tensor can be reduced to

$$[D] = \begin{bmatrix} D_{x'x'} & 0 & 0 \\ 0 & D_{y'y'} & 0 \\ 0 & 0 & D_{z'z'} \end{bmatrix} \tag{16.6.26}$$

The local axes x', y', and z' are the principal axes of dispersion and $D_{x'x'}$, $D_{y'y'}$, and $D_{z'z'}$ are the principal values of the coefficient of dispersion. These coefficients can be expressed in terms of the longitudinal average linear pore velocity as

$$D_{x'x'} = D_d + \alpha_L \bar{v}, \quad \text{etc.} \tag{16.6.27}$$

where α_L and α_T are longitudinal and lateral dispersion coefficients, respectively. The dispersion coefficients that have dimensions of length can be viewed as characteristic lengths of the porous medium at the pore scale. However, in real applications these values are much larger and have been found to depend on the size of the plume (scale dependent).

Combining advective flux given by Equation (16.6.18) and dispersive flux given by Equation (16.6.24) and applying the principal of mass conservation for the solute, one obtains

$$\frac{\partial(nC)}{\partial t} = \nabla\cdot(nD\cdot\nabla C - Cq) \tag{16.6.28}$$

By substituting the approximation for Darcy's velocity in Equation (16.6.28), the governing equation for solute transport in saturated porous media is obtained as

$$\frac{\partial C}{\partial t} = D\cdot\nabla C - C\bar{v} \tag{16.6.29}$$

The above equation is referred to as the *advection–dispersion equation*. The initial and boundary value problem obtained by combining the above second-order PDE with the initial concentration distribution in the aquifer and the concentration and mass flux at the aquifer boundary is solved to obtain the time and space distribution of the solute concentration in contaminant plumes. It should be noted that to solve the advection–dispersion equation it is necessary to first solve for the groundwater velocities using the groundwater flow equation.

Surface Water Pollution Transport Modeling

Ronald R. Hewitt Cohen and Nevis Cook

The study of water quality modeling bloomed in the late 1960s and through the 1970s. Administrators and bureaucrats with minimal mathematical and science backgrounds were greatly impressed by presentations of pages of PDEs, and model outputs were often treated as absolute truth. As the field and model users matured, it was recognized that a model is just a group of hypotheses about the way the modeler believes the world works, all put in mathematical terms. The limitations, shortcomings, and difficulties with environmental models are well recognized and accepted. Models are now used as *tools* for decision making and planning.

An industrial facility may want to assess how reducing or increasing the mass or concentration of some pollutant in a discharge will impact the receiving waters. It may be that a dramatic, negative impact might be predicted. Reducing the level of pollutant in the discharge may result in little to no improvement to water quality. Obviously, the results of the modeling effort will dictate the level of effort and cost going toward the treatment of the pollutant.

The same facility may be instructed by the USEPA or the state to control discharges such that water quality criteria in the receiving waters are met. Good models can be used to address the question "what are the implications to the receiving waters if various facility process modifications are applied." Thus, a decision could be made as to the process modifications to be focused upon to match the criteria or standards.

It is not anticipated that every industrial facility has an individual with the capabilities to construct a water quality transport model. There are many models available to run on microcomputers and can be obtained through the USEPA.

Impact Pathway Methodology

Ari Rabl and Peter S. Curtiss

A step beyond conventional dispersion modeling includes the physical and economic impacts of air pollution. Rational management of the environment requires an assessment of the damage caused by pollution. The logically correct way to analyze environmental impacts is the impact pathway methodology whose principal steps are the following:

- Specification of the relevant technologies and the environmental burdens they impose (e.g., kilograms per second of particulates emitted by the plant);
- Calculation of increased pollutant concentration in all affected regions (e.g., micrograms per cubic meter of particulates, using models of atmospheric dispersion and chemistry);
- Calculation of physical impacts (e.g., number of cases of asthma due to these particulates, using a dose–response function);
- In some cases a fourth step may be called for: the economic valuation of these impacts (e.g., multiplication by the cost of a case of asthma).

The numbers are summed over all receptors (population, crops, buildings, …) that are affected by this pollutant. Formally, the procedure can be represented as an equation for the incremental damage D due to an incremental quantity Q of a pollutant emitted by the plant

$$D = \sum_i f_{dr,i}\left(f_{\text{disp}-i}(Q)\right) \tag{16.6.30}$$

where $f_{\text{disp}-i}(Q) = c$ = increase in pollutant concentration for receptor i and $f_{\text{dr},i}(c)$ = dose–response function for receptor i; the summation index i runs over all receptors (people, crops, buildings, etc.) of concern.

Which receptors are of concern depends on the circumstances. One can distinguish three kinds of situation:

1. Episodic values (typically for litigation after pollution episodes);
2. Peak values (typically for obtaining a permit for a new plant, by showing that impacts are below a damage threshold or regulatory limit);
3. Expectation values (typically for policy applications such as setting of regulations, by showing that average impacts are acceptable).

For the first two of these the summation will typically be over a limited set of receptors, for instance, the residents in a town. For the third application one will usually want to know the total damage, and the sum should cover all receptors that make a significant contribution to the total.

The notation in Equation (16.6.30) allows the possibility that the impact may be different for different individual receptors. This equation expresses the damage in functional form; hence, this methodology is also known under the name *damage function*. Of course, while this methodology is logically correct, the practical implementation may not always be feasible for lack of appropriate data or models.

The dose–response function

$$Y = f_{dr}(X) \tag{16.6.31}$$

relates the quantity X of a pollutant that affects a receptor (e.g., population) to the physical impact Y on this receptor (e.g., incremental number of deaths). In the narrow sense of the term, X should be the dose actually absorbed by a receptor. But often one uses, as we do in the present section, the term dose–response function in the sense of exposure–response function where X represents the concentration of a pollutant in the ambient air; in that case $f_{dr}(X)$ accounts implicitly for the absorption of the pollutant from the air into the body. Dose–response functions for the classic air pollutants (NO_x, SO_x, O_3, and particulates) are typically of that kind. One can even define aggregated dose–response functions that include more-complicated pathways, for instance, dioxins passing through the food chain, if one interprets the dose–response function to include the aggregated effects of the pathways from a point at the Earth's surface to all final receptors. In the next sections we take a closer look at the major steps of the methodology.

The Source Term

The first step of the impact pathway analysis is relatively straightforward. One identifies the site and circumstances of a pollution source, e.g., the tons of NO per $kWhr_e$ emitted by particular power plant. For the major air pollutants (CO_2, CO, NO, SO_2, VOCs, particulate matter) the emission rates for a given technology are quite well known. For the example of power plants the rate of CO_2 emission is especially well determined. Emissions of CO, NO, SO_2, VOCs, and particulate matter are somewhat less certain, and they can vary with operating conditions. NO emissions, for instance, are likely to increase above the manufacturer's specifications if a selective catalytic reduction unit is not well maintained. There are different grades of oil and coal, and their sulfur content can differ by an order of magnitude; obviously, the emissions of SO_2 depend on the quality of the fuel that will be used. Usually, there are strict regulations that enforce an upper limit on the emissions; due to cost constraints power plants are unlikely to operate significantly below these limits.

The situation is less clear with regard to trace pollutants such as lead and mercury, since their content in different grades of coal can vary by much more than an order of magnitude. Furthermore, some of these pollutants are emitted in such small concentrations that their measurement is difficult. The dirtier the fuel, the greater the uncertainty of emissions. Especially with waste incineration, there has been concern over trace pollutants that are emitted into the air.

Probably the most uncertain emissions are emissions from the disposal and storage of wastes, because they depend on events in the future. Solid waste from coal-fired boilers could be dumped into a simple hole in the ground or it could be placed into an engineered landfill with watertight liners; the possible

impacts will be totally different. There may or may not be a breach of containment, depending on the quality of construction and management and on natural events such as floods or earthquakes. The main risk from a landfill is the leaching of toxic minerals into groundwater; such risk can be kept negligible by proper construction and management.

Transport Modes

Pollutants can be emitted to air, water, or soil. The majority of pollutants are first emitted into the air, even if they later pass into the water or the soil. Therefore, most of this section focuses on atmospheric dispersion. Transport in the soil is difficult to model because it can involve complex processes that depend on the physical and chemical properties of the soil at each site. Furthermore, for new installations, such as new landfills, the emissions into the soil are not known in advance; they depend on the integrity of the containment structure over the indefinite future.

Transport by surface water, i.e., rivers, lakes, and the sea, is relatively simple to analyze if fine geographical resolution is not required. Thus, one can divide these bodies of water into a reasonably small number of compartments that are treated as uniformly mixed. For example, a river may be divided into ten sections. A differential equation with empirical coefficients relates the concentration in a section under consideration to the concentration in the section immediately upstream and to the emission into this section. Sedimentation, removal, and decay processes are included.

Similarly, for the dispersion into marine waters one uses a compartment model where each compartment communicates with one or several neighbors, and the volumes and flow rates are known. For instance, in a model used for the analysis of nuclear power plants (EC, 1995c), the European seas have been divided into 34 compartments.

For dispersion in the atmosphere, in general both physical and chemical processes need to be considered (Seinfeld, 1986; Zannetti, 1990). Some pollutants, e.g., CO_2, CH_4, and ^{133}Xe, are sufficiently inert chemically that only the physical transport needs to be analyzed. Some are moderately reactive and their chemical transformation needs to be taken into account. SO_2, for instance, leads to the formation of SO_3, H_2SO_4 as well as sulfates (the latter from the interaction with NH_3 emitted by, among others, agricultural activities); this can have significant implications for impact analysis on a regional and global scale.* Ozone is a secondary pollutant, formed by the combination of NO_x, VOC, and light, and the chemistry is extremely complex.

Even though the modeling of the physical transport of pollutants is difficult, it is far simpler than weather modeling. The reason is that pollutants can be considered a small admixture, passively transported by the currents of the surrounding medium. Such transport is linear: the increase in concentration at a receptor site is proportional to the emission (the only exception arises from secondary pollutants such as ozone whose formation depends on other variables, coupled through nonlinear phenomena).

Furthermore, for most policy applications one needs only expectation values of environmental impacts. While it is well known that chaotic phenomena in the atmosphere render the prediction of the weather impossible beyond a short time, this does not prevent the prediction of expectation values. The climate is much more certain than the weather. For expectation values of air pollution damage it suffices to know the average motion of the surrounding medium from past observations, by contrast to weather modeling where that very motion needs to be predicted in detail.

Transport in Air

A simple model for atmospheric dispersion is the Gaussian plume, discussed earlier. According to this model the concentration of a pollutant is described by the product of two Gaussian distributions, one for the spread in the vertical direction and one for the spread in the horizontal direction perpendicular to the prevailing wind direction. The plume width parameters are based on empirical correlations and take into account the relevant meteorological conditions.

* For example, ammonia sulfate aerosols can reduce the impact of global warming (Charlson and Wigley, 1994).

The Gaussian plume is considered adequate for the short range, up to tens of kilometers from the source, even for episodic events (Zannetti, 1990). The use of this model at distances beyond 100 km is generally not recommended, although it is acceptable for the prediction of the average values if correction terms are included for reflection at the surface and at the PBL of the Earth, and if the depletion mechanisms (deposition, chemical transformation, radioactive decay) are correctly accounted for. As an example of dispersion software based on a Gaussian plume, one can cite the ISC model of the USEPA (Wackter and Foster, 1987).

For regional modeling most analysts prefer to rely on more-detailed computer simulations, for example the Harwell Trajectory Model (1993) or the EMEP model of the Norwegian Meteorological Service (Barrett, 1992; Sandnes, 1993; Iversen, 1993). The latter model is used for the official allocation of acid rain budgets among the countries of Europe.

A crucial question concerns the geographic range over which the analysis needs to be extended in order to capture most of the impacts. This involves a balance among the rates of emission, of dispersion, and of removal of a pollutant. A look at the results of long-range transport models for SO_2 and NO, for instance, those calculated by EMEP (Sandnes, 1993), shows that these pollutants are transported over hundreds, even thousands of kilometers. This is illustrated in Figure 16.6.3 using the EMEP data for a source at Nantes, assuming uniform receptor density and a linear dose–response function. The range of the analysis must be extended to over 1000 km if one wants to capture 80 to 90% of the total impact. The same holds for any air pollutants with comparable removal rate, as has been confirmed explicitly for radionuclides by Kelly and Jones (1985).

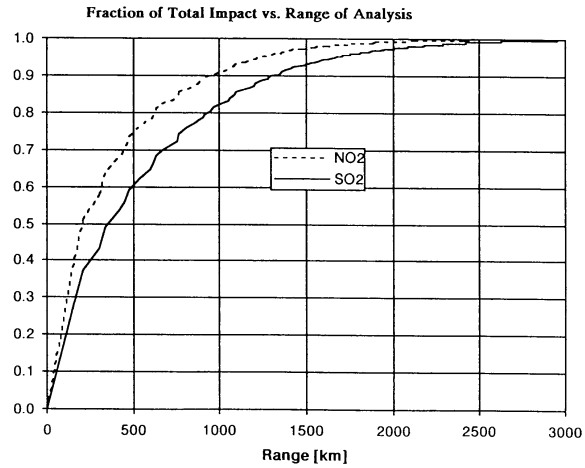

FIGURE 16.6.3 Fraction of total impact vs. range of analysis, for uniform receptor density and linear dose–response function, based on EMEP data (Barrett, 1994). Wiggles are due to discretization.

Secondary Pollutants

Many pollutants are transformed into secondary pollutants by chemical reactions in the atmosphere. For example, the reactions shown in Figure 16.6.4 create acid rain (wet deposition of H_2SO_4) and ammonium sulfate particulates from SO_2.

Another important secondary pollutant is ozone. It is formed when several chemical reactions take place in sequence. The only reaction that forms ozone directly is

$$O + O_2 + M \rightarrow O_3 + M$$

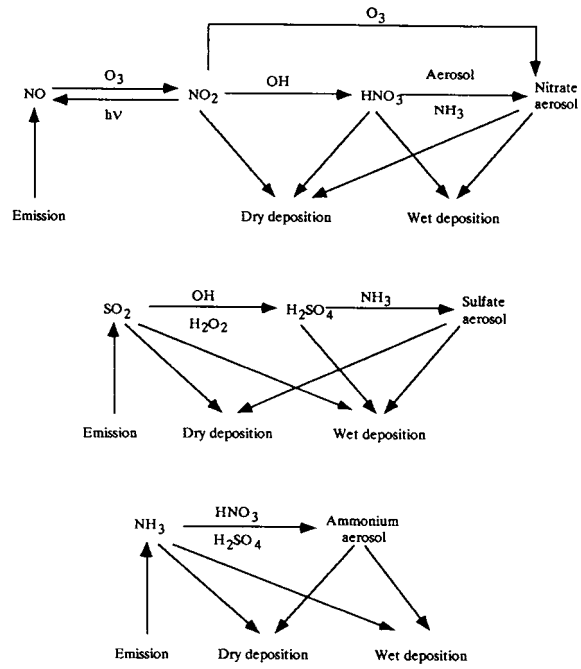

FIGURE 16.6.4 Chemical reactions included in Harwell Trajectory Model. (From EC, 1995c.)

where M is a molecule such as N_2 or O_2 whose participation is necessary to conserve energy and momentum. The oxygen atom involved in the formation of ozone is derived from photolysis of NO_2 under the action of sunlight (indicated by $h\nu$)

$$NO_2 + h\nu \rightarrow O + NO$$

The presence of VOCs is necessary to prevent the ozone formed from being immediately consumed by NO to produce NO_2 in the following reaction:

$$NO + O_3 \rightarrow O_2 + NO_2$$

VOCs enable the transformation of NO into NO_2 without consuming ozone. Finally, note also that NO_2 plays a double role, since, while being necessary to form ozone, it consumes the radicals needed by VOCs to transform NO into NO_2. In fact, an equilibrium is created between these reactions. The concentration of ozone therefore is very dependent on changes in the concentrations of other products, and, due to the complexity of the phenomena, it is observed for example that if VOCs are low (as in the case of an electricity power plant plume), the increase in NO may reduce O_3. Figure 16.6.5 shows the influence of the concentrations of nitrogen oxides and VOCs on the concentration of ozone. In particular, we observe the phenomenon mentioned above: the consequence of an increase in NO on atmospheric ozone depends on the concentration of the organic compounds. The ozone content is also strongly dependent on the $[NO_2]$:[NO] ratio. If this ratio is low, the $[O_3]$ content will remain low.

Dose–Response Functions

Form of the Dose–Response Function. By definition, a dose–response function starts at the origin, and in most cases it increases monotonically with dose *X,* as sketched schematically in Figure 16.6.6. At very high doses the function may level off in S-shaped fashion, implying saturation. Dose-response functions are determined from epidemiological studies or from laboratory studies. Since the latter are

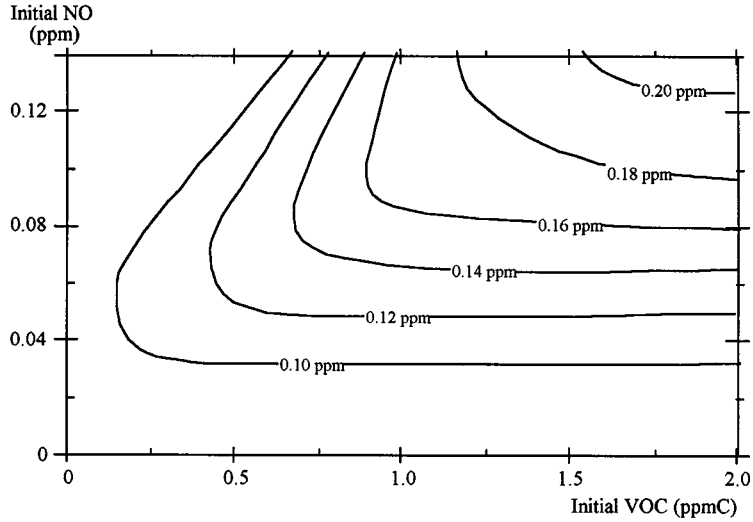

FIGURE 16.6.5 Isopleth plot for the maximum ozone concentration reached during a fixed length of time as a function of initial NO and VOC concentrations. Details of such a plot depend on site and on weather. (From EPRI 1992.)

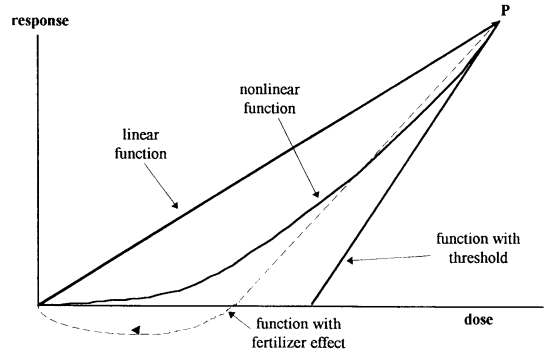

FIGURE 16.6.6 Possible behavior of dose–response functions at low doses: the four functions shown have the same value at P. For the function with threshold the discontinuity in slope at the threshold is a simplification; in reality there is a smooth transition.

mostly limited to animals, the extrapolation to humans introduces large uncertainties. Another major difficulty is that one needs relatively high doses in order to obtain observable nonzero responses in a sample of realistic size; such doses are usually far in excess of the levels one is concerned with in environmental impact studies. Thus, there is a serious problem of how to extrapolate from the observed data toward low doses. Figure 16.6.6 indicates several possibilities. The simplest is the linear model, i.e., a straight line from the origin through the observed data point(s). Cancer from radioactivity is an example. Linearity also seems to be observed for mortality from fine particulates (Dockery et al., 1993; Dockery and Pope, 1994; Lipfert, 1994).

Another possibility is a straight line down to some threshold, and zero effect below that threshold. Thresholds occur when an organism has a natural repair mechanism that can prevent or counteract damage up to a certain limit. Many dose–response functions for noncancer toxicity are of this type.

There is even the possibility of a "fertilizer effect" at low doses, as indicated by the dashed line in Figure 16.6.6. This can be observed, for example, in the dose–response functions for the impact of NO_x and SO_x on crops: a low dose of these pollutants can increase the crop yield; in other words, the damage

is negative. Such a fertilizer effect can occur with pollutants that provide trace elements needed by an organism. It depends on local conditions, in particular the overall balance of nutrients. The fertilizer effect illustrates the link between the understanding of the underlying processes and the choice of the appropriate form for the dose–response function: since N and S are known to be important nutrients for plants, a functional form like the dashed line in Figure 16.6.6 is the most plausible.

If nothing is known about a threshold and a fertilizer effect can be ruled out, the dose–response function could be anywhere between zero and the straight line through the origin, for instance, the curved solid line shown in Figure 16.6.6. *A priori* there is no general rule about the extrapolation to low doses, other than there being no known cases of a dose–response function above the straight line. There is even a case where the same substance causes different cancers according to different dose–response functions, one with and one without threshold. This was established in an experiment (sometimes referred to as the megamouse experiment) in which some 24,000 mice were exposed to the carcinogen 2-acetyl-amino-fluorene at several different dose levels (Frith et al., 1981). The response for liver tumor is linear, whereas the one for bladder tumor has a threshold.

Site Dependence of Marginal Impacts

From here on we limit ourselves to the important case where the dose–response function $f_{dr}(\mathbf{x},c(\mathbf{x}))$ can be approximated by

$$f_{dr}\left(\mathbf{x},c(\mathbf{x})\right) \approx d(\mathbf{x})c(\mathbf{x}) \quad \text{where} \quad d(\mathbf{x}) = \frac{df_{dr}\left(\mathbf{x},c(\mathbf{x})\right)}{dc} \tag{16.6.32}$$

is the slope of the dose–response function. With that assumption one can write the damage in the form

$$D = \int dx \int dy\, r(\mathbf{x}) d(\mathbf{x}) c(\mathbf{x}) \tag{16.6.33}$$

This is obviously exact for any pollutant whose dose–response function is linear, or a straight line with a threshold that is everywhere below the background. It is also valid, regardless of dose–response function, for the evaluation of any marginal impacts, i.e., impacts from small pollutant increments because in that case one can linearize the dose–response function. Since $c(\mathbf{x})$ is linear in the emission, it follows that Equation (16.6.33), and the remainder of this section, are equally applicable to steady-state situations and to emissions that vary with time.

It is instructive to relate the concentration $c(\mathbf{x})$ to the removal rate of the pollutant. There are essentially three mechanisms by which an air pollutant can disappear from the atmosphere (Seinfeld 1986):

1. dry deposition (uptake at the Earth's surface by soil, water, or vegetation);
2. wet deposition (absorption into droplets followed by droplet removal by precipitation);
3. decay or transformation (e.g., decay of radionuclides or chemical transformation of SO_2 to $(NH_4)_2SO_4$).

When evaluating the damage of the original pollutant, this pollutant is no longer counted in the equation once it has been transformed; rather from that point on a different dose–response function comes into play for the secondary pollutant. That issue will be addressed below.

The dry deposition rate is proportional to the concentration $c(\mathbf{x})$ at the Earth's surface, and it is customarily written in the form

$$F_{\text{dry}}(\mathbf{x}) = v_{\text{dry}} c(\mathbf{x}) \tag{16.6.34}$$

where $F_{dry}(\mathbf{x})$ = deposition flux (in kg/m^2·sec) and v_{dry} = dry deposition velocity (m/sec).

Wet deposition and decay or transformation can likewise be characterized in terms of fluxes $F_{wet}(\mathbf{x})$ and $F_{trans}(\mathbf{x})$, defined as the rate at which the pollutant is removed by these mechanisms per square meter and per second. Even though in general these fluxes are not proportional to the surface concentration but rather to the average concentration in the air column above x, we can write the total removal flux,

$$F(\mathbf{x}) = F_{dry}(\mathbf{x}) + F_{wet}(\mathbf{x}) + F_{trans}(\mathbf{x}) \tag{16.6.35}$$

in terms of the surface concentration $c(\mathbf{x})$ as

$$F(\mathbf{x}) = k(\mathbf{x})c(\mathbf{x}) \tag{16.6.36}$$

if we allow the proportionality constant $k(\mathbf{x})$ to vary with $\mathbf{x}$. The units of k are m/sec, and it could be called removal velocity. Using $F(\mathbf{x})$ and $k(\mathbf{x})$, we can write the damage in the form:

$$D = \int dx \int dy\, r(\mathbf{x}) d(\mathbf{x}) F(\mathbf{x})/k(\mathbf{x}) \tag{16.6.37}$$

This equation is exact if we interpret Equation (16.6.36) as the definition of $k(\mathbf{x})$.

If the world were homogeneous, with uniform receptor density $r(\mathbf{x}) = r_{uni}$, uniform dose–response function slope $d(\mathbf{x}) = d_{uni}$, and uniform removal velocity $k(\mathbf{x}) = k_{uni}$, the integral in Equation (16.6.37) would be simply

$$D = D_{uni} = d_{uni} r_{uni} Q/k_{uni} \tag{16.6.38}$$

because the surface integral of the removal flux equals the emission

$$Q = \int dx \int dy\, F(\mathbf{x}) \tag{16.6.39}$$

by conservation of matter.

Even though the assumption $k(\mathbf{x}) = k_{uni}$ may not appear very realistic, especially near a point source, the sensitivity to deviations from uniformity turns out to be surprisingly small, as we will demonstrate below in Figure 16.6.7. The reason is that for typical values of atmospheric dispersion parameters the total impact is dominated by regions sufficiently far from the source that the pollutant can be considered to be vertically well mixed in the PBL, at least as far as expectation values are concerned.

Thus, the simple Equation (16.6.38) can be a useful first estimate, good to an order of magnitude or better, independent of the details of atmospheric dispersion (Curtiss and Rabl, 1996b). It is intuitively plausible that the damage is proportional to the slope d of the dose–response function, to the density r of receptors, and to the emission rate Q. Furthermore, it is inversely proportional to the removal velocity k. If there were no removal mechanism, the pollutant concentration would increase without limit and the damage would be infinite. This approach can also be adapted for the damage due to a secondary pollutant.

To verify the relevance of Equation (16.6.38) we compare it with real site-dependent results, calculated with the PATHWAYS software package (Curtiss and Rabl, 1995; Curtiss and Rabl, 1996c), which carries out an accurate numerical integration of atmospheric dispersion results over geographic data for population and other receptors. To add substance to the results, we consider a specific impact: the increase in mortality due to SO_2 emitted by coal-fired power plants. The dose–response function (based on Sunyer et al., 1996) is linear and can be written in the form:

$$\Delta\text{deaths per year per person} = 5.34 \times \Delta PM_{10}\ \text{concentration}\left(\text{in } g/m^3\right) \qquad (16.6.40)$$

Example

We consider an annual SO_2 output of Q = 1000 ton/year = 30 g/sec. For the atmospheric dispersion we take a curve fit to the EMEP data for a grid cell in the center of France, which yields a removal velocity $k = 0.01$ m/sec. Inserting $Q = 30.9$ g/sec, $k_{uni} = 0.01$ m/sec, $d_{uni} = 5.34$ (deaths/year)/(g/m^3) and $r_{uni} = 1.05 \times 10^{-4}$ m^{-2} (for France) into Equation (16.6.38), we obtain

$$D_{uni} = \frac{5.34\ \text{deaths}/\left(\text{person}\cdot\text{yr}\right)/\left(g/m^3\right) \times 1.05\text{E-}4\ \text{persons}/m^2 \times 30.9\ g/\text{sec}}{0.01\ m/\text{sec}} = 1.78\ \text{deaths/yr}$$

This number is shown as the thick solid line in Figure 16.6.7, where the number of deaths per year is plotted vs. emission height h_e. The points, connected by lines, show the impacts for five specific sites. We have chosen these sites because there are in fact fossil fuel power plants at these sites (the nearest big city, 25 to 50 km away, is indicated in parentheses). Although the real emissions at the different sites are different, here we have assumed the emissions of the Cordemais plant at all sites to bring out the point of the comparison. The impact is about 2 to 6 times larger than D_{uni} for the site near Paris and about 0.4 to 0.5 times D_{uni} for Cordemais, a rural site on the Atlantic Ocean. We also see that there is little variation with stack height.

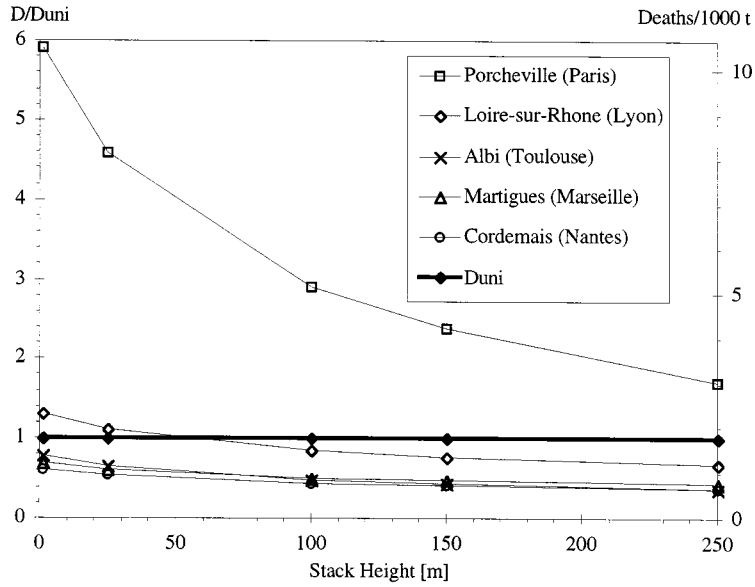

FIGURE 16.6.7 An example of dependence on site and on height of source: mortality from particulate matter from a coal-fired power plant, for five sites in France and for uniform world model (Equation (16.6.38)). Annual SO_2 emission 1000 ton/year.

Analysis of Uncertainties

By contrast to the relatively small uncertainties and normal (Gaussian) frequency distributions typically encountered in science and engineering, the uncertainties in impact analysis are so large that it would be inappropriate to use error intervals that are additively symmetric about the mean. Instead, one should specify multiplicative intervals, in other words, intervals that are additive on a logarithmic scale. The frequency distributions are not symmetric, with implications that may appear counterintuitive to people

not accustomed to them. It is helpful to think in terms of lognormal distributions because they are frequently encountered in impact analysis, analogous to the normal distributions so familiar in the more exact sciences. A variable x has a lognormal distribution if the variable $\ln(x)$ has a normal distribution; in other words, it is normal on a logarithmic scale.

Analogous to the ordinary normal (also known as Gaussian) distribution, which is characterized by two parameters, the mean and the standard deviation, the lognormal distribution can be characterized by the geometric mean and the geometric standard deviation s_G. For this distribution the geometric mean is equal to the median: half of the distribution is above, the other half below the median. The geometric standard has a simple interpretation in terms of the 68% confidence interval (a familiar number because for Gaussian distributions 68% of all values are within one standard deviation of the mean): for a lognormal distribution 68% of the values are within the interval $(1/s_G,s_G)$. Likewise, 95% are within the interval $[(1/s_G)^2,(s_G)^2]$. Note, however, that these values are centered around the median rather than the mean; the lognormal distribution is not symmetric. For impacts of primary air pollutants with relatively well-determined dose–response functions, e.g., mortality due to particulates, s_G may be as small as 3. For other impacts, e.g., cancers due to dioxins, the uncertainties could be an order of a magnitude or more.

It is appropriate to note that technical or scientific uncertainties (e.g., uncertainties of emitted quantities or of dose–response functions) are not the only ones. For long-term impacts, such as cancers caused by radioactive waste, one needs to make assumptions about scenarios for the future: what quantities of radionuclides will leak into the environment and how many people will be affected by them. For the estimation of damage costs, there is also the matter of policy/ethical choice, e.g., about discount rate and value of human life.

16.7 Global Climate Change

Frank Kreith

There is consensus in the scientific community that continuing the emission of CO_2 and other "greenhouse" gases (methane, nitrous oxide, ozone, and chlorofluorocarbons or CFCs) into the atmosphere at current rates will lead to a warming of the Earth. General circulation models of the atmosphere indicate that a doubling of CO_2 concentration in the atmosphere will trap sufficient solar radiation to increase the average global temperature by the middle of the 21st century at least 2°C, but possibly as much as 5°C according to the Congressional Research Service (Morrison, 1989). Although critics of these projections argue that the available models do not accurately portray the potential feedback mechanisms from clouds and oceans to warming, and question the amount, timing, and location of the temperature increase, there is agreement that greenhouse gases trap radiation and increase the global temperature. The latest international scientific assessment concluded that "evidence suggests that there is a discernible human influence on global climate" (Watson et al., 1995).

Despite uncertainty over the magnitude, timing, and potential impacts of global warming, there is general agreement that those policies and technologies that reduce the emission of greenhouse gases and have no adverse economic impact should be implemented now. Highest priorities relate to energy conservation, improved efficiency in energy generation, emission reduction from transportation, reforestation, and phasing out of CFCs (see Chapter 9). These proposed actions represent challenges to many facets of mechanical engineering.

Technical Background

The greenhouse effect is a natural phenomenon and one of the most well established theories in atmospheric science (see Figure 16.7.1). Most of the solar radiation impinging on Earth is in the frequency range below 3 μm. Radiation in this frequency band can readily penetrate Earth's atmosphere and is absorbed by the Earth. But most of the thermal radiation emitted by the Earth is infrared, i.e., in a frequency range above 3 μm, which is partly absorbed and reflected by the atmosphere. Gases in the atmosphere thus prevent part of the radiation emitted by the Earth from escaping into space and trap enough radiation to maintain our climate equilibrium. The atmosphere acts like the glass windows in a greenhouse — hence, the name *greenhouse effect*. Without this effect the Earth would be about 60°F cooler and life as we know it would not exist.

Figure 16.7.2 shows the distribution of the gases in the atmosphere that participate in the greenhouse effect, as well as the industrial sectors emitting them. An increase in the amount of atmospheric greenhouse gases increases the amount of radiation absorbed by the atmosphere and thus reduces the amount of radiation emitted by the Earth that can pass into space. This causes warming of the Earth. Carbon dioxide is the principal greenhouse gas, responsible for over one half of the predicted warming of the Earth. Most of the generation of CO_2 results from the burning of fossil fuels. Its primary sources are electric utilities (33%), transportation (31%), industrial processes (24%), and heating and cooling of buildings (12%). Methane, CFCs, ozone, and nitrous oxide constitute the balance of greenhouse emission. Carbon dioxide emissions have increased globally by 25% since the industrial revolution 200 years ago, and there has been an over 10% increase in the last 30 years alone. In the same period, methane concentration has more than doubled (from 800 to 1700 ppb).

Temperature records compiled by the United Kingdom Meteorological Office indicate that the Earth's average temperate has risen roughly 1°F since 1860 (see Figure 16.7.3). Since CO_2 is the principal greenhouse gas, estimating its growth is important for future prediction of climate change. Although all fossil fuels emit CO_2 when burned, their emission per unit energy produced is not equal. Natural gas is the cleanest fossil fuel. Oil combustion emits between 38 and 43% more CO_2 than natural gas, whereas coal combustion contains from 72 to 95% more CO_2 per unit energy released than natural gas. Ocean

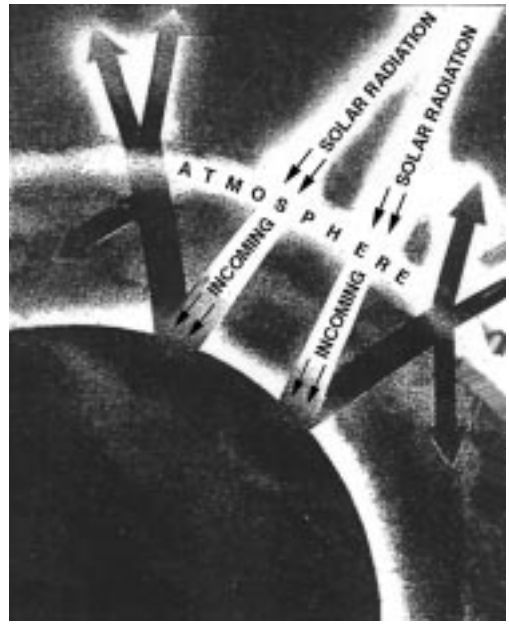

FIGURE 16.7.1 Schematic diagram of the greenhouse effect.

and trees act as carbon sinks because they absorb CO_2. Trees absorb CO_2 during the process of photosynthesis. Deforestation is important because it not only eliminates a mitigating factor of global warming, but when wood is burned, it too emits carbon dioxide directly into the atmosphere.

Potential Impacts of Global Climate Change

In its 1989 report to Congress, the USEPA sought to identify the impacts of global warming on specific geographic areas. The agency used simulations from three general circulation models — Goddard Institute for Space Studies (GISS), Geophysical Fluids Dynamics Laboratory (GFDL), and Oregon State University (OSU) — to project the effects of climate change on four regions: Southeast, Great Lakes, Great Plains, and California. The three models are in general agreement that a doubling of carbon dioxide in the atmosphere will increase the temperature, but they differ in magnitude, predicting between 3 and 5°C. Although they concur that annual precipitation will increase, their regional projections vary — the GFDL model predicts reduced precipitation in the Southeast, the GISS in the Great Plains, and the OSU in California. The report acknowledges, however, that the reliability of these regional predictions is limited.

The USEPA assessment of the potential impact of climate change on natural resources and the environment has serious implications for forests, agriculture, water resources, biodiversity, and sea-level rise. The southern boundary of forest species is expected to move northward and drier soils could alter the plant composition with grasslands and hardwoods replacing commercially valuable conifers. Also, fire and pest disturbances could become more frequent. Agricultural productivity would shift northward, causing economic dislocations for farmers in southern states.

One of the most important effects of global warming is a rise in sea level resulting from melting glaciers. Projections of future sea-level rise range from 0.3 to 1.1 m (1 to 3.5 ft) by the end of the next century. A 1-m rise could flood between 26 and 60% of the nation's coastal wetlands and cost up to $100 billion to protect developed areas that would otherwise be flooded.

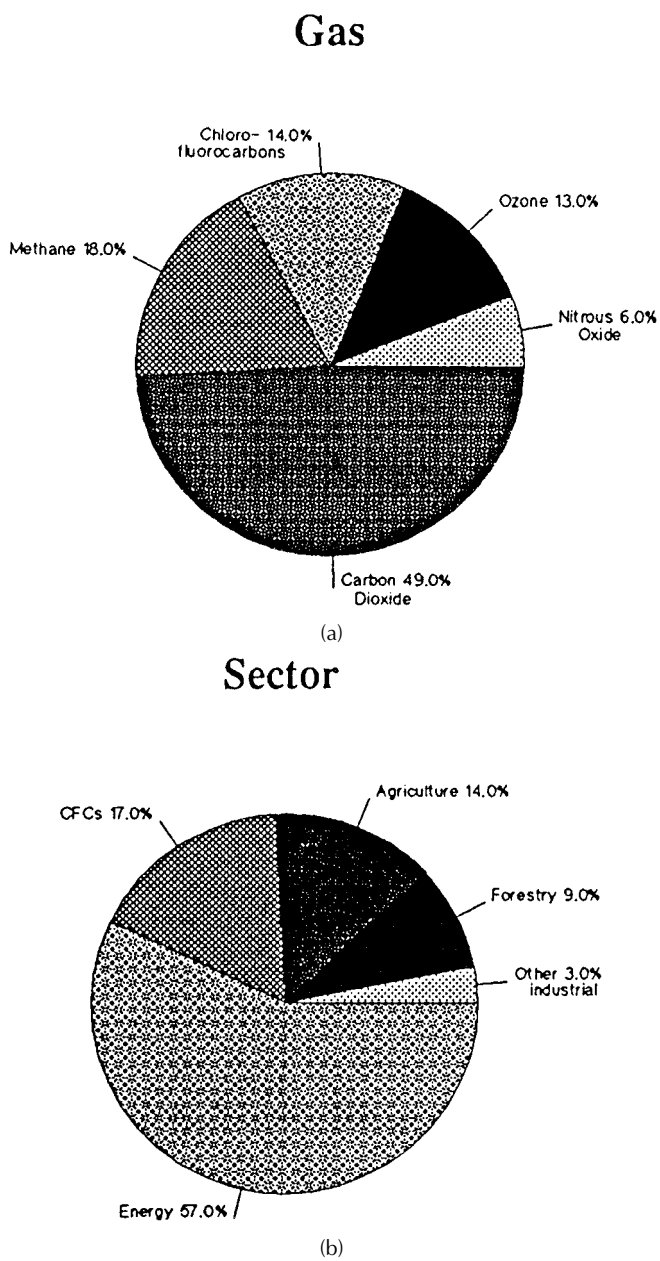

FIGURE 16.7.2 Greenhouse gas profile. (From U.S. Environmental Protection Agency, 1989.)

Mitigation Options for Global Warming

There is general agreement that an initial global warming will result from increases in greenhouse gases in the atmosphere, and the position of the U.S. Government, according to the Office of Science and Technology Policy issued in 1996, is that "we collectively must redouble our efforts in identifying the most cost-effective global approaches to reduce emissions in both the near- and long-term utilizing a broad portfolio of actions." However, the scientific uncertainty regarding the timing and severity of future climate impacts and their consequences creates a policy dilemma of what actions should be taken.

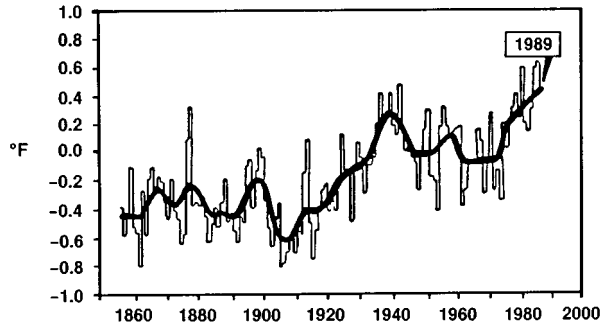

FIGURE 16.7.3 Global temperature change since 1860. Variation of annual surface temperatures for the world. The solid line shows long-term trends. The planet has warmed an average of almost 1° F. (From United Kingdom Meteorological Office, 1989.)

Because measures to limit greenhouse gas emission require efforts lasting many years and could affect the economic health of a country, the costs of climate policy and the technical means of achieving emission reduction must be considered with the focus on obtaining the largest reduction in potential greenhouse warming at the lowest cost to society. To date, CO_2 from combustion of fossil fuels has been the primary focus of attention. A comprehensive look at mitigation options, however, must consider the emission of all greenhouse gases to compare the relative importance of different emissions. The concept of a global warming potential to estimate the CO_2-equivalent emission of each of the major greenhouse gases is useful. Table 16.7.1 shows an estimate of greenhouse gas emissions from various human activities.

Various scenarios of the CO_2-equivalent reduction achievable by various mitigation measures have been studied. The various mitigation measures were grouped into two categories. The "best practice" technology options shown in Table 16.7.2 can be implemented now at no cost or even at net savings, but they are not used because of institutional and other barriers. Additional options shown in Table 16.7.3 either cost money or have benefits that are not readily quantified or face other implementation obstacles. In this study, no forecasts or scenarios for the future were used, but the results were applied to a 1989 base year.

Inspection of Table 16.7.2 indicates that improved energy efficiency in residential and commercial buildings will reduce demand for fossil fuel and, thereby, also reduce emissions. Conservation measures that reduce the use of electric power are the most significant. For example, improved commercial lighting to reduce the energy consumption by about 45% would not only save money, but if installed in commercial buildings, would result in electricity savings of about 10% from space-conditioning requirements.

The potential for reducing electricity consumption in the industrial sector with currently available technology is about 30%. A case study of energy-intensive industries such as steel mills and petrochemical plants indicates that energy savings of the order of 25 to 30% in direct industrial fuel use may be available economically by investing in more-efficient furnaces, energy recovery systems, and other process equipment. Also, increased use of cogeneration technologies would produce cost-effective CO_2 reductions as shown in Table 16.7.2.

The other important sector in which large reductions in greenhouse gas emissions can be achieved is transportation. These reductions in greenhouse gas emissions are largely through improved fuel economy and better transportation management methods that reduce traffic congestion (see Section 10, Transportation).

Mitigation measures outside the energy sector involve landfills, CFC use, agricultural activity, and forests. For example, the collection and combustion of landfill gas could reduce methane emission by about 65%. For a discussion of the other mitigation methods, the reader is referred to the original studies cited.

TABLE 16.7.1 Estimate of Current Greenhouse Gas Emissions from Human Activity

Source	Annual Emissions (Mt/year)[a]		CO_2-Equivalent (Mt/year)[a]	
	World	U.S.	World	U.S.
	CO_2 emissions			
Commercial energy	18,800		18,800	
Tropical deforestation	2,600		2,600	
Other	400		400	
Total CO_2	**21,800**	**4,800**	**21,800**	**4,800**
	CH_4 emissions			
Rice cultivation	110		2,300	
Enteric fermentation	70		1,500	
Fuel production	60		1,300	
Landfills	30		600	
Tropical deforestation	20		400	
Other	30		600	
Total CH_4	**320**	**50**	**6,700**	**1,050**
	CFC emissions			
Total CFCs	**0.6**	**0.3**	**3,200**	**1,640**
	N_2O emissions			
Fertilizer use	1.5		440	
Coal combustion	1.0		290	
Tropical deforestation	0.5		150	
Agricultural wastes	0.4		120	
Land cultivation	0.4		120	
Fuel and industrial biomass	0.2		60	
Total N_2O	**4.0**	**1.4**	**1,180**	**410**
Overall total			**32,880**	**7,900**

[a] Millions of metric tons based on the estimated global warming potential (GWP) for a 100-year averaging time (6): CO_2 = 1, CH_4 = 21, N_2O = 290, CFC-11 = 3500, CFC-12 = 7300 and CFC-113 = 4200. Values give the CO_2-equivalent radiative forcing for an instantaneous injection of 1 kg of gas into the atmosphere. Values for CH_4 include the estimated indirect effects of CO_2 produced. However, the GWP does not incorporate complex couplings with other greenhouse gases such as stratospheric and tropospheric ozone and their precursor emissions. The GWP thus provides only a preliminary basis for comparing diverse mitigation strategies.

TABLE 16.7.2 Best-Practice Technology Options Available at Little or No Net Cost that are not Fully Implemented Due to Institutional and Other Barriers (continued)

Option	CO_2-Equivalent Reduction[a]	Net Cost[b]

Numbers with options refer to steps in Figure 1. Com., commercial; Res, residential; Ind, industrial.

[a] Equivalent CO_2 reduction in millions of metric tons based on 1989 fuel and electricity use. [b]Net implemented cost in dollars per ton of CO_2-equivalent. Costs are mid-range estimates based on a 6% real discount rate, constant 1989 dollars. Parentheses give low/high range for average cost reflecting real discount rates of 3 to 10% plus uncertainty across different studies or estimates. [c]Plant shade trees and paint roofs white at 50% of residences to reduce air conditioning use and the urban heat island effect by 25%. [d]Replace incandescent lighting (2.5 inside and 1 outside light bulb per residence) with compact fluorescents to reduce lighting energy consumption by 50%. [e]Efficient tanks, increased insulation, low-flow devices, and alternative water heating systems to improve efficiency by 40 to 70%. [f]Residential measures above, plus heat pumps and heat recovery systems to improve efficiency by 40 to 60%. [g]Replace 100% of commercial light fixtures with compact fluorescent lighting, reflectors, occupancy sensors, and day lighting to reduce lighting energy consumption by 30 to 60%. [h]Additional insulation, seals, improved heating elements, reflective pans, and other measures to increase efficiency by 20 to 30%. [i]Improved heat pumps, chillers, window treatments, and other measures to reduce commercial cooling energy use by 30 to 70%. [j]Improved compressors, air barriers, food case enclosures, and other measures to improve efficiency 20 to 40%. [k]Implementation of new appliance standards for refrigeration and use of no-heat drying cycles in dishwashers to improve efficiency of refrigeration and dishwashers by 10 to 30%. [l]Improved and increased insulation, window glazing, and weather stripping along with increased use of heat pumps and solar heating to reduce energy consumption by 40 to 60%. [m]Use measures similar to residential sector to reduce energy consumption by 20 to 30%. [n]Improved distribution systems, energy-efficient motors, and other measures to improve efficiency 30 to 50%. [o]Efficiency measures similar to those for electricity to reduce fossil fuel energy use by 50%. [p]Switch 10% of building electricity use from electric resistance heat to natural gas heating to improve overall efficiency by 60 to 70%. [q]More efficient motors, electrical drive systems, lighting and industrial process modifications to improve electricity efficiency by 30%. [r]Energy management, waste heat recovery, boiler modifications, and other industrial process enhancements to reduce fuel consumption by 30%. [s]An additional 25,000 MW of co-generation plants to replace existing industrial energy systems. [t]Use existing technology to improve fuel economy to 32.5 mpg (CAFE) with no changes in the existing fleet. [u]Use existing technology to improve fuel economy to 18.2 mpg (CAFE) with no changes in the existing fleet. [v]Improve efficiency of existing plants by 3% through improved plant operation and maintenance. [w]Improve efficiency by 5% through equipment modernization and maintenance. [x]Increase the annual average capacity factor of existing plants from 60 to 65% through improved maintenance and operation. [y]Reduce landfill gas generation by 60 to 65% by collecting and burning in a flare or energy recovery system.

[a] Equivalent CO_2 reduction in millions of metric tons based on 1989 fuel and electricity use. [b]Net implemented cost in dollars per ton of CO_2-equivalent. Includes direct costs only. Many of these measures have additional indirect costs that could be significant (see text). Values are mid-range cost estimates based on a 6% real discount rate, constant 1989 dollars. Values in parentheses give low/high range for average cost for real discount rates of 3 to 10% plus uncertainty across different studies or estimates. [c]Switch current coal consumption in industrial plants to natural gas or oil where technically feasible (estimated at 0.6 quadrillion Btu). [d]Estimate 25% of employer-provided parking spaces and tax remaining spaces to reduce solo commuting by 15 to 20%. [e]Improve on-road fuel economy from 32.5 to 46.8 mpg (CAFE) with additional technology measures and downsizing that require changes in the existing fleet mix. [f]Implement improved fan jet and other technologies to improve fuel efficiency by 20%. [g]Potential emission reductions apply only to one technology at a time and are not cumulative. All cost-effectiveness estimates are relative to existing (1989) coal plants. [h]Based on advanced pulverized coal plants. [i]Based on the use of combined cycle systems in place of coal. Co-firing natural gas at existing coal-fired plants has similar costs but lower reduction potential. [j]Based on advanced light-water reactors replacing current fossil-fuel capacity for baseload and intermediate load operation. [k]Based on replacing all fossil fuel plants in the 1989 generating mix. Replacement of coal plants only yields 1470 Mt/year. Remaining potential after maximum demand reductions and plant upgrades is 950 Mt/year. [l]Includes chlorofluorocarbons (CFC), hydrofluorocarbons (HFC), and hydrochlorofluorocarbons (HCFC). [m]Modify or replace existing equipment to use non-CFC materials as cleaning and blowing agents, aerosols, and refrigerants where technically possible. [n]Upgrade equipment and retrain personnel to improve conservation and recycling of CFCs. [o]Substitute cleaning and blowing agents and aerosols with fluorocarbon substitutes. [p]Retrofit or replace all existing chillers to use fluorocarbon substitutes. [q]Replace existing automobile air conditioners with equipment using fluorocarbon substitutes. [r]Replace commercial refrigeration equipment such as used in supermarkets and transportation with equipment using fluorocarbon substitutes. [s]Reduce nitrogenous fertilizer use by 5%. [t]Eliminate all U.S. paddy rice production. [u]Reduce ruminant animal production by 25%. [v]Reforest 28.7 Mha of economically or environmentally marginal crop and pasture lands and nonfederal forest lands. [w]Increase recycling and reduce energy consumption primarily in the primary metals, pulp and paper, chemicals, and petroleum refining industries through new, less energy intensive technology. [x]Based on replacement of highway transport fuels with alternative fuels that emit no greenhouse gases.

Defining Terms

Aerosol: Small solid particle or liquid droplet suspended in the air.
Anthropogenic: Man-made.
Deterministic: Dealing with cause and effect.
Ensemble average: Theoretical average, i.e., the value that could be expected as the average from an infinite number of realizations.
Global warming: The warming of the earth as a result of the atmosphere which traps solar radiation. Currently, the term global warming is used to denote the temperature increase due to carbon dioxide, methane and other greenhouse gases.
Greenhouse Gases: Carbon dioxide, methane and other gases resulting from human activities that increase the amount of solar radiation trapped by the atmosphere.
Numerical advection errors: Numerical errors generated by finite-difference solutions of transport terms using an Eulerian grid model.
Organic compounds: Chemical species containing one or more carbon atoms.
Photochemical: Chemical reactions influenced by light.
Photolysis: Chemical decomposition by the action of light.
Planetary boundary layer, PBL: The atmospheric layer which is affected by the momentum and heat fluxes generated by the Earth surface (typically, the first 500–1000 m of the atmosphere).
Stratospheric: Related to the stratosphere, the portion of the atmosphere approximately between 10 to 50 km above the ground.
Tropospheric: Related to the troposphere, the lower level of the atmosphere approximately from the surface to 10 km above.
Wind shear: The change in wind speed and direction as a function of height.

17.1 Engineering Economic Decisions

Decisions made during the engineering design phase of product development determine the majority (some say 85%) of the costs of manufacturing that product. Thus, a competent engineer in the 21st century must have an understanding of the principles of economics as well as engineering. This chapter examines the most important economic concepts that should be understood by engineers.

Engineers participate in a variety of decision-making processes, ranging from manufacturing to marketing to financing decisions. They must make decisions involving materials, plant facilities, the in-house capabilities of company personnel, and the effective use of capital assets such as buildings and machinery. One of the engineer's primary tasks is to plan for the acquisition of equipment (fixed asset) that will enable the firm to design and produce products economically. These decisions are called *engineering economic decisions.*

17.2 Establishing Economic Equivalence

A typical engineering economic decision involves two dissimilar types of dollar amounts. First, there is the investment, which is usually made in a lump sum at the beginning of the project, a time that for analytical purposes is called today, or time 0. Second, there is a stream of cash benefits that are expected to result from this investment over a period of future years.

In such a fixed asset investment funds are committed today in the expectation of earning a return in the future. In the case of a bank loan, the future return takes the form of interest plus repayment of the principal. This is known as the *loan cash flow.* In the case of the fixed asset, the future return takes the form of cash generated by productive use of the asset. The representation of these future earnings along with the capital expenditures and annual expenses (such as wages, raw materials, operating costs, maintenance costs, and income taxes) is the *project cash flow.* This similarity between the loan cash flow and the project cash flow brings us an important conclusion—that is, first we need to find a way to evaluate a money series occurring at different points in time. Second, if we understand how to evaluate a loan cash flow series, we can use the same concept to evaluate the project cash flow series.

Interest: The Cost of Money

Money left in a savings account earns interest so that the balance over time is greater than the sum of the deposits. In the financial world, money itself is a commodity, and like other goods that are bought and sold, money costs money. The cost of money is established and measured by an *interest rate,* a percentage that is periodically applied and added to an amount (or varying amounts) of money over a specified length of time. When money is borrowed, the interest paid is the charge to the brrower for the use of the lender's property; when money is loaned or invested, the interest earned is the lender's gain from providing a good to another. *Interest,* then, may be defined as the cost of having money available for use.

The operation of interest reflects the fact that money has a time value. This is why amounts of interest depend on lengths of time; interest rates, for example, are typically given in terms of a percentage per year. This principle of the time value of money can be formally defined as follows: the economic value of a sum depends on when it is received. Because money has earning power over time (it can be put to work, earning more money for its owner), a dollar received today has a greater value than a dollar received at some future time.

The changes in the value of a sum of money over time can become extremely significant when we deal with large amounts of money, long periods of time, or high interest rates. For example, at a current annual interest rate of 10%, $1 million will earn $100,000 in interest in a year; thus, waiting a year to receive $1 million clearly involves a significant sacrifice. In deciding among alternative proposals, we must take into account the operation of interest and the time value of money to make valid comparisons of different amounts at various times.

The Elements of Transactions Involving Interest

Many types of transactions involve interest — for example, borrowing or investing money, purchasing machinery on credit — but certain elements are common to all of them:

1. Some initial amount of money, called the *principal* (*P*) in transactions of debt or investment
2. The *interest rate* (*i*), which measures the cost or price of money, expressed as a percentage per period of time
3. A period of time, called the *interest period* (or *compounding period*), that determines how frequently interest is calculated
4. The specified length of time that marks the duration of the transaction and thereby establishes a certain *number of interest periods* (*N*)
5. A *plan for receipts or disbursements* (A_n) that yields a particular cash flow pattern over the length of time (for example, we might have a series of equal monthly payments [A] that repay a loan)
6. A *future amount of money* (F) that results from the cumulative effects of the interest rate over a number of interest periods

Cash Flow Diagrams

It is convenient to represent problems involving the time value of money in graphic form with a cash flow diagram (see Figure 17.2.1), which represents time by a horizontal line marked off with the number of interest periods specified. The cash flows over time are represented by arrows at the relevant periods: upward arrows for positive flows (receipts) and downward arrows for negative flows (disbursements).

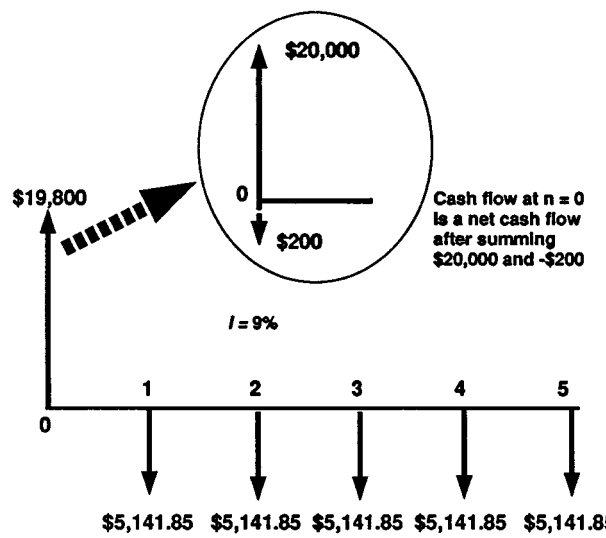

FIGURE 17.2.1 A cash flow diagram for a loan transaction — borrow $20,000 now and pay off the loan with five equal annual installments of $5,141.85. After paying $200 for the loan origination fee, the net amount of financing is $19,800. The borrowing interest rate is 9%.

End-of-Period Convention

In practice, cash flows can occur at the beginning or in the middle of an interest period, or at practically any point in time. One of the simplifying assumptions we make in engineering economic analysis is the *end-of-period convention*, which is the practice of placing all cash flow transactions at the end of an interest period. This assumption relieves us of the responsibility of dealing with the effects of interest within an interest period, which would greatly complicate our calculations.

Compound Interest

Under the compound interest scheme, the interest in each period is based on the total amount owed at the end of the previous period. This total amount includes the original principal plus the accumulated interest that has been left in the account. In this case, you are in effect increasing the deposit amount by the amount of interest earned. In general, if you deposited (invested) P dollars at interest rate i, you would have P + iP = P(1 + i) dollars at the end of one period. With the entire amount (principal and interest) reinvested at the same rate i for another period, you would have, at the end of the second period,

$$P(1+i)+i\left[P(1+i)\right]=P(1+i)(1+i)$$

$$=P(1+i)^2$$

This interest-earning process repeats, and after N periods, the total accumulated value (balance) F will grow to

$$F=P(1+i)^N \tag{17.2.1}$$

Equivalence Calculations

Economic equivalence refers to the fact that a cash flow — whether it is a single payment or a series of payments — can be said to be converted to an *equivalent* cash flow at any point in time; thus, for any sequence of cash flows, we can find an equivalent single cash flow at a given interest rate and a given time.

Equivalence calculations can be viewed as an application of the compound interest relationships developed in Equation 17.2.1. The formula developed for calculating compound interest, $F = P(1 + i)^N$, expresses the equivalence between some present amount, P, and a future amount, F, for a given interest rate, i, and a number of interest periods, N. Therefore, at the end of a 3-year investment period at 8%, $1000 will grow to

$$\$1000(1+0.08)^3=\$1259.71$$

Thus at 8% interest, $1000 received now is equivalent to $1,25l9.71 received in 3 years and we could trade $1000 now for the promise of receiving $1259.71 in 3 years. Example 17.2.1 demonstrates the application of this basic technique.

Example 17.2.1 — Equivalence

Suppose you are offered the alternative of receiving either $3000 at the end of 5 years or P dollars today. There is no question that the $3000 will be paid in full (no risk). Having no current need for the money, you would deposit the P dollars in an account that pays 8% interest. What value of P would make you indifferent in your choice between P dollars today and the promise of $3000 at the end of 5 years from now?

Discussion. Our job is to determine the present amount that is economically equivalent to $3000 in 5 years, given the investment potential of 8% per year. Note that the problem statement assumes that you would exercise your option of using the earning power of your money by depositing it. The “indifference” ascribed to you refers to economic indifference; that is, within a marketplace where 8% is the applicable interest rate, you could trade one cash flow for the other.

Solution. From Equation (17.2.1), we establish

$$\$3000=P(1+0.08)^5$$

Rearranging to solve for P,

$$P = \$3000/(1+0.08)^5 = \$2042$$

Comments. In this example, it is clear that if P is anything less than $2042, you would prefer the promise of $3000 in 5 years to P dollars today; if P were greater than $2042, you would prefer P. It is less obvious that at a lower interest rate, P must be higher to be equivalent to the future amount. For example, at i = 4%, P = $2466.

Interest Formulas

In this section is developed a series of interest formulas for use in more complex comparisons of cash flows. It classifies four major categories of cash flow transactions, develops interest formulas for them, and presents working examples of each type.

Single Cash Flow Formulas

We begin our coverage of interest formulas by considering the simplest cash flows: single cash flows. Given a present sum P invested for N interest periods at interest rate i, what sum will have accumulated at the end of the N periods? You probably noticed quickly that this description matches the case we first encountered in describing compound interest. To solve for F (the future sum) we use Equation (17.2.1):

$$F = P(1+i)^N = P(F/P,i,N)$$

Because of its origin in compound interest calculation, the factor (F/P, i, N), which is read as "find F, given P, i, and N" is known as the *single payment compound amount factor.* Like the concept of equivalence, this factor is one of the foundations of engineering economic analysis. Given this factor, all the other important interest formulas can be derived. This process of finding F is often called the compounding process. (Note the time-scale convention. The first period begins at n = 0 and ends at n = 1.) Thus, in the preceding example, where we had $F = \$1000(1.08)^3$, we can write F = $1000(F/P, 8%, 3). We can directly evaluate the equation or locate the factor value by using the 8% interest table* and finding the factor of 1.2597 in the F/P column for N = 3.

Finding present worth of a future sum is simply the reverse of compounding and is known as *discounting process.* In Equation (17.2.1), we can see that if we were to find a present sum P, given a future sum F, we simply solve for P.

$$P = F\left[\frac{1}{(1+i)^N}\right] = F(P/F,i,N) \qquad (17.2.2)$$

The factor $1/(1 + i)^N$ is known as the *single payment present worth factor* and is designated (P/F, i, N). Tables* have been constructed for the P/F factors for various values of i and N. The interest rate i and the P/F factor are also referred to as *discount rate* and *discounting factor*, respectively. Because using the interest tables is often the easiest way to solve an equation, this factor notation is included for each of the formulas derived in the following sections.

* All standard engineering economy textbooks (such as *Contemporary Engineering Economics* by C. S. Park, Addison Wesley, 1997) provide extensive sets of interest tables. Or you can obtain such interest tables on a World Wide Web site at http://www.eng.auburn.edu/-park/cee.html, which is a textbook web site for *Contemporary Engineering Economics.*

A Stream of Cash Flow Series

A common cash flow transaction involves a series of disbursements or receipts. Familiar situations such as car loans and insurance payments are examples of series payments. Payments of car loans and insurance bills typically involve identical sums paid at regular intervals. However, when there is no clear pattern of payment amounts over a series, one calls the transaction an *uneven cash-flow series*.

The present worth of any stream of payments can be found by calculating the present value of each individual payment and summing the results. Once the present worth is found, one can make other equivalence calculations, such as calculating the future worth by using the interest factors developed in the previous section.

Example 17.2.2 — Present Value of an Uneven Series by Decomposition into Single Payments

Wilson Technology, a growing machine shop, wishes to set aside money now to invest over the next 4 years in automating their customer service department. They now earn 10% on a lump sum deposited, and they wish to withdraw the money in the following increments:

Year 1: $25,000 to purchase a computer and data base software designed for customer service use
Year 2: $3000 to purchase additional hardware to accommodate anticipated growth in use of the system
Year 3: No expenses
Year 4: $5000 to purchase software upgrades

How much money must be deposited now to cover the anticipated payments over the next 4 years?

Discussion. This problem is equivalent to asking what value of P would make you indifferent in your choice between P dollars today and the future expense stream of ($25,000, $3000, $0, $5000). One way to deal with an uneven series of cash flows is to calculate the equivalent present value of each single cash flow and sum the present values to find P. In other words, the cash flow is broken into three parts as shown in Figure 17.2.2.

Solution.

$$P = \$25{,}000(P/F,10\%,1) + \$3000(P/F,10\%,2) + \$5000(P/F,10\%,4)$$

$$= \$28{,}622$$

Cash Flow Series with a Special Pattern

Whenever one can identify patterns in cash flow transactions, one may use them in developing concise expressions for computing either the present or future worth of the series. For this purpose, we will classify cash flow transactions into three categories: (1) equal cash flow series, (2) linear gradient series, and (3) geometric gradient series. To simplify the description of various interest formulas, we will use the following notation:

1. Uniform Series: Probably the most familiar category includes transactions arranged as a series of equal cash flows at regular intervals, known as an *equal-payment series* (or *uniform series*) (Figure 17.2.3a). This describes the cash flows, for example, of the common installment loan contract, which arranges for the repayment of a loan in equal periodic installments. The equal cash flow formulas deal with the equivalence relations of P, F, and A, the constant amount of the cash flows in the series.
2. Linear Gradient Series: While many transactions involve series of cash flows, the amounts are not always uniform: yet they may vary in some regular way. One common pattern of variation occurs when each cash flow in a series increases (or decreases) by a fixed amount (Figure 17.2.3b). A 5-year loan repayment plan might specify, for example, a series of annual payments that

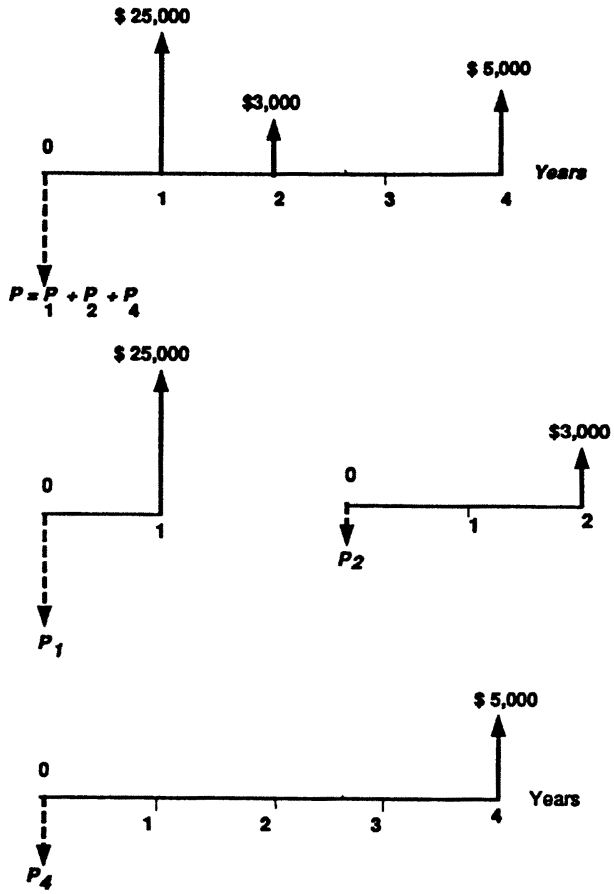

FIGURE 17.2.2 Decomposition of uneven cash flow series into three single-payment transactions. This decomposition allows us to use the single-payment present worth factor.

increased by $50 each year. We call such a cash flow pattern a *linear gradient series* because its cash flow diagram produces an ascending (or descending) straight line. In addition to P, F, and A, the formulas used in such problems involve the constant amount, G, of the change in each cash flow.

3. Geometric Gradient Series: Another kind of gradient series is formed when the series in cash flow is determined, not by some fixed amount like $50, but by some fixed *rate*, expressed as a percentage. For example, in a 5-year financial plan for a project, the cost of a particular raw material might be budgeted to increase at a rate of 4% per year. The curving gradient in the diagram of such a series suggests its name: a *geometric gradient series* (Figure 17.2.3c). In the formulas dealing with such series, the rate of change is represented by a lowercase g.

Table 17.2.1 summarizes the interest formulas and the cash flow situations in which they should be used. For example, the factor notation (F/A, i, N) represents the situation where you want to calculate the equivalent lump-sum future worth (F) for a given uniform payment series (A) over N period at interest rate i. Note that these interest formulas are applicable only when the interest (compounding) period is the same as the payment period. Also in this table we present some useful interest factor relationships. The next two examples illustrate how one might use these interest factors to determine the equivalent cash flow.

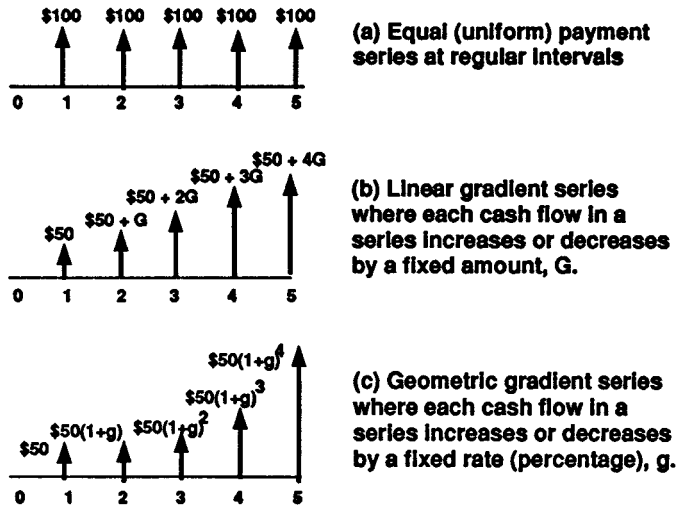

FIGURE 17.2.3 Five types of cash flows: (a) equal (uniform) payment series; (b) linear gradient series; and (c) geometric gradient series.

Example 17.2.3 — Uniform Series: Find F, Given i, A, N

Suppose you make an annual contribution of $3000 to your savings account at the end of each year for 10 years. If your savings account earns 7% interest annually, how much can be withdrawn at the end of 10 years? (See Figure 17.2.4.)

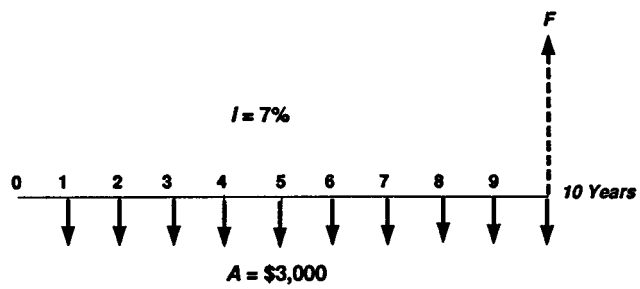

FIGURE 17.2.4 Cash flow diagram (Example 17.2.3).

Solution.

$$F = \$3000(F/A, 7\%, 10)$$

$$= \$3000(13.8164)$$

$$= \$41,449.20$$

Example 17.2.4 — Geometric Gradient: Find P, Given A_1, g, i, N

Ansell Inc., a medical device manufacturer, uses compressed air in solenoids and pressure switches in the machines to control the various mechanical movements. Over the years the manufacturing floor has changed layouts numerous times. With each new layout more piping was added to the compressed air delivery system to accommodate the new locations of the manufacturing machines. None of the extra, unused old pipe was capped or removed; thus the current compressed air delivery system is inefficient and fraught with leaks. Because of the leaks in the current system, the compressor is expected to run

TABLE 17.2.1 Summary of Discrete Compounding Formulas with Discrete Payments

Flow Type	Factor Notation	Formula	Cash Flow Diagram	Factor Relationship
Single	Compound amount ($F/P, i, N$) Present worth ($P/F, i, N$)	$F = P(1+i)^N$ $P = F(1+i)^{-N}$		$(F/P, i, N) = i(F/A, i, N) + 1$ $(P/F, i, N) = 1 - (P/A, i\ N)i$
Equal Payment Series	Compound amount ($F/A, i, N$)	$F = A\left[\frac{(1+i)^N - 1}{i}\right]$		$(A/F, i, N) = (A/P, i, N) - i$
	Sinking fund ($A/F, i, N$)	$A = F\left[\frac{i}{(1+i)^N - 1}\right]$		
	Present worth ($P/A, i, N$)	$P = A\left[\frac{(1+i)^N - 1}{i(1+i)^N}\right]$		$(A/P, i, N) = \frac{i}{1-(P/F, i, N)}$
	Capital recovery ($A/P, i, N$)	$A = P\left[\frac{i(1+i)^N}{(1+i)^N - 1}\right]$		
Gradient Series	Uniform gradient Present worth ($P/G, i, N$)	$P = C\left[\frac{(1+i)^N - iN - 1}{i^2(1+i)^N}\right]$		$(F/G, i, N) = (P/G, i, N)(F/P, i, N)$ $(A/G, i, N) = (P/G, i, N)(A/P, i, N)$
	Geometric gradient Present worth ($P/A_1, g, i, N$)	$P = \begin{cases} A_1\left[\frac{1-(1+g)^N(1+i)^{-N}}{i-g}\right] \\ \frac{NA_1}{1+i} \quad (\text{if } i = g) \end{cases}$		$(F/A_1, g, i, N) = (P/A_1, g, i, N)(F/P, i\ N)$

Tables are constructed for various interest factors and you can obtain such interest tables on a World Wide Web site at http://www.eng.auburn.edu/~park/cee.html, which is a textbook web site for *Contemporary Engineering Economics*.

70% of the time that the plant is in operation during the upcoming year, which will require 260 kW/hr of electricity at a rate of $0.05/kW-hr. (The plant runs 250 days a year for 24 hr a day.) If Ansell continues to operate the current air delivery system, the compressor run time will increase by 7% per year for the next 5 years due to ever-deteriorating leaks. (After 5 years, the current system cannot meet the plant's compressed air requirement, so it has to be replaced.) If Ansell decides to replace all of the old piping now, it will cost $28,570. The compressor will still run the same number of days; however, it will run 23% less (or 70% (1 – 0.23) = 53.9% usage during the day) because of the reduced air pressure loss. If Ansell's interest rate is 12%, is it worth fixing now?

Solution.

- Step 1. Calculate the cost of power consumption of the current piping system during the first year. The power consumption is equal to:

$$\begin{aligned}\text{power cost} &= \%\text{ of day operating} \times \text{days operating per year} \times \text{hours per day} \\ &\quad \times \text{kW/hr} \times \$/\text{kW-hr} \\ &= (70\%) \times (250\ \text{days/year}) \times (24\ \text{hr/day}) \times (260\ \text{kW/hr}) \times (\$0.05/\text{kW-hr}) \\ &= \$54,440\end{aligned}$$

- Step 2. Each year the annual power cost will increase at the rate of 7% over the previous year's power cost. Then the anticipated power cost over the 5-year period is summarized in Figure 17.2.5. The equivalent present lump-sum cost at 12% for this geometric gradient series is

$$\begin{aligned}P_{Old} &= \$54,440\left(P/A_1, 7\%, 12\%, 5\right) \\ &= \$54,440\left[\frac{1-(1+0.07)^5(1+0.12)^{-5}}{0.12-0.07}\right] \\ &= \$222,283\end{aligned}$$

- Step 3. If Ansell replaces the current compressed air system with the new one, the annual power cost will be 23% less during the first year and will remain at that level over the next 5 years. The equivalent present lump-sum cost at 12% is

$$\begin{aligned}P_{New} &= \$54,440(1-0.23)\left(P/A, 12\%, 5\right) \\ &= \$41,918.80(3.6048) \\ &= \$151,108\end{aligned}$$

- Step 4. The net cost for not replacing the old system now is $71,175 (= $222,283 – $151,108). Since the new system costs only $28,570, the replacement should be made now.

Nominal and Effective Interest Rates

In all our examples in the previous section, we implicitly assumed that payments are received once a year, or annually. However, some of the most familiar financial transactions in both personal financial matters and engineering economic analysis involve nonannual payments; for example, monthly mortgage payments and daily earnings on savings accounts. Thus, if we are to compare different cash flows with different compounding periods, we need to address them on a common basis. The need to do this has led to the development of the concepts of *nominal interest rate* and *effective interest rate.*

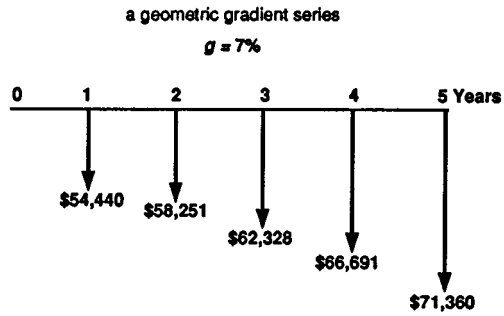

FIGURE 17.2.5 Expected power expenditure over the next 5 years due to deteriorating leaks if no repair is performed (Example 17.2.4).

Nominal Interest Rate

Even if a financial institution uses a unit of time other than a year — a month or quarter, for instance — in calculating interest payments, it usually quotes the interest rate on an annual basis. Many banks, for example, state the interest arrangement for credit cards in this way: "18% compounded monthly." We say 18% is the *nominal interest rate* or *annual percentage rate* (APR), and the compounding frequency is monthly (12). To obtain the interest rate per compounding period, we divide 18% by 12 to obtain 1.5% per month. Therefore, the credit card statement above means that the bank will charge 1.5% interest on unpaid balance for each month.

Although the annual percentage rate, or APR, is commonly used by financial institutions and is familiar to customers, when compounding takes place more frequently than annually, the APR does not explain precisely the amount of interest that will accumulate in a year. To explain the true effect of more frequent compounding on annual interest amounts, we need to introduce the term effective interest rate.

Effective Annual Interest Rate

The *effective interest rate* is the only one that truly represents the interest earned in a year or some other time period. For instance, in our credit card example, the bank will charge 1.5% interest on unpaid balance at the end of each month. Therefore, the 1.5% rate represents an effective interest rate — on a monthly basis, it is the rate that predicts the actual interest payment on your outstanding credit card balance.

Suppose you purchase an appliance on credit at 18% compounded monthly. Unless you pay off the entire amount within a grace period (let's say, a month), any unpaid balance (P) left for a year period would grow to

$$\begin{aligned} F &= P(1+i)^N \\ &= P(1+0.015)^{12} \\ &= 1.1956P \end{aligned}$$

This implies that for each dollar borrowed for 1 year, you owe $1.1956 at the end of the year, including the principal and interest. For each dollar borrowed, you pay an equivalent annual interest of 19.56 cents. In terms of an effective annual interest rate (i_a), we can rewrite the interest payment as a percentage of the principal amount

$$i_a = (1+0.015)^{12} - 1 = 0.1956, \text{ or } 19.56\%$$

Thus, the effective annual interest rate is 19.56%.

Clearly, compounding more frequently increases the amount of interest paid for the year at the same nominal interest rate. We can generalize the result to compute the effective interest rate for *any time duration*. As you will see later, we normally compute the effective interest rate based on payment (transaction) period. For example, cash flow transactions occur quarterly but interest rate is compounded monthly. This quarterly conversion allows us to use the interest formulas in Table 17.2.1. To consider this, we may define the effective interest rate for a given payment period as

$$\begin{aligned} i &= (1 + r/M)^C - 1 \\ &= (1 + r/CK)^C - 1 \end{aligned} \tag{17.2.3}$$

where

M = the number of interest periods per year
C = the number of interest periods per payment period
K = the number of payment periods per year

When M = 1, we have the special case of annual compounding. Substituting M = 1 into Equation (17.2.3), we find it reduces to $i_a = r$. That is, when compounding takes place once annually,* effective interest is equal to nominal interest. Thus, in all our earlier examples, where we considered only annual interest, we were by definition using effective interest rates.

Example 17.2.5 — Calculating Auto Loan Payments

Suppose you want to buy a car priced $22,678.95. The car dealer is willing to offer a financing package with 8.5% annual percentage rate over 48 months. You can afford to make a down payment of $2678.95, so the net amount to be financed is $20,000. What would be the monthly payment?

Solution. The ad does not specify a compounding period, but in automobile financing the interest and the payment periods are almost always both monthly. Thus, the 8.5% APR means 8.5% compounded monthly. In this situation, we can easily compute the monthly payment using the *capital recovery factor* in Table 17.2.1:

$$i = 8.5\%/12 = 0.7083\% \text{ per month}$$

$$N = (12)(4) = 48 \text{ months}$$

$$A = \$20,000(A/P, 0.7083\%, 48) = \$492.97$$

* For an extreme case, we could consider a continuous compounding. As the number of compounding periods (M) becomes very large, the interest rate per compounding period (r/M) becomes very small. As M approaches infinity and r/M approaches zero, we approximate the situation of *continuous compounding*.

$$i = e^{r/K} - 1$$

To calculate the effective annual interest rate for continuous compounding, we set K equal to 1, resulting in:

$$i_a = e^r - 1$$

As an example, the effective annual interest rate for a nominal interest rate of 12% compounded continuously is $i_a = e^{0.12} - 1 = 12.7497\%$.

Example 17.2.6 — Compounding More Frequent Than Payments

Suppose you make equal quarterly deposits of $1000 into a fund that pays interest at a rate of 12% compounded monthly. Find the balance at the end of year 2 (Figure 17.2.6).

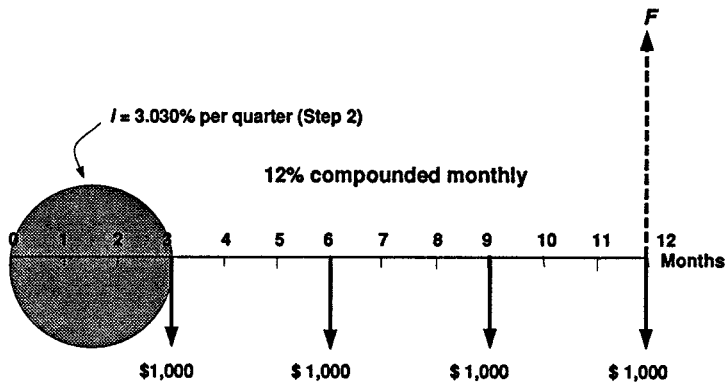

FIGURE 17.2.6 Quarterly deposits with monthly compounding (Example 17.2.6).

Solution. We follow the procedure for noncomparable compounding and payment periods described above.

1. Identify the parameter values for M, K, and C:

$$M = 12 \text{ compounding periods per year}$$

$$K = 4 \text{ payment periods per year}$$

$$C = 3 \text{ interest periods per payment period}$$

2. Use Equation (17.2.3) to compute effective interest per quarter.

$$\text{i} = \left(1 + 0.12/12\right)^3 - 1$$

$$= 3.030\% \text{ per quarter}$$

3. Find the total number of payment periods, N.

$$N = K(\text{number of years}) = 4(2) = 8 \text{ quarters}$$

4. Use i and N in the (F/A, i, N) factor from Table 17.2.1:

$$F = \$1000\left(F/A, 3.030\%, 8\right) = \$8901.81$$

Loss of Purchasing Power

It is important to differentiate between the time value of money as we used it in the previous section and the effects of inflation. The notion that a sum is worth more the earlier it is received can refer to its earning potential over time, to decreases in its value due to inflation over time, or to both. Historically, the general economy has usually fluctuated in such a way that it experiences *inflation*, a loss in the purchasing power of money over time. Inflation means that the cost of an item tends to increase over time or, to put it another way, the same dollar amount buys less of an item over time. *Deflation* is the

opposite of inflation (negative inflation), in that prices decrease over time and hence a specified dollar amount gains in purchasing power. In economic equivalence calculations, we need to consider the change of purchasing power along with the earning power.

The Average Inflation Rate

To account for the effect of varying yearly inflation rates over a period of several years, we can compute a single rate that represents an *average inflation rate.* Since each individual year's inflation rate is based on the pervious year's rate, they have a compounding effect. As an example, suppose we want to calculate the average inflation rate for a 2-year period for a typical item. The first year's inflation rate is 4% and the second year's is 8%, using a base price index of 100.

- Step 1. We find the price at the end of the second year by the process of compounding:

$$\underbrace{100(1+0.04)}_{\qquad}\underbrace{(1+0.08)}_{\qquad\qquad\qquad} = 112.32$$

- Step 2. To find the average inflation rate f over a 2-year period, we establish the following equivalence equation:

$$100(1+f)^2 = 112.32 \leftarrow 100(F/P, f, 2) = 112.32$$

  Solving for f yields

$$f = 5.98\%$$

We can say that the price increases in the last 2 years are equivalent to an average annual percentage rate of 5.98% per year. In other words, our purchasing power decreases at the annual rate of 5.98% over the previous year's dollars. If the average inflation rate is calculated based on the *consumer price index* (CPI), it is known as a *general inflation rate* ($\bar{f}$).

Actual vs. Constant Dollars

To introduce the effect of inflation into our economic analysis, we need to define several inflation-related terms.*

- Actual (current) dollars (A_n): Estimates of future cash flows for year n which take into account any anticipated changes in amount due to inflationary or deflationary effects. Usually these amounts are determined by applying an inflation rate to base year dollar estimates.
- Constant (real) dollars (A'_n): Dollars of constant purchasing power independent of the passage of time. In situations where inflationary effects have been assumed when cash flows were estimated, those estimates can be converted to constant dollars (base year dollars) by adjustment using some readily accepted *general inflation rate*. We will assume that the base year is always time 0 unless we specify otherwise.

* Based on the ANSI Z94 Standards Committee on Industrial Engineering Terminology. 1988. *The Engineering Economist.* Vol. 33(2): 145–171.

Equivalence Calculation under Inflation

In previous sections, our equivalence analyses have taken into consideration changes in the *earning power* of money — that is, interest effects. To factor in changes in *purchasing power* as well — that is, inflation — we may use either (1) constant dollar analysis or (2) actual dollar analysis. Either method will produce the same solution; however, each uses a different interest rate and procedure.

There are two types of interest rate for equivalence calculation: (1) the market interest rate and (2) the inflation-free interest rate. The interest rate that is applicable depends on the assumptions used in estimating the cash flow.

- Market interest rate (i): This interest rate takes into account the combined effects of the earning value of capital (earning power) and any anticipated inflation or deflation (purchasing power). Virtually all interest rates stated by financial institutions for loans and savings accounts are market interest rates. Most firms use a market interest rate (also known as *inflation-adjusted rate of return* [*discount rate*]) in evaluating their investment projects.
- Inflation-free interest rate (i′): An estimate of the true earning power of money when inflation effects have been removed. This rate is commonly known as *real interest rate* and can be computed if the market interest rate and inflation rate are known.

In calculating any cash flow equivalence, we need to identify the nature of project cash flows. There are three common cases:

Case 1. All cash flow elements are estimated in constant dollars. Then, to find the equivalent present value of a cash flow series in constant dollars, use the inflation-free interest rate.

Case 2. All cash flow elements are estimated in actual dollars. Then, use the market interest rate to find the equivalent worth of the cash flow series in actual dollars.

Case 3. Some of the cash flow elements are estimated in constant dollars and others are estimated in actual dollars. In this situation, we simply convert all cash flow elements into one type — either constant or actual dollars. Then we proceed with either constant-dollar analysis for case 1 or actual-dollar analysis for case 2.

Removing the effect of inflation by deflating the actual dollars with $\bar{f}$ and finding the equivalent worth of these constant dollars by using the inflation-free interest rate can be greatly streamlined by the efficiency of the *adjusted-discount method*, which performs deflation and discounting in one step. Mathematically we can combine this two-step procedure into one by

$$i = i' + \bar{f} + i'\bar{f} \tag{17.2.4}$$

This implies that the market interest rate is a function of two terms, i′, $\bar{f}$. Note that if there is no inflationary effect, the two interest rates are the same ($\bar{f} = 0 \rightarrow$ i = i′). As either i′ or $\bar{f}$ increases, i also increases. For example, we can easily observe that when prices are increasing due to inflation, bond rates climb, because lenders (that is anyone who invests in a money-market fund, bond, or certificate of deposit) demand higher rates to protect themselves against the eroding value of their dollars. If inflation were at 3%, you might be satisfied with an interest rate of 7% on a bond because your return would more than beat inflation. If inflation were running at 10%, however, you would not buy a 7% bond; you might insist instead on a return of at least 14%. On the other hand, when prices are coming down, or at least are stable, lenders do not fear the loss of purchasing power with the loans they make, so they are satisfied to lend at lower interest rates.

17.3 Measures of Project Worth

This section shows how to compare alternatives on equal basis and select the wisest alternative from an economic standpoint. The three common measures based on cash flow equivalence are (1) equivalent present worth, (2) equivalent annual worth, and (3) rate of return. The present worth represents a measure of future cash flow relative to the time point "now" with provisions that account for earning opportunities. Annual worth is a measure of the cash flow in terms of the equivalent equal payments on an annual basis. The third measure is based on *yield* or percentage.

Describing Project Cash Flows

When a company purchases a fixed asset such as equipment, it makes an investment. The company commits funds today in the expectation of earning a return on those funds in the future. Such an investment is similar to that made by a bank when it lends money. For the bank loan, the future cash flow consists of interest plus repayment of the principal. For the fixed asset, the future return is in the form of cash flows from the profitable use of the asset. In evaluating a capital investment, we are concerned only with those cash flows that result directly from the investment. These cash flows, called *differential* or *incremental cash flows*, represent the change in the firm's total cash flow that occurs as a direct result of the investment.

We must also recognize that one of the most important parts of the capital budgeting process is the estimation of the relevant cash flows. For all examples in this section, however, net cash flows can be viewed as before-tax values or after-tax values for which tax effects have been recalculated. Since some organizations (e.g., governments and nonprofit organizations) are not taxable, the before-tax situation can be a valid base for that type of economic evaluation. This view will allow us to focus on our main area of concern, the economic evaluation of an investment project. The procedures for determining after-tax net cash flows in taxable situations are developed in Section 17.4.

Example 17.3.1 — Identifying Project Cash Flows

Merco Inc., a machinery builder in Louisville, KY, is considering making an investment of $1,250,000 in a complete structural-beam-fabrication system. The increased productivity resulting from the installation of the drilling system is central to the justification. Merco estimates the following figures as a basis for calculating productivity:

- Increased fabricated steel production: 2000 tons/year
- Average sales price/ton fabricated steel: $2566.50/ton
- Labor rate: $10.50/hr
- Tons of steel produced in a year: 15,000 tons
- Cost of steel per ton (2205 lb): $1950/ton
- Number of workers on layout, holemaking, sawing, and material handling: 17
- Additional maintenance cost: $128,500 per year

With the cost of steel at $1950/ton and the direct labor cost of fabricating 1 lb at 10 cents, the cost of producing a ton of fabricated steel is about $2170.50. With a selling price of $2566.50/ton, the resulting contribution to overhead and profit becomes $396/ton. Assuming that Merco will be able to sustain an increased production of 2000 tons per year by purchasing the system, the projected additional contribution has been estimated to be 2000 tons $\times$ $396 = $792,000.

Since the drilling system has the capacity to fabricate the full range of structural steel, two workers can run the system, one on the saw and the other on the drill. A third operator is required as a crane operator for loading and unloading materials. Merco estimates that to do the equivalent work of these

three workers with conventional manufacture requires, on the average, an additional 14 people for centerpunching, holemaking with radial or magnetic drill, and material handling. This translates into a labor savings in the amount of $294,000 per year ($10.50 × 40 hr/week × 50 weeks/year × 14). The system can last for 15 years with an estimated after-tax salvage value of $80,000. The expected annual corporate income taxes would amount to $226,000. Determine the net cash flow from undertaking the investment. Determine the net cash flows from the project over the service life.

Solution. The net investment cost as well as savings are as follows:

- Cash inflows:
  - Increased annual revenue: $792,000
  - Projected annual net savings in labor: $294,000
  - Projected after-tax salvage value at the end of year 15: $80,000
- Cash outflows:
  - Project investment cost: $1,250,000
  - Projected increase in annual maintenance cost: $128,500
  - Projected increase in corporate income taxes: $226,000

Now we are ready to summarize a cash flow table as follows:

Year	Cash Inflows	Cash Outflows	Net Cash Flows
0	0	$1,250,000	–$1,250,000
1	1,086,000	354,500	731,500
2	1,086,000	354,500	731,500
⋮	⋮	⋮	⋮
15	1,086,000 + 80,000	354,500	811,500

The project's cash flow diagram is shown in Figure 17.3.1.

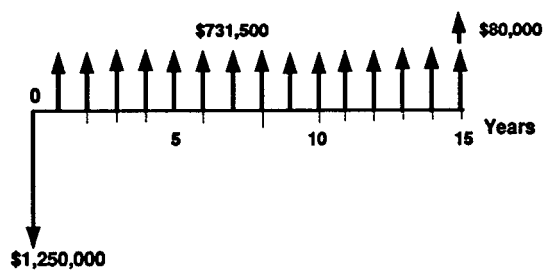

FIGURE 17.3.1 Cash flow diagram (Example 17.3.1).

Assuming these cost savings and cash flow estimates are correct, should management give the go-ahead for installation of the system? If management has decided not to install the fabrication system, what do they do with the $1,250,000 (assuming they have it in the first place)? The company could buy $1,250,000 of Treasury bonds. Or it could invest the amount in other cost-saving projects. How would the company compare cash flows that differ both in timing and amount for the alternatives it is considering? This is an extremely important question because virtually every engineering investment decision involves a comparison of alternatives. These are the types of questions this section is designed to help you answer.

Present Worth Analysis

Until the 1950s, the paycheck method* was widely used as a means of making investment decisions. As flows in this method were recognized, however, business people began to search for methods to improve project evaluations. This led to the development of discounted cash flow techniques (DCF), which take into account the time value of money. One of the DCFs is the net present worth method (NPW). A capital investment problem is essentially one of determining whether the anticipated cash inflows from a proposed project are sufficiently attractive to invest funds in the project. In developing the NPW criterion, we will use the concept of cash flow equivalence discussed in Section 17.2. Usually, the most convenient point at which to calculate the equivalent values is often time 0. Under the NPW criterion, the present worth of all cash inflows is compared against the present worth of all cash outflows that are associated with an investment project. The difference between the present worth of these cash flows, called the *net present worth* (NPW), determines whether or not the project is an acceptable investment. When two or more projects are under consideration. NPW analysis further allows us to select the best project by comparing their NPW figures.

We will first summarize the basic procedure for applying the present worth criterion to a typical investment project.

- Determine the interest rate that the firm wishes to earn on its investments. This represents an interest rate at which the firm can always invest the money in its *investment pool*. We often refer to this interest rate as either a *required rate of return* or a *minimum attractive rate of return* (MARR). Usually this selection will be a policy decision by top management. It is possible for the MARR to change over the life of a project, but for now we will use a single rate of interest in calculating NPW.
- Estimate the service life of the project.**
- Determine the net cash flows (net cash flow = cash inflow – cash outflow).
- Find the present worth of each net cash flow at the MARR. Add up these present worth figures; their sum is defined as the project's NPW.
- Here, a positive NPW means the equivalent worth of inflows are greater than the equivalent worth of outflows, so project makes a profit. Therefore, if the PW(i) is positive for a single project, the project should be accepted; if negative, it should be rejected. The decision rule is

$$\text{If } PW(i) > 0, \text{ accept the investment}$$

$$\text{If } PW(i) = 0, \text{ remain indifferent}$$

$$\text{If } PW(i) < 0, \text{ reject the investment}$$

Note that the decision rule is for a single project evaluation where you can estimate the revenues as well as costs associated with the project. As you will find later, when you are comparing alternatives with

* One of the primary concerns of most business people is whether and when the money invested in a project can be recovered. The *payback method* screens projects on the basis of how long it takes for net receipts to equal investment outlays. A common standard used in determining whether or not to pursue a project is that no project may be considered unless its payback period is shorter than some specified period of time. If the payback period is within the acceptable range, a formal project evaluation (such as the present worth analysis) may begin. It is important to remember that payback screening is not an *end* itself, but rather a method of screening out certain obvious unacceptable investment alternatives before progressing to an analysis of potentially acceptable ones. But the much-used payback method of equipment screening has a number of serious drawbacks. The principal objection to the payback method is its failure to measure profitability; that is, there is no "profit" made during the payback period. Simply measuring how long it will take to recover the initial investment outlay contributes little to gauging the earning power of a project.

the same revenues, you can compare them based on the cost only. In this situation (because you are minimizing costs, rather than maximizing profits), you should accept the project that results in smallest, or least negative, NPW.

Example 17.3.2 — Net Present Worth

Consider the investment cash flows associated with the metal fabrication project in Example 17.3.1. If the firm's MARR is 15%, compute the NPW of this project. Is this project acceptable?

Solution. Since the fabrication project requires an initial investment of $1,250,000 at n = 0 followed by the 15 equal annual savings of $731,500, and $80,000 salvage value at the end of 15 years, we can easily determine the NPW as follows:

$$PW(15\%)_{outflow} = \$1,250,000$$

$$\begin{aligned} PW(15\%)_{inflow} &= \$731,500(P/A,15\%,15) + \$80,000(P/F,15\%,15) \\ &= \$4,284,259 \end{aligned}$$

Then, the NPW of the project is

$$\begin{aligned} PW(15\%) &= PW(15\%)_{in\ flow} - PW(15\%)_{out\ flow} \\ &= \$4,284,259 - \$1,250,000 \\ &= \$3,034,259 \end{aligned}$$

Since PW (15%) > 0, the project would be acceptable.

Annual Equivalent Method

The annual equivalent worth (AE) criterion is a basis for measuring investment worth by determining equal payments on an annual basis. Knowing that we can convert any lump-sum cash amount into a series of equal annual payments, we may first find the NPW for the original series and then multiply the NPW by the capital recovery factor:

** Another special case of the PW criterion is useful when the life of a proposed project is *perpetual* or the planning horizon is extremely long. The process of computing the PW cost for this infinite series is referred to as the *capitalization* of project cost. The cost is known as the *capitalized cost.* It represents the amount of money that must be invested today to yield a certain return A at the end of each and every period forever, assuming an interest rate of i. Observe the limit of the uniform series present worth factor as N approaches infinity:

$$\lim_{N\to\infty}(P/A,i,N) = \lim_{N\to\infty}\left[\frac{(1+i)^N - 1}{i(1+i)^N}\right] = \frac{1}{i}$$

Thus, it follows that

$$PW(i) = A(P/A,i,N\to\infty) = \frac{A}{i} \tag{17.5}$$

Another way of looking at this, PW(i) dollars today, is to ask what constant income stream could be generated by this in perpetuity. Clearly, the answer is A = iPW(i). If withdrawals were greater than A, they could be eating into the principal, which would eventually reduce to 0.

$$AE(i) = PW(i)(A/P, i, N) \tag{17.3.1}$$

The accept-reject decision rule for a single *revenue* project is

If $AE(i) > 0$, accept the investment

If $AE(i) = 0$, remain indifferent

If $AE(i) < 0$, reject the investment

Notice that the factor (A/P, i, N) in Table 17.2.1 is positive for $-1 < i < \infty$. This indicates that the AE(i) value will be positive if and only if PW(i) is positive. In other words, accepting a project that has a positive AE(i) value is equivalent to accepting a project that has a positive PW(i) value. Therefore, the AE criterion should provide a basis for evaluating a project that is consistent with the NPW criterion.

As with the present worth analysis, when you are comparing mutually exclusive *service* projects whose revenues are the same, you may compare them based on *cost* only. In this situation, you will select the alternative with the minimum annual equivalent cost (or least negative annual equivalent worth).

Unit Profit/Cost Calculation

There are many situations in which we want to know the unit profit (or cost) of operating an asset. A general procedure to obtain such a unit profit or cost figure involves the following two steps:

- Determine the number of units to be produced (or serviced) each year over the life of the asset.
- Identify the cash flow series associated with the production or service over the life of the asset.
- Calculate the net present worth of the project cash flow series at a given interest rate and then determine the equivalent annual worth.
- Divide the equivalent annual worth by the number of units to be produced or serviced during each year. When you have the number of units varying each year, you may need to convert them into equivalent annual units.

To illustrate the procedure, we will consider Example 17.3.3, where the annual equivalent concept can be useful in estimating the savings per machine hour for a proposed machine acquisition.

Example 17.3.3 — Unit Profit per Machine Hour

Tiger Machine Tool Company is considering the proposed acquisition of a new metal-cutting machine. The required initial investment of $75,000 and the projected cash benefits and annual operating hours over the 3-year project life are as follows.

End of Year	Net Cash Flow	Operating Hours
0	–$75,000	
1	24,400	2,000
2	27,340	2,000
3	55,760	2,000

Compute the equivalent savings per machine hour at i = 15%.

Solution. Bringing each flow to its equivalent at time zero, we find

$$PW(15\%) = -\$75,000 + \$24,400(P/F, 15\%, 1) + \$27,340(P/F, 15\%, 2) + \$55,760(P/F, 15\%, 3)$$

$$= \$3553$$

Since the project results in a surplus of $3553, the project would be acceptable. We first compute the annual equivalent savings from the use of the machine. Since we already know the NPW of the project, we obtain the AE by

$$AE(15\%) = \$3553(A/P,15\%,3) = \$1556$$

With an annual usage of 2000 hr, the equivalent savings per machine hour would be

$$\text{Savings per machine hour} = \$1556/\$2000 \text{ hr} = \$0.78/\text{hr}$$

Comments. Note that we cannot simply divide the NPW amount ($3553) by the total number of machine hours over the 3-year period (6000 hr), or $0.59/hr. This $0.59 figure represents the *instant savings* in present worth for each hourly use of the equipment, but does not consider the time over which the savings occur. Once we have the annual equivalent worth, we can divide by the desired time unit if the compounding period is 1 year. If the compounding period is shorter, then the equivalent worth should be calculated for the compounding period.

Rate of Return Analysis

Along with the NPW and AE, the third primary measure of investment worth is based on yield, known as *rate of return*. The NPW measure is easy to calculate and apply. Nevertheless, many engineers and financial managers prefer rate of return analysis to the NPW method because they find it intuitively more appealing to analyze investments in terms of percentage rates of return than in dollars of NPW.

Internal Rate of Return

Many different terms refer to rate of return, including yield (that is, the yield to maturity, commonly used in bond valuation), internal rate of return, and marginal efficiency of capital. In this section, we will define *internal rate of return* as the break-even interest rate, i^*, which equates the present worth of a project's cash outflows to the present worth of its cash inflows, or

$$\begin{aligned} PW(i^*) &= PW_{\text{cash inflows}} - PW_{\text{cash outflows}} \\ &= 0 \end{aligned}$$

Note that the NPW expression is equivalent to

$$PW(i^*) = \frac{A_0}{(1+i^*)^0} + \frac{A_1}{(1+i^*)^1} + \cdots + \frac{A_N}{(1+i^*)^N} = 0 \qquad (17.3.2)$$

Here we know the value of A_n for all n, but not the value of i^*. Since it is the only unknown, we can solve for i^*. There will inevitably be N values of i^* that satisfy this equation. In most project cash flows you would be able to find a unique positive i^* that satisfies Equation (17.3.2). However, you may encounter some cash flow that cannot be solved for a single rate of return greater than –100%. By the nature of the NPW function in Equation (17.3.2), it is certainly possible to have more than one rate of return for a certain type of cash flow.* (For some cash flows, we may not find any rate of return at all.)

Finding the IRR

We don't need laborious manual calculations to find i^*. Many financial calculators have built-in functions for calculating i^*. It is also worth noting here that many spreadsheet packages have i^* functions, which solve Equation (17.3.2) very rapidly. This is normally done by entering the cash flows through a computer

keyboard or by reading a cash flow data file. As an alternative, you could try the trial-and-error method to locate the break-even interest that makes the net present worth equal to zero.

Accept/Reject Decision Rules

Why are we interested in finding the particular interest rate that equates a project's cost with the present worth of its receipts? Again, we may easily answer this by examining Figure 17.3.2. In this figure, we notice two important characteristics of the NPW profile. First, as we compute the project's PW(i) at a varying interest rate (i), we see that the NPW becomes positive for $i < i^*$, indicating that the project would be acceptable under the PW analysis for those values of i. Second, the NPW becomes negative for $i > i^*$, indicating that the project is unacceptable for those values of i. Therefore, the i^* serves as a *break-even* interest rate. By knowing this break-even rate, we will be able to make an accept/reject decision that is consistent with the NPW analysis.

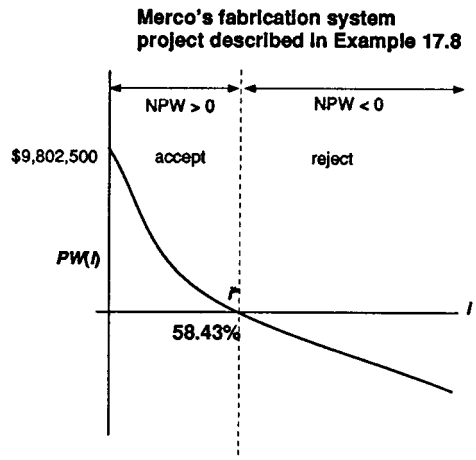

FIGURE 17.3.2 A net present worth profile for the cash flow series given in Figure 17.3.1 at varying interest rates. The project breaks even at 58.43% so that the NPW will be positive as long as the discount rate is less than 58.43%.

At the MARR the company will more than break even. Thus, the IRR becomes a useful gauge against which to judge project acceptability, and the decision rule for a simple project is

---

* When applied to projects that require investments at the outset followed by a series of cash inflows (or a simple project), the i^* provides an unambiguous criterion for measuring profitability. However, when multiple rates of return occur, none of them is an accurate portrayal of project acceptability or profitability. Clearly, then, we should place a high priority on discovering this situation early in our analysis of a project's cash flows. The quickest way to predict multiple i^*s is to generate a NPW profile and check to see if it crosses the horizontal axis more than once.

In addition to the NPW profile, there are good — although somewhat more complex — analytical methods for predicting multiple i^*s. Perhaps more importantly, there is a good method, which uses a *cost of capital*, of refining our analysis when we do discover multiple i^*s. Use of a cost of capital allows us to calculate a single accurate rate of return (also known as *return on invested capital*); it is covered in *Contemporary Engineering Economics*, C.S. Park, Addison-Wesley, 1997. If you choose to avoid these more complex applications of rate-of-return techniques, you must at a minimum be able to predict multiple i^*s via the NPW profile and, when they occur, select an alternative method such as NPW or AE analysis for determining project acceptability.

If IRR > MARR, accept the project

If IRR = MARR, remain indifferent

If IRR < MARR, reject the project

Note that this decision rule is designed to be applied for a single project evaluation. When we have to compare mutually exclusive investment projects, we need to apply the incremental analysis, as we shall see in a later section.

Example 17.3.4 — Rate of Return Analysis

Reconsider the fabrication investment project in Example 17.3.1. (a) What is the projected IRR on this fabrication investment? (b) If Merco's MARR is known to be 15%, is this investment justifiable?

Solution.

- (a) The net present worth expression as a function of interest rate (i) is

$$PW(i) = -\$1,250,000 + \$731,500(P/A,i,15) + \$80,000(P/F,i,15)$$
$$= 0$$

  Using Excel's financial function (IRR), we find the IRR to be 58.43%. (See Figure 17.3.2.) Merco will recover the initial investment fully and also earn 58.43% interest on its invested capital.
- (b) If Merco does not undertake the project, the $1,250,000 would remain in the firm's investment pool and continue to earn only 15% interest. The IRR figure far exceeds the Merco's MARR, indicating that the fabrication system project is an economically attractive one. Merco's management believes that, over a broad base of structural products, there is no doubt that the installation of its fabricating system would result in a significant savings, even after considering some potential deviations from the estimates used in the analysis.

Mutually Exclusive Alternatives

Until now, we have considered situations in which only one project was under consideration, and we were determining whether to pursue it, based on whether its present worth or rate of return met our MARR requirements. We were making an accept or reject decision about a *single* project.

In the real world of engineering practice, however, it is more typical for us to have two or more choices of projects for accomplishing a business objective. *Mutually exclusive* means that any one of several alternatives will fulfill the same need and that selecting one alternative means that the others will be excluded.

Analysis Period

The *analysis period* is the time span over which the economic effects of an investment will be evaluated. The analysis period may also be called the *study period* or *planning horizon*. The length of the analysis period may be determined in several ways: it may be a predetermined amount of time set by company policy, or it may be either implied or explicit in the need the company is trying to fulfill. In either of these situations, we consider the analysis period to be a *required service period*. When no required service period is stated at the outset, the analyst must choose an appropriate analysis period over which to study the alternative investment projects. In such a case, one convenient choice of analysis period is the period of useful life of the investment project.

When useful life of the investment project does not match the analysis or required service period, we must make adjustments in our analysis. A further complication, when we are considering two or more mutually exclusive projects, is that the investments themselves may have differing useful lives. We must

compare projects with different useful lives over an *equal time span*, which may require further adjustments in our analysis.

Analysis Period Equals Project Lives

Let's begin our analysis with the simplest situation where the project lives equal the analysis period. In this case, we compute the NPW for each project and select the one with highest NPW for revenue projects or least negative NPW for service projects. Example 17.3.5 will illustrate this point.

Example 17.3.5 — Two Mutually Exclusive Alternatives

A pilot wants to start her own company to airlift goods to the Commonwealth of Independent States (formerly the U.S.S.R.) during their transition to a free-market economy. To economize the start-up business, she decides to purchase only one plane and fly it herself. She has two mutually exclusive options: an old aircraft (A1) or a new jet (A2) with which she expects to have higher purchase costs, but higher revenues as well because of its larger payload. In either case, she expects to fold up business in 3 years because of competition from larger companies. The cash flows for the two mutually exclusive alternatives are given in thousand dollars:

n	A1	A2
0	–3,000	–$12,000
1	1,350	4,200
2	1,800	6,225
3	1,500	6,330

Assuming that there is no do-nothing alternative, which project would she select at MARR = 10%?

Solution. Since the required service period is 3 years, we should select the analysis period of 3 years. Since the analysis period coincides with the project lives, we simply compute the NPW value for each option. The equivalent NPW figures at i = 10% would be as follows:

- For A1:

$$PW(15\%)_{A1} = -\$3000 + \$1350(P/F,10\%,1) + \$1800(P/F,10\%,2) + \$1500(P/F,10\%,3)$$
$$= \$842$$

- For A2:

$$PW(15\%)_{A2} = -\$12,000 + \$4200(P/F,10\%,1) + \$6225(P/F,10\%,2) + \$6330(P/F,10\%,3)$$
$$= \$1719$$

Clearly, A2 is the most economical option.

Project Lives Differ from a Specified Analysis Period

Often project lives do not match the required analysis period and/or do not match each other. For example, two machines may perform exactly the same function, but one lasts longer than the other and both of them last longer than the analysis period for which they are being considered. We are then left with some unused portion of the equipment, which we include as salvage value in our analysis. Salvage value is the amount of money for which the equipment could be sold after its service or the dollar measure of its remaining usefulness.

When project lives are shorter than the required service period, we must consider how, at the end of the project lives, we will satisfy the rest of the required service period. Replacement projects — additional

projects to be implemented when the initial project has reached the limits of its useful life — are needed in such a case. Sufficient replacement projects must be analyzed to match or exceed the required service period.

To simplify our analysis, we sometimes assume that the replacement project will be exactly the same as the initial project, with the same corresponding costs and benefits. However, this assumption is not necessary. For example, depending on our forecasting skills, we may decide that a different kind of technology — in the form of equipment, materials, or processes — is a preferable replacement. Whether we select exactly the same alternative or a new technology as the replacement project, we are ultimately likely to have some unused portion of the equipment to consider as salvage value at the end of the required service period. On the other hand, if a required service period is relatively short, we may decide to lease the necessary equipment or subcontract the remaining work for the duration of the analysis period. In this case, we can probably exactly match our analysis period and not worry about salvage values.

Example 17.3.6 — Present Worth Comparison — Project Lives Shorter Than Analysis Period

The Smith Novelty Company, a mail-order firm, wants to install an automatic mailing system to handle product announcements and invoices. The firm has a choice between two different types of machines. The two machines are designed differently but have identical capacities and do exactly the same job. The $12,500 semiautomatic model A will last 3 years with a salvage value of $2000, while the fully automatic model B will cost $15,000 and last 4 years with a salvage value of $1500. The expected cash flows for the two machines including maintenance, salvage value, and tax effects are as follows:

n	Model A	Model B
0	–12,500	–$15,000
1	–5,000	–4,000
2	–5,000	–4,000
3	–5,000 + 2,000	–4,000
4		–4,000 + 1,500
5		

As business grows to a certain level, neither of the models can handle the expanded volume at the end of year 5. If that happens, a fully computerized mail-order system will need to be installed to handle the increased business volume. With this scenario, which model should the firm select at MARR = 15%?

Solution. Since both models have a shorter life than the required service period (5 years), we need to make an explicit assumption of how the service requirement is to be met. Suppose that the company considers leasing comparable equipment that has an annual lease payment of $6000 (after taxes) for the remaining required service period. In this case, the cash flow would look like Figure 17.3.3.

n	*Model A*	*Model B*
0	–12,500	–$15,000
1	–5,000	–4,000
2	–5,000	–4,000
3	–3,000	–4,000
4	**–6,000** –5,000	–2,500
5	**–6,000** –5,000	**–6,000** –5,000

Here the bold figures represent the annual lease payments. (It costs $6000 to lease the equipment and $5000 to operate anually. Other maintenance will be paid by the leasing company.) Note that both alternatives now have the same required service period of 5 years. Therefore, we can use NPW analysis.

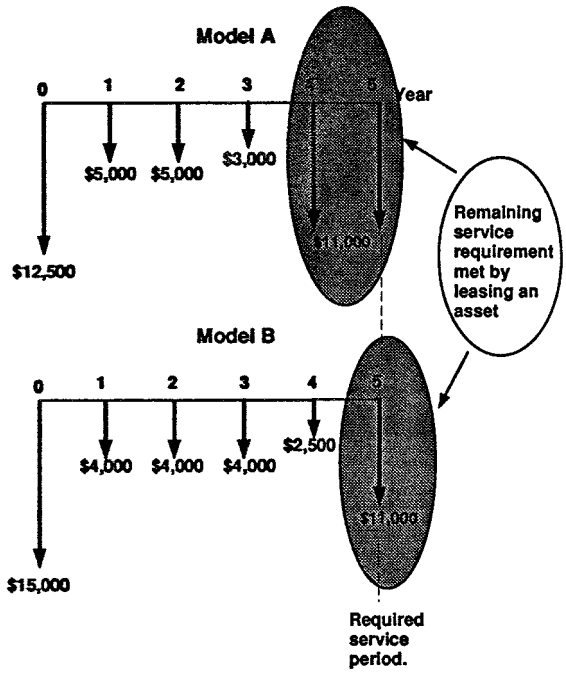

FIGURE 17.3.3 Comparison for unequal-lived projects when the required service period is longer then the individual project life (Example 17.3.6.)

$$PW(15\%)_A = -\$12,500 - \$5000(P/A,15\%,2) + \$3000(P/F,15\%,3)$$
$$- \$11,000(P/A,15\%,2)(P/F,15\%,3)$$
$$= -\$34,359$$

$$PW(15\%)_B = -\$15,000 - \$4000(P/A,15\%,3) - \$2500(P/F,15\%,4) - \$11,000(P/F,15\%,5)$$
$$= -\$32,747$$

Since these are service projects, model B is the better choice.

Flaws in Project Ranking by IRR. Under NPW, the mutually exclusive project with the highest worth figure was preferred. Unfortunately, the analogy does not carry over to IRR analysis. The project with the highest IRR may *not* be the preferred alternative. To illustrate the flaws of comparing IRRs to choose from mutually exclusive projects, suppose you have two mutually exclusive alternatives, each with a 1-year service life; one requires an investment of \$1000 with a return of \$2000 and the other requires \$5000 with a return of \$7000. You already obtained the IRRs and NPWs at MARR = 10% as follows:

n	A1	A2
0	–\$1000	–\$5000
1	222000	7000
IRR	100%	40%
PW(10%)	\$818	\$1364

Would you prefer the first project simply because you expect a higher rate of return?

We can see that A2 is preferred over A1 by the NPW measure. On the other hand, the IRR measure gives a *numerically* higher rating for A1. This inconsistency in ranking is due to the fact that the NPW is an *absolute (dollar)* measure of investment worth, while the IRR is a *relative (percentage)* measure and cannot be applied in the same way. That is, the IRR measure ignores the *scale* of the investment. Therefore, the answer is no; instead, you would prefer the second project with the lower rate of return, but higher NPW. The NPW measure would lead to that choice, but comparison of IRRs would rank the smaller project higher. Another approach, called *incremental analysis*, is needed.

Rate of Return on Incremental Investment

In our previous ranking example, the more costly option requires an incremental investment of $4000 at an incremental return of $5000. If you decide to take the more costly option, certainly you would be interested in knowing that this additional investment can be justified at the MARR. The 10% of MARR value implies that you can always earn that rate from other investment sources — $4400 at the end of 1 year for $4000 investment. However, by investing the additional $4000 in the second option, you would make an additional $5000, which is equivalent to earning at the rate of 25%. Therefore, the incremental investment can be justified.

Now we can generalize the decision rule for comparing mutually exclusive projects. For a pair of mutually exclusive projects (A, B), rate of return analysis is done by computing the *internal rate of return on incremental investment* (IRR_Δ) between the projects. Since we want to consider increments of investment, we compute the cash flow for the difference between the projects by subtracting the cash flow for the lower investment-cost project (A) from that of the higher investment-cost project (B). Then, the decision rule is select B, if $IRR_{B\text{-}A} > MARR$. Otherwise select A.

Example 17.3.7 — IRR on Incremental Investment: Two Alternatives

Reconsider the two mutually exclusive projects in Example 17.3.5.

n	B1	B2	B2–B1
0	–$3,000	–$12,000	–$9,000
1	1,350	4,200	2,850
2	1,800	6,225	4,425
3	1,500	6,330	4,830
IRR	25%	17.43%	

Since B1 is the lower cost investment project, we compute the incremental cash flow for B2–B1. Then we compute the IRR on this increment of investment by solving

$$-\$9000 + \$2850(P/F,i,1) + \$4425(P/F,i,2) + \$4830(P/F,i,3) = 0$$

We obtain $i^*_{B2\text{-}B1} = 15\%$. Since $IRR_{B2\text{-}B1} > MARR$, we select B2, which is consistent with the NPW analysis.

Comments. Why did we choose to look at the increment B2-B1 instead of B1-B2? We want the increment to have investment during at least some part of the time span so that we can calculate an IRR. Subtracting the lower initial investment project from the higher guarantees that the first increment will be investment flow. Ignoring the investment ranking, we might end up with an increment which involves borrowing cash flow and has no internal rate of return. This is the case for B1-B2. ($i^*_{B1\text{-}B2}$ is also 15%, not –15%.) If we erroneously compare this i^* with MARR, we might have accepted project B1 over B2.

17.4 Cash Flow Projections

With the purchase of any fixed asset such as equipment, we need to estimate the profits (more precisely, cash flows) that the asset will generate during its service period. An inaccurate estimate of asset needs can have serious consequences. If you invest too much in assets, you incur unnecessarily heavy expenses. Spending too little on fixed assets also is harmful, for then the firm's equipment may be too obsolete to produce products competitively and without an adequate capacity you may lose a portion of your market share to rival firms. Regaining lost customers involves heavy marketing expenses and may even require price reductions and/or product improvements, all of which are costly. We will begin this section by giving an overview on how a company determines its operating profit.

Operating Profit — Net Income

Firms invest in a project because they expect it to increase their wealth. If the project does this — if project revenues exceed project costs — we say it has generated a *profit*, or *income*. If the project reduces the owner's wealth, we say that the project has resulted in a *loss*. One of the most important roles of the accounting function within an organization is to measure the amount of profit or loss a project generates each year or in any other relevant time period. Any profit generated will be taxed. The accounting measure of a project's after-tax profit during a particular time period is known as *net income*.

Accountants measure the net income of a specified operating period by subtracting expenses from revenues for that period. These terms can be defined as follows:

1. The *project revenue* is the income earned by a business as a result of providing products or services to outsiders. Revenue comes from sales of merchandise to customers and from fees earned by services performed for clients or others.
2. The *project expenses* incurred are the cost of doing business to generate the revenues of that period. Some common expenses are the cost of the goods sold (labor, material, inventory, and supplies), depreciation, the cost of employees' salaries, the operating cost (such as the cost of renting a building and the cost of insurance coverage), and income taxes.

The business expenses listed above are all accounted for in a straightforward fashion on the income statement and balance sheet: the amount paid by the organization for each item would translate dollar for dollar into expenses in financial reports for the period. One additional category of expenses, the purchase of new assets, is treated by depreciating the total cost gradually over time. Because it plays a role in reducing taxable income, depreciation accounting is of special concern to a company.

Accounting Depreciation

The acquisition of fixed assets is an important activity for a business organization, whether the organization is starting up or acquiring new assets to remain competitive. The systematic allocation of the initial cost of an asset in parts over a time known as its depreciable life is what we mean by *accounting depreciation*. Because accounting depreciation is the standard of the business world, we sometimes refer to it more generally as *asset depreciation*.

The process of depreciating an asset requires that we make several preliminary determinations:

1. *What can be depreciable?* Depreciable property includes buildings, machinery, equipment, and vehicles. Inventories are not depreciable property because they are held primarily for sale to customers in the ordinary course of business. If an asset has no definite service life, the asset cannot be depreciated. For example, *you can never depreciate land*.
2. *What cost base should be used in asset depreciation?* The *cost base* of an asset represents the total cost that is claimed as an expense over an asset's life, that is, the sum of the annual depreciation expenses. The cost base generally includes the actual cost of the asset and all the other incidental expenses, such as freight, site preparation, and installation. This total cost, rather

than the cost of the asset only, must be the depreciation base charged as an expense over the asset's life.

3. *What is the asset's value at the end of its useful life?* The salvage value is an asset's value at the end of its life; it is the amount eventually recovered through sale, trade-in, or salvage. The eventual salvage value of an asset must be estimated when the depreciation schedule for the asset is established. If this estimate subsequently proves to be inaccurate, then an adjustment must be made.
4. *What is the depreciable life of the asset?* Historically, depreciation accounting included choosing a depreciable life that was based on the service life of an asset. Determining the service life of an asset, however, was often very difficult, and the uncertainty of these estimates often led to disputes between taxpayers and the IRS. To alleviate the problems, the IRS published guidelines on lives for categories of assets known as *Asset Depreciation Ranges*, or ADRs. These guidelines specified a range of lives for classes of assets based on historical data, and taxpayers were free to choose a depreciable life within the specified range for a given asset.
5. *What method of depreciation do we choose?* Companies generally calculate depreciation one way when figuring taxes and another way when reporting income (profit) to investors: (1) they use the straight-line method (or declining balance or sum-of-years' digits) for investors and (2) they use the fastest rate permitted by law (known as "modified accelerated cost recovery system [MACRS]") for tax purposes. Under the straight-line method, for an asset with a 5-year life which costs $10,000 and has a $1000 salvage value, the annual depreciation charge is ($10,000 – $1000)/5 = $1800. For tax purposes, Congress created several classes of assets, each with a more or less arbitrarily prescribed life called a *recovery period* or *class life*. The depreciable base is not adjusted for salvage value, which is the estimated market value of the asset at the end of its useful life. Table 17.4.1 describes what types of property fit into the different class life groups and the allowed depreciation percentages. Congress developed these recovery allowance percentages based on the declining balance method, with a switch to straight-line depreciation at some point in the asset's life. The MACRS recovery percentages as shown in Table 17.4.1 also employ the half-year convention — that is, they assume that all assets are put into service at midyear and, hence, generate a half-year's depreciation.

Corporate Income Taxes

Corporate taxable income is defined as follows:

$$\text{taxable income} = \text{gross income (revenues)} - (\text{cost of goods sold} + \text{depreciation} + \text{operating expenses})$$

Once taxable income is calculated, income taxes are determined by

$$\text{income taxes} = (\text{tax rate}) \times (\text{taxable income})$$

The corporate tax rate structure for 1996 is relatively simple. There are four basic rate brackets (ranging from 15 to 35%) plus two surtax rates (5 and 3%) based on taxable incomes, and businesses with lower taxable incomes continue to be taxed at lower rates than those with higher taxable incomes.

Tax Treatment of Gains or Losses for Depreciable Assets

When a depreciable asset used in business is sold for an amount different from its book value, this gain or loss has an important effect on income taxes. An asset's book value at any given time is determined by

TABLE 17.4.1 MACRS Depreciation Schedules for Personal Properties with Half-Year Convention

	Personal Property						
Year	Class Depreciation Rate	3 200% DB	5 200% DB	7 200% DB	10 200% DB	15 150% DB	20 150% DB
1		33.33	20.00	14.29	10.00	5.00	3.750
2		44.45	32.00	24.49	18.00	9.50	7.219

4		7.41	11.52*	12.49	11.52	7.70	6.177
5			11.52	8.93*	9.22	6.93	5.713
6			5.76	8.92	7.37	6.23	5.285
7				8.93	6.55*	5.90*	4.888
8				4.46	6.55	5.90	4.522
9					6.56	5.91	4.462*
10					6.55	5.90	4.461
11					3.28	5.91	4.462
12						5.90	4.461
13						5.91	4.462
14						5.90	4.461
15						5.91	4.462
16						2.95	4.461
17							4.462
18							4.461
19							4.462
20							4.461
21							2.231

Note: "*" denotes year to switch from declining balance to straight line.

Property Class	Applicable Property
3-year	Machine tools
5-year	Automobiles, light trucks, high-tech equipment
7-year	Manufacturing equipment, office furniture
10-year	Vessels, barges, tugs, railroad cars
15-year	Utility property (water, telephone)
20-year	Municipal sewers, electrical power plant

$$\text{book value} = \text{cost base} - \text{total amount of depreciation}$$

The gain or loss is found by

$$\text{gains (losses)} = \text{salvage value} - \text{book value}$$

where the salvage value represents the proceeds from the sale less any selling expense or removal cost.

These gains, commonly known as *depreciation recapture*, are taxed as ordinary income. In the unlikely event that if an asset is sold for an amount greater than its initial cost, the gains (salvage value – book value) are divided into two parts (ordinary gains and capital gains) for tax purposes:

$$\text{gains} = \text{salvage value} - \text{book value}$$

$$= \underbrace{(\text{salvage value} - \text{cost base})}_{\text{capital gains}} + \underbrace{(\text{cost base} - \text{book value})}_{\text{ordinary gains}}$$

Capital gains are normally taxed at a different rate from that of ordinary gains.

After-Tax Cash Flow Analysis

In developing an after-tax flow, we are concerned only with those cash flows that result directly from the project. These cash flows, called *incremental cash flows*, represent the change in the firm's total cash flows that occurs as a direct result of undertaking the project. There are several elements that contribute toward the project cash flows. In preparing the cash flow statement which shows sources and uses of cash in project undertaking, we may group them into three areas: (1) cash flow elements associated with operations, (2) cash flow elements associated with investment activities (capital expenditures), and (3) cash flow elements associated with project financing (such as borrowing). The main purpose of this grouping is to provide information about the operating, investing, and financing activities of a project.

- *Operating Activities:* In general, cash flows from operations include current sales revenue, cost of goods sold, operating expense, and income taxes. Cash flows from operations should generally reflect the cash effects of transactions entering into the determination of net income. The interest portion of a loan repayment is a deductible expense when determining net income, and it is included in the operating activities. Since we will usually look only at yearly flows, it is logical to express all cash flows on a yearly basis. We can determine the net cash flow from operations either (1) based on net income or (2) based on cash flow by computing income taxes directly. When we use net income as the starting point for cash flow determination, we should add any noncash expenses (mainly depreciation) back to net income to compute the net cash flow. Thus,

$$\text{net operating cash flow} = \text{net income} + \text{noncash expenses}$$

$$(\text{depreciation})$$

Approach 1	**Approach 2**
Cash revenues (savings)	Cash revenues (savings)
–Cost of goods sold	–Cost of goods sold
–Depreciation	
–Operating expense	–Operating expense
–Interest expense	–Interest expense
Taxable income	
–Income taxes	–Income taxes
Net income + depreciation	Operating cash flow

In business practice, accountants usually prepare the cash flow statements based on the net income, namely, using Approach 1, whereas Approach 2 is commonly used in many traditional engineering economic texts. If you learn only Approach 2, it is more than likely that you need to be retrained to learn Approach 1 to communicate with the financing and accounting professionals within your organization. Therefore, we will use the income statement approach (Approach 1) whenever possible throughout this section.

- *Investing Activities:* Three types of investment flows are associated with buying a piece of equipment: the original investment, salvage value at the end of its useful life, and working capital investment* or recovery.** We will assume that our outflow for both capital investment and working capital investment is as if they take place in year 0. It is quite possible that both investments will not occur instantaneously, but rather over a few months as the project gets into gear; we could then use year 1 as an investment year. (Capital expenditures may occur over several years before a large investment project becomes fully operational. In this case, we should enter all expenditures as they occur.) For a small project, either method of timing these flows is satisfactory, because the numerical differences are likely to be insignificant.
- *Financing Activities:* Cash flows classified as financing activities include (1) the amount of borrowing and (2) repayment of principal. Recall that interest payments are tax deductible expenses so that they are usually classified as operating, not financing, activities.

Then, net cash flow for a given year is simply the sum of the net cash flows from these three activities.

Example 17.4.1 — Developing a Cash Flow Statement

A computerized machining center has been proposed for a small tool manufacturing company. If the new system costing $125,000 is installed, it will generate annual revenues of $100,000 and require $20,000 in annual labor, $12,000 in annual material expenses, and another $8000 in annual overhead (power and utility) expenses. The automation facility would be classified as a 7-year MACRS property. The company expects to phase out the facility at the end of 5 years, at which time it will be sold for $50,000. The machining center will require an investment of $23,331 in working capital (mainly spare parts inventory), which will be recovered in full amount at the end of the project life. Assume that $62,500 of the $125,000 paid for the investment is obtained through a bank loan which is to be repaid in equal annual installments at 10% interest over 5 years. The remaining $62,500 will be provided by equity (for example, from retained earnings). Find the year-by-year after-tax net cash flow for the project at a 40% marginal tax rate based on the net income (Approach 1), and determine the after-tax net present worth of the project at the company's MARR of 15%.

Discussion. We will use the business convention that no signs (positive or negative) are used in preparing the income statement, except in the situation where we have a negative taxable income or tax savings. In this situation we will use ( ). However, in preparing the cash flow statement, we will observe explicitly the sign convention: a positive sign indicating cash inflow, a negative sign or ( ) indicating cash outflow.

Solution. Before presenting the cash flow table, we need some preliminary calculations. The following notes explain the essential items in Table 17.4.2.

- *Depreciation Calculation*:
  1. If it is held for all 7 years, we depreciate a 7-year property in respective percentages of 14.29, 24.49, 17.49, 12.49, 8.93, 8.92, 8.93, and 4.46% (see Table 17.4.1).
  2. If the asset is sold at the end of the fifth tax year (during the recovery period), the applicable depreciation amounts would be $17,863, $30,613, $21,863, $15,613, and $5581. Since the

* Normally, additional inventories are required to support a new operation and increased accounts receivable. These increases in current assets must be financed. On the other hand, accounts payable will also increase as a result of business expansion and this will reduce the net cash needed to finance inventories and accounts receivable. The difference is known as *net change in working capital.* If this difference is positive, an investment in working must be made.

** As the project approaches termination, inventories are sold off and not replaced, and account receivables are eventually collected. As this change occurs, the firm experiences an end-of-project cash flow (known as *working capital recovery*) that is equal to the net working capital investments that were made when the project was begun.

TABLE 17.4.2 Cash Flow Statement for the Automated Machining Center Project with Debt Financing (Example 17.4.1)

	0	1	2	3	4	5
Income Statement						
Revenues		$100,000	$100,000	$100,000	$100,000	$100,000
Labor		20,000	20,000	20,000	20,000	20,000
Material		12,000	12,000	12,000	12,000	12,000
Overhead		8,000	8,000	8,000	8,000	8,000
Depreciation		17,863	30,613	21,863	15,613	5,581
Debt interest		6,250	5,226	4,100	2,861	1,499
Taxable income		$35,887	$24,161	$34,037	$41,526	$52,920
Income taxes (40%)		14,355	9,664	13,615	16,610	21,168
Net income		$21,532	$14,497	$20,433	$24,916	$31,752
Cash Flow Statement						
Operating activities						
Net income		21,532	14,497	20,422	24,916	31,752
Depreciation		17,863	30,613	21,863	15,613	5,581
Investment activities						
Investment	(125,000)					
Salvage						50,000
Gains tax						(6,613)
Working capital	(23,331)					23,331
Financing activities						
Borrowed funds	62,500					
Principal repayment		(10,237)	(11,261)	(12,387)	(13,626)	(14,988)
Net cash flow	$(85,831)	$29,158	$33,849	$29,898	$26,903	$89,063

asset is disposed of in the fifth tax year, the last year's depreciation, which would ordinarily be $11,163, is halved due to the half-year convention.

- *Salvage Value and Gain Taxes*: In year 5, we must deal with two aspects of the asset's disposal — salvage value and gains (both ordinary as well as capital). We list the estimated salvage value as a positive cash flow. Taxable gains are calculated as follows:
  1. The total depreciation in years 1 to 5 is $17,863 + $30,613 + $21,863 + $15,613 + $5581 = $91,533.
  2. The book value at the end of period 5 is the cost base minus the total depreciation, or $125,000 – $91,533 = $33,467.
  3. The gains on the sale are the salvage value minus the book value, or $50,000 – $33,467 = $16,533. (The salvage value is less than the cost base, so all the gain is ordinary.)
  4. The tax on the ordinary gains is $16,633 × 40% = $6,613. This is the amount that is placed in the table under "gains tax".
- *Interest and principal repayment*: We first need to compute the size of the annual installments:

$$\$62,500(A/P,10\%,5) = \$16,487$$

Next, we determine the repayment schedule of the loan by itemizing both the interest and the principal represented in each annual repayment as follows:

The interest payments are listed under the income statement and the principal payments are listed under the cash flow statement as shown in Table 17.4.2.

Year	Beginning Balance	Interest Payment	Principal Payment	Ending Balance
1	$62,500	$6,250	$10,237	$52,263
2	52,263	5,226	11,261	41,002
3	41,002	4,100	12,387	28,615
4	28,615	2,861	13,626	14,989
5	14,989	1,499	14,988	0

- *Investment Analysis:* Once we obtain the project's after-tax net cash flows, we can determine their equivalent present worth at the firm's interest rate of 15%. The present value equivalent of the after-tax cash flow series is

$$PW(15\%) = -\$85,351 + \$29,158(P/F,15\%,1) + \ldots + \$89,063(P/F,15\%,5)$$
$$= \$44,439$$

This means that investing $125,000 in this automated facility would bring in enough revenue to recover the initial investment and the cost of funds with a surplus of $44,439.

Effects of Inflation on Project Cash Flows

We now introduce inflation into estimating project cash flows. We are especially interested in two elements of project cash flows — depreciation expenses and interest expenses — that are essentially immune to the effects of inflation. We also consider the complication of how to proceed when multiple price indexes have been used in generating various project cash flows.

Because depreciation expenses (as well as loan repayment) are calculated on some base-year purchase amount, they do not increase over time to keep pace with inflation. Thus, they lose some of their value to defer taxes as inflation drives up the general price level and hence taxable income. Similarly, salvage values of depreciable assets can increase with the general inflation rate and, because any gains on salvage values are taxable, they can result in increased taxes.

Example 17.4.2 — After-Tax Cash Flows under Inflation

A construction firm is offered a fixed-price contract for a 5-year period. The firm will be paid $23,500 (actual dollars) per year for the contract period. In order to accept the contract, the firm must purchase equipment costing $15,000 and requiring $13,000 (constant dollars) per year to operate. The equipment qualifies for 5-year MACRS depreciation and is expected to have a salvage value of $1000 at the end of 5 years. Use a tax rate of 40% and an inflation-free interest rate of 20%. If the general inflation rate $(\bar{f})$ is expected to average 5% over the next 5 years, salvage value at the annual rate of 5%, and operating expenses at 8% per year for the project duration, should the contractor accept the contract?

Solution. The analysis of this situation should explicitly consider inflation, since the contractor is being offered a fixed-price contract and cannot increase the fee to compensate for increased costs. In this problem, as is common practice, we assume that all estimated costs are expressed in today's dollars, and actual costs will be increased due to inflation.

The Excel spreadsheet analysis is shown in Table 17.4.3, where the first five rows are designated as the input fields. Then column C in both the income statement and the cash flow statement is reserved for entering the specific inflation rate for the item listed in that row. Since the O&M costs are responsive to inflation, we can automate the cell entries by using the following cell formulas:

TABLE 17.4.3 Excel's Spreadsheet Application to "What If" Questions — What General Inflation Rate Does the Project Break Even? (Example 17.15)

	A	B	C	D	E	F	G	H	I
1									
2		INPUT:	O&M Cost	$ 13,000			General Inflation Rate	5.00%	
3			Salvage	$ 1,000			Inflation-Free Interest	20.00%	
4			Contract $	$ 23,000			Market Interest Rate	26.00%	
5			Investment	$ 15,000			Income Tax Rate	40.00%	
6									
7			Inflation Rate	0	1	2	3	4	5
8		Income Statement							
9									
10		Revenues			$ 23,500	$ 23,500	$ 23,500	$ 23,500	$ 23,500
11		Expenses:							
12		O&M	8%		14,040	15,163	16,376	17,686	19,101
13		Depreciation			3,000	4,800	2,880	1,728	864
15		Taxable Income			$ 6,460	$ 3,537	$ 4,244	$ 4,086	$ 3,535
16		Income Taxes (40%)			2,584	1,415	1,697	1,634	1,414
18		Net Income			$ 3,876	$ 2,122	$ 2,546	$ 2,451	$ 2,121
19									
20		Cash Flow Statement							
21									
22		Operating Activities:							
23		Net Income			3,876	2,122	2,546	2,451	2,121
24		Depreciation			3,000	4,800	2,880	1,728	864
25		Investment Activities:							
26		Investment		(15,000)					
27		Salvage	5%						1,276
28		Gains Tax							181
30		Net Cash Flow		$ (15,000)	$ 6,876	$ 6,922	$ 5,426	$ 4,179	$ 4,442
31		(in actual dollars)							
32		Net Cash Flow		$ (15,000)	$6,549	$6,279	$4,687	$3,438	$3,480
33		(in constant dollars)							
34		Equ. Present Worth		$ (15,000)	$5,457	$4,360	$2,713	$1,658	$1,399
36		Net Present Worth	$587						
37		Internal Rate of Return	22.03%						

$$\text{cell E12} = \$D\$2^{*}(1+\$C\$12)$$

$$\text{cell F12} = E12^{*}(1+\$C\$12)$$

$$\vdots \quad \vdots$$

$$\text{cell I12} = H12^{*}(1+\$C\$12)$$

Note that the salvage value in cell I27 has been increased at 5%. (When no inflation rate is given for a specific cost category, it is normally assumed that the general inflation rate holds.) Gains taxes on disposal are based on the difference between book value and salvage value, in this case, $1276 – $1728 = ($452) or loss of $452. This results in a tax savings of ($452) (0.40) = $181, as shown in cell I28.

In row 12, operating expenses have been increased at 8%. As explained in the section "Loss of Purchasing Power," actual-dollar cash flows are converted to constant-dollar flows by "deflating" at the general inflation rate. The IRR is calculated at 22.03%, based on the constant-dollar cash flows. This is compared to the MARR of 20%, the inflation-free interest rate, indicating that this is an acceptable contract as long as the 5 and 8% escalation rates are correct.

Since no one can predict inflation rates in any precise manner, it is always wise to investigate the effects of changes in these rates. This is very easy to do with a spreadsheet. For example, we can easily determine the value of the general inflation rate at which this project exactly earns 20%. The value of $\bar{f}$ was adjusted manually until the IRR was exactly 20%. This would not be a good project if $\bar{f}$ were greater than 6.77% (cell H2). (Note that at the exact value of $\bar{f}$ (6.771%), the NPW in cell C36 will be zero or its rate of return would be 20%.) Similarly, you can vary the O&M cost and salvage value to see how the project's profitability changes.

17.5 Sensitivity and Risk Analysis

In previous sections, the cash flows from projects were assumed to be known with complete certainty, and our analysis was concerned with measuring the economic worth of projects and selecting the best investment projects. Although these results can provide reasonable decision bases for many investment situations, we should certainly consider the more usual situation where forecasts of cash flows are subject to some degree of uncertainty. In this situation, management rarely has precise expectations regarding the future cash flows to be derived from a particular project. In fact, the best that the firm can reasonably expect to do is to estimate the range of possible future costs and benefits and the relative chances of achieving a certain return on the investment. We can use the term risk in describing an investment project whose cash flow is not known in advance with absolute certainty, but for which an array of alternative outcomes and their probabilities (odds) are known. We will also use the term project risk to refer to the variability in a project's NPW. A greater project risk means that there is a greater variability in the project's NPW, or simply saying that *risk is the potential for loss*. We may begin analyzing project risk by first determining the uncertainty inherent in a project's cash flows. We can consider risk in a number of ways ranging from making informal judgments to calculating complex economic and statistical analyses. In this section, we will introduce three methods of describing project risk: (1) sensitivity analysis, (2) scenario analysis, and (3) risk analysis. We shall explain each method with a single example (Boston Metal Company).

Project Risk

The decision to make a major capital investment such as the introduction of a new product requires cash flow information over the life of the project. The profitability estimate of the investment depends on cash flow estimations, which are generally uncertain. Many cash flow elements (such as demand) are subject to substantial uncertainty. The common approach is to make single-number "best estimates" for each of the uncertain factors and then to calculate measures of profitability such as NPW or rate of return for the project. This approach has two drawbacks:

1. There is no guarantee that the "best estimates" will ever match actual values.
2. There is no way to measure the risk associated with the investment or the project risk. In particular, the manager has no way of determining either the probability that the project will lose money or the probability that it will generate very large profits.

Because cash flows can be so difficult to estimate accurately, project managers frequently consider a range of possible values for cash flow elements. If there is a range of possible values for individual cash flows, it follows that there is a range of possible values for the NPW of a given project. Clearly, the analyst will want to try to gauge the probability and reliability of individual cash flows occurring and, consequently, the level of certainty about achieving the overall project worth.

Sensitivity Analysis

One way to glean a sense of the possible outcomes of an investment is to perform a sensitivity analysis. This analysis determines the effect on NPW of variations in the input variables (such as revenues,

operating cost, and salvage value) used to estimate after-tax cash flows. A *sensitivity analysis* reveals how much the NPW will change in response to a given change in an input variable. In a calculation of cash flows, some items have a greater influence on the final result than others. In some problems, we may easily identify the most significant item. For example, the estimate of sales volume is often a major factor in a problem in which the quantity sold varies among the alternatives. In other problems, we may want to locate the items that have an important influence on the final results so that they can be subjected to special scrutiny.

Sensitivity analysis is sometimes called "what-if" analysis because it answers questions such as: What if incremental sales are only 1000 units, rather than 2000 units? Then what will the NPW be? Sensitivity analysis begins with a base-case situation, which is developed using the most-likely values for each input. Then we change the specific variable of interest by several specific percentages above and below the most-likely value, holding other variables constant. Next, we calculate a new NPW for each of these values. A convenient and useful way to present the results of a sensitivity analysis is to plot *sensitivity graphs*. The slopes of the lines show how sensitive the NPW is to changes in each of the inputs: the steeper the slope, the more sensitive the NPW is to a change in the particular variable. It identifies the crucial variables that affect the final outcome most. We will use Example 17.5.1 to illustrate the concept of sensitivity analysis.

Example 17.5.1 — Sensitivity Analysis

Boston Metal Company (BMC), a small manufacturer of fabricated metal parts, must decide whether to enter the competition to be the supplier of transmission housings for Gulf Electric. Gulf Electric has its own in-house manufacturing facility to produce transmission housings, but it has almost reached its maximum production capacity. Therefore, Gulf is looking for an outside supplier. To compete, the firm must design a new fixture for the production process and purchase a new forge. The new forge would cost $125,000, including tooling costs for the transmission housings. If BMC gets the order, it may be able to sell as many as 2000 units per year to Gulf Electric for $50 each, and the variable production costs,* such as direct labor and direct material costs, will be $15 per unit. The increase in fixed costs** other than depreciation will amount to $10,000 per year. The firm expects that the proposed transmission-housings project would have about a 5-year product life. The firm also estimates that the amount ordered by Gulf Electric for the first year will be ordered in each of the subsequent 4 years. (Due to the nature of contracted production, the annual demand and unit price would remain the same over the project after the contract is signed.) The initial investment can be depreciated on a MACRS basis over the 7-year period, and the marginal income tax rate is expected to remain at 40%. At the end of 5 years, the forge machine is expected to retain a market value of about 35% of the original investment. Based on this information, the engineering and marketing staffs have prepared the cash flow forecasts shown in Table 17.5.1. Since NPW is positive ($40,169) at the 15% opportunity cost of capital (MARR), the project appears to be worth undertaking.

However, BMC's managers are uneasy about this project because there are too many uncertain elements that have not been considered in the analysis. If decided, BMC must make the investment in the forging machine to provide some samples with Gulf Electric as a part of the bidding process. If Gulf Electric does not like BMC's sample, BMC stands to lose the entire investment in the forging machine. On the other hand, if Gulf likes BMC's sample but it is overpriced, BMC would be under pressure to bring the price in line with competing firms. There is even a possibility that BMC would get a smaller order as Gulf may utilize their overtime capacity to produce some extra units. They also are not certain about the variable and fixed cost figures. Recognizing these uncertainties, the managers want to assess the various potential future outcomes before making a final decision. (a) Perform a sensitivity analysis to each variable and (b) develop a sensitivity graph.

---

* Expenses that change in direct proportion to the change in volume of sales or production.

** Expenses that do not vary as the volume of sales or production changes. For example, property taxes, insurance, depreciation, and rent are usually fixed expenses.

TABLE 17.5.1 A Typical Excel Worksheet Design to Perform Sensitivity Analyses (Example 17.5.1)

Discussion. Table 17.5.1 shows BMC's expected cash flows — but there is no guarantee that they will indeed materialize. BMC is not particularly confident in is revenue forecasts. The managers think that if competing firms enter the market, BMC will lose a substantial portion of the projected revenues. Before undertaking the project described, the company wants to identify the key variables that determine whether the project will succeed or fail. The marketing department has estimated revenue as follows:

$$\text{annual revenue} = (\text{product demand})(\text{unit price})$$

$$= (2000)(\$50) = \$100,000$$

The engineering department has estimated variable costs such as labor and material per unit at $15. Since the projected sales volume is 2000 units per years, the total variable cost is $30,000.

Having defined the unit sales, unit price, unit variable cost, and fixed cost, we conduct a sensitivity analysis with respect to these key input variables. This is done by varying each of the estimates by a

given percentage and determining what effect the variation in that item has on the final results. If the effect is large, the result is sensitive to that item. Our objective is to locate the most sensitive item(s).

Solution.

(a) *Sensitivity analysis:* We begin the sensitivity analysis with a "base-case" situation, which reflects the best estimate (expected value) for each input variable. In developing Table 17.5.2, we changed a given variable by 20% in 5% increments, above and below the base-case value, and calculated new NPWs, holding other variables constant. The values for both sales and operating costs were the expected, or base-case, values, and the resulting $40,169 is called the base-case NPW. Now we ask a series of "what-if" questions: What if sales are 20% below the expected level? What if operating costs rise? What if the unit price drops from $50 to $45? Table 17.5.2 summarizes the results of varying the values of the key input variables.

(b) *Sensitivity graph:* Figure 17.5.1 shows the transmission project's sensitivity graphs for six of the key input variables. The base-case NPW is plotted on the ordinate of the graph at the value 1.0 on the abscissa. Next, the value of product demand is reduced to 0.95 of its base-case value, and the NPW is recomputed with all other variables held at their base-case value. We repeat the process by either decreasing or increasing the relative deviation from the base case. The lines for the variable unit price, variable unit cost, fixed costs, and salvage value are obtained in the same manner. In Figure 17.5.1, we see that the project's NPW is very sensitive to changes in product demand and unit price, is fairly sensitive to changes in the variable costs, and is relatively insensitive to changes in the fixed cost and the salvage value.

Graphic displays such as those in Figure 17.5.1 provide a useful means to communicate the relative sensitivities of the different variables on the corresponding NPW value. However, the sensitivity graph does not explain any variable interactions among the variables or the likelihood of realizing any specific deviation from the base case. Certainly, it is conceivable that an answer might not be very sensitive to changes in either of the two items, but very sensitive to combined changes in them.

Scenario Analysis

Although sensitivity analysis is useful, it does have limitations. It is often difficult to specify precisely the relationship between a particular variable and the NPW. The relationship is further complicated by interdependencies among the variables. Holding operating costs constant while varying unit sales may ease the analysis, but in reality, operating costs do not behave in that manner. Yet it may complicate the analysis too much to permit movement in more than one variable at a time. A scenario analysis is a technique that does consider the sensitivity of NPW both to changes in key variables and to the range of likely variable values. For example, the decision-maker may consider two extreme cases, a "worst-case" scenario (low unit sales, low unit price, high variable cost per unit, high fixed cost, and so on) and a "best-case" scenario. The NPWs under the worst and best conditions are then calculated and compared to the expected, or base-case, NPW. Example 17.5.2 will illustrate a plausible scenario analysis for the BMC's transmission-housings project.

Example 17.5.2 — Scenario Analysis

Consider again BMC's transmission-housing project in Example 17.5.2. Assume that the company's managers are fairly confident of their estimates of all the projects's cash flow variables except that for unit sales. Further, assume that they regard a decline in unit sales to below 1600 or a rise above 2400 as extremely unlikely. Thus, decremental annual sales of 400 units define the lower bound, or the worst-case scenario, whereas incremental annual sales of 400 units define the upper bound, or the best-case scenario. (Remember that the most-likely value was 2000 in annual unit sales.) Discuss the worst- and best-case scenarios, assuming that the unit sales for all 5 years would be equal.

TABLE 17.5.2 Sensitivity Analysis for Six Key Input Variables (Example 17.5.1)

Deviation	-20%	-15%	-10%	-5%	Base 0%	5%	10%	15%	20%
Unit price	$ (57)	$ 9,999	$ 20,055	$ 30,111	$ 40,169	$ 50,225	$ 60,281	$ 70,337	$ 80,393
Demand	$ 12,010	$ 19,049	$ 26,088	$ 33,130	$ 40,169	$ 47,208	$ 54,247	$ 61,286	$ 68,325
Variable cost	$ 52,236	$ 49,219	$ 46,202	$ 43,186	$ 40,169	$ 37,152	$ 34,135	$ 31,118	$ 28,101
Fixed cost	$ 44,191	$ 43,185	$ 42,179	$ 41,175	$ 40,169	$ 39,163	$ 38,157	$ 37,151	$ 36,145
Salvage value	$ 37,782	$ 38,378	$ 38,974	$ 39,573	$ 40,169	$ 40,765	$ 41,361	$ 41,957	$ 42,553
MARR	$ 53,588	$ 50,075	$ 46,670	$ 43,369	$ 40,169	$ 37,064	$ 34,051	$ 32,128	$ 28,289

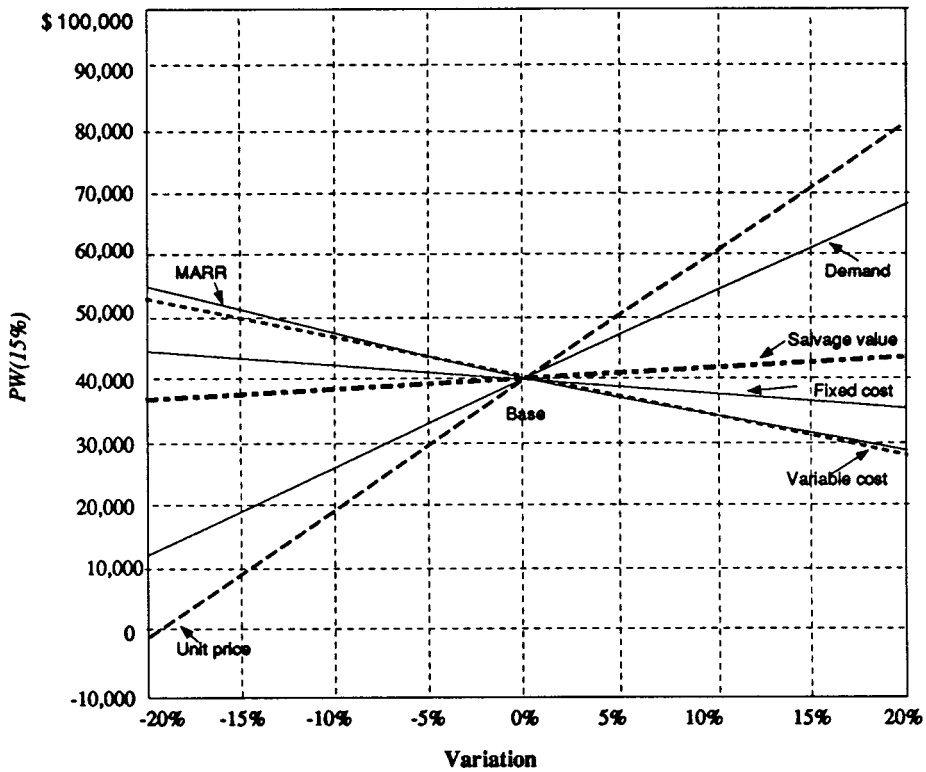

FIGURE 17.5.1 Sensitivity graph — BMC's transmission-housings project (Example 17.5.1).

Discussion. To carry out the scenario analysis, we ask the marketing and engineering staffs to give optimistic (best-case) and pessimistic (worst-case) estimates for the key variables. Then we use the worst-case variable values to obtain the worst-case NPW and the best-case variable values to obtain the best-case NPW. Table 17.5.3 summarizes the results of our analysis. We see that the base case produces a positive NPW, the worst case produces a negative NPW, and the best case produces a large positive NPW.

TABLE 17.5.3 Scenario Analysis for BMC (Example 17.5.2)

Variable Considered	Worst-Case Scenario	Most-Likely-Case Scenario	Best-Case Scenario
Unit demand	1,600	2,000	2,400
Unit price ($)	48	50	53
Variable cost ($)	17	15	12
Fixed cost ($)	11,000	10,000	8,000
Salvage value ($)	30,000	40,000	50,000
PW (15%)	–$5,856	$40,169	$104,295

By just looking at the results in Table 17.5.3, it is not easy to interpret scenario analysis or to make a decision based on it. For example, we can say that there is a chance of losing money on the project, but we do not yet have a specific probability for this possibility. Clearly, we need estimates of the probabilities of occurrence of the worst case, the best case, the base case (most likely), and all the other possibilities. This need leads us directly to the next step, developing a probability distribution. If we can predict the effects on the NPW of variations in the parameters, why should we not assign a probability distribution to the possible outcomes of each parameter and combine these distributions in some way

to produce a probability distribution for the possible outcomes of the NPW? We shall consider this issue in the next section.

Risk Analysis

Quantitative statements about risk are given as numerical probabilities, or as values for likelihoods (odds) of occurrence. Probabilities are given as decimal fractions in the interval 0.0 to 1.0. An event or outcome that is certain to occur has a probability of 1.0. As the probability of an event approaches 0, the event becomes increasingly less likely to occur. The assignment of probabilities to the various outcomes of an investment project is generally called *risk analysis*. In this section, we shall assume that the analyst has available the probabilities (likelihoods) of future events from either previous experience in a similar project or a market survey. The use of probability information can provide management with a range of possible outcomes and the likelihood of achieving different goals under each investment alternative.

Procedure for Developing an NPW Distribution

To develop the NPW distribution, we may follow these steps:

1. Identify all cash flows elements that are random variables. (A *random variable*) is a variable that can have more than one possible value.)
2. Express the NPW (or cash flow series) as a function of random variables.
3. Determine the probability distribution for each random variable.
4. Determine the joint events and their probabilities.
5. Evaluate the NPW equation at these joint events.
6. Order the NPW values in increasing order of NPW.

These steps can best be illustrated by Example 17.5.3.

Example 17.5.3 — Developing an NPW Probability Distribution

Consider the BMC's transmission-housing project. If the unit sales (X) and unit price (Y) were to vary with the following probabilities, determine the NPW probability distribution. Here we assume the situation where both random variables are independent. In other words, observing a typical outcome for random variable X does not have any influence on predicting the outcome for random variable Y.

Demand (X)	Probability	Unit Price (Y)	Probability
1600	0.20	$48	0.30
2000	0.60	$50	0.50
2400	0.20	$53	0.20

Discussion. If the product demand X and the unit price Y are independent random variables, the PW (15%) will also be a random variable. To determine the NPW distribution, we need to consider all the combinations of possible outcomes. The first possibility is the event where x = 1600 and y = $48. With these values as input in Table 17.5.1, we compute the resulting NPW outcome to be $5574. Since X and Y are considered to be independent random variables, the probability of this joint event is

$$\begin{aligned} P(x = 1600, y = \$48) &= P(x = 1600)\,P(y = \$48) \\ &= (0.20)(0.30) \\ &= 0.06 \end{aligned}$$

TABLE 17.5.4 The NPW Probability Distribution with Independent Random Variables (Example 17.5.3)

Event No.	x	y	P(x,y)	Cumulative Joint Probability	NPW
1	1600	$48.00	0.06	0.06	$5,574
2	1600	$50.00	0.10	0.16	$12,010
3	1600	$53.00	0.04	0.20	$21,664
4	2000	$48.00	0.18	0.38	$32,123
5	2000	$50.00	0.30	0.68	$40,168
6	2000	$53.00	0.12	0.80	$52,236
7	2400	$48.00	0.06	0.86	$58,672
8	2400	$50.00	0.10	0.96	$68,326
9	2400	$53.00	0.04	1.00	$82,808
